Mary Lou Kohn

An inspiration to all perioperative nurses and caregivers of the past, present, and future.

This page intentionally left blank

Preface to the Fourteenth Edition

This time-honored text has its roots in the operating room (OR) orientation manual created by Mary Louise Kohn in the late 1940s while working as an OR educator at University Hospitals of Cleveland, Ohio. Her impeccable notes were a source of interest to many OR supervisors and educators who wanted to standardize their teaching techniques in accordance with Mary Louise's orientation tool. Many observers requested copies of her writings, and eventually the cost of providing copies became prohibitive.

In 1951, at the request of her publisher and with the encouragement of her superiors, Mary Louise assembled her orientation material into a manuscript suitable for publication. She spent countless hours writing and revising material until the birth of her daughter. Her dedication to her family led her to seek assistance for this project from Edna Cornelia Berry, who became her willing partner and coauthor through the first four editions.

The first edition of *Introduction to Operating Room Technique* by Edna Cornelia Berry and Mary Louise Kohn was published in 1955. I was fortunate to have obtained a copy for my collection. The first edition was dedicated to "those nurses who accept the tension and challenge of coordinated teamwork as they minister to the patient in the operating room." The main emphasis was on intraoperative care of the patient.

Berry and Kohn's Operating Room Technique has been the perioperative text of choice for 60 years because it emphasizes the importance of the patient and presents the material in concise, understandable language. The name remains "Operating Room Technique" because that is how it has been commonly known and identified, although the text has a comprehensive perioperative focus. It would be a disservice to our patients to merely describe the intraoperative phase and not include preoperative and postoperative care.

Every new edition of this classic perioperative text has addressed changing roles, needs, and evolving technologies while maintaining the fundamental focus that still remains valid—the care of the surgical patient. This edition of the text identifies the knowledge and skill needs of the caregiver and strives to incorporate components of patient care from preoperative, intraoperative, and postoperative practice areas. A systems approach is used to help organize patient care to minimize the risk for human error.

Berry and Kohn's *Operating Room Technique* is designed to meet the needs of educators, learners, caregivers in diverse disciplines, and managerial personnel who care for surgical or interventional patients in many types of environments. Knowing the "why" of patient care is as important as knowing the "how." Additionally, it is important to stress that outcomes must be evaluated to support evidence-based practice. This text is the book of choice for certification preparation in diverse disciplines and incorporates all elements of the core curricula specified by several accrediting and certifying bodies.

Features of the Fourteenth Edition

- A user-friendly 12-section arrangement.
- A logical and sequential order of the subject matter.
- Incorporation of the *AORN Guidelines for Perioperative Practice* (2019) and AST's *Core Curriculum for Surgical Technology,* 6th edition, to reflect modern perioperative practice.
- A focus on the physiologic and psychologic considerations of perioperative patients to provide guidelines and standards for planning and implementing safe individualized care.
- Use of the systems approach as a foundation to support solid evidence-based practice to establish patient care procedures in such a way that all team members can identify their roles in a cooperative spirit of safety and efficiency.
- In-depth discussion of patients with special needs related to age or health status considerations.
- Discussion of perioperative patient care in inpatient, ambulatory, and alternative sites/locations to highlight considerations based on the setting, as well as the surgical procedure.
- Encouragement of the patient care team to identify and examine personal and professional development issues that influence the manner in which care is rendered.
- Detailed information about the fundamentals of perioperative nursing and surgical technology roles.
- Building of knowledge in a logical sequence—from fundamental concepts to implementation during surgical intervention—to enable readers to apply theory to practice.
- Comprehensive coverage of a broad range of essential topics to provide a thorough understanding of fundamental principles and techniques and an understanding of their applications in various surgical procedures.
- Descriptions of specific surgical procedures in each specialty chapter to assist the learner and caregiver in planning and delivering patient care in the perioperative environment.
- An Evolve website that has learning and teaching aids to enhance the classroom experience and support assimilation of knowledge. For the student, this includes tips for the scrub person and circulating nurse, historical perspectives, body spectrum software, student interactive questions, and an audio glossary. For the instructor, this includes a TEACH manual with a lesson plan, lecture outline, case studies, and PowerPoint slides for each chapter; test bank; and collection of all the images in the book.

New to the Fourteenth Edition

- New and revised art is provided throughout the book.
- Insightful Pros & Cons boxes throughout the text examine the two sides of a patient care topic and provide references for further reading.

- Updated references highlight the evidence-based practice approach used in the book.
- Terminology and key words have been updated to reflect modern practice.
- Each chapter has been revised to emulate current practice and knowledge.

Organization

Section 1 describes education, learning, and professional issues. The correlation of theory and practice is integral to the success of patient care in the perioperative environment. Fundamental professional and personal attributes of the caregiver are examined, with an emphasis on objectivity in the development of the plan of care. Legal and ethical issues are discussed.

Section 2 delineates the roles of the members of the health care team as both direct and indirect caregivers. Nonphysician first assistant roles and credentials are discussed in a separate chapter. Management of the perioperative patient care areas is described, including Magnet Status.

Section 3 provides in-depth information on patient assessment and the development of an individualized plan of care, with the patient viewed as a unique individual. Special needs are identified by health condition and age. Geriatric and pediatric chapters are included.

Section 4 examines the physical plant of the perioperative environment—both hospital-based, freestanding ambulatory facilities and alternative locations. Diagrams of conventional and nonconventional perioperative suite designs are included with airflow designs. Care of the perioperative environment, occupational hazards, and safety issues are examined in depth.

Section 5 explains microbiology and the importance of microbiologic control in the perioperative environment, with an emphasis on standard precautions. It delineates aseptic and sterile techniques as fundamental to intermediate aspects, such as attire, scrubbing, gowning, and gloving. Separate chapters are provided regarding the sterilization and disinfection of surgical instrumentation and patient care supplies.

Section 6 details the primary surgical instrumentation and equipment used during surgical procedures. The safe use of specialized surgical equipment is presented. Electricity is explained.

Section 7 discusses preoperative patient care and includes the family/significant other in the plan of care. Diagnostic procedures and specimen handling are described.

Section 8 covers methods of anesthetic administration and the role of caregivers during this process. Physiologic patient responses and related potential perioperative complications are discussed in detail. Surgical pharmacology is included.

Section 9 describes intraoperative patient care, including positioning, prepping, and draping. The interactive roles of the circulator and the scrub person are specified in Chapter 25. Economy of motion and the properties of physics are applied. Physiologic monitoring of the perioperative patient is described.

Section 10 focuses on the surgical site. Incisions, hemostasis, and wound closure are discussed in detail. Wound assessment, dressing, and healing throughout the perioperative care period are described.

Section 11 presents an expanded view of postoperative patient care. The postanesthesia care unit is explained. Prevention of patient complications is described. The death of a patient is discussed, and the importance of legal evidence is stressed.

Section 12 covers the surgical specialties. Salient surgical anatomy and procedures are described and illustrated in line drawings for clarity.

Preface to the First Edition

The material in this text is the outgrowth of the coauthors' experience in the operating room—one as instructor of students, the other as head nurse with some responsibility for instructing and guiding students. It is an adaptation of the instructor's teaching outline for which there have been many requests.

The aim of the book is to facilitate the nurse's study of aseptic technique and care of the patient in the operating room. Although this text is intended primarily for the student, the authors hope it may prove useful to the graduate nurse as well.

Because it is assumed that the student has studied pathologic conditions necessitating surgical treatment, these conditions are not discussed. When applicable, and as a matter of emphasis, there is a reiteration of principles of sterile technique and safety factors for the patient. It is hoped this will aid in fixing the principles as patterns of thought and work.

Although operative routines vary in different hospitals, underlying principles are the same. Consequently, basic principles are emphasized, and the authors have endeavored to keep the material as general as possible. Principles must be adapted to suit the situations found in individual hospitals. Specific linen, equipment, and procedures are mentioned merely to serve as a framework on which to demonstrate principles or as samples for points of departure. However, the specific examples mentioned are workable procedures that have evolved. They are kept as uncomplicated as possible for student teaching and for use in the practical situation.

Instruments for operations are not listed and few are mentioned because each hospital has its instrument lists, standardized for each case, to which students can refer.

Emphasis is placed on meeting the psychological as well as the physical needs of the surgical patient. An endeavor is made where possible to correlate briefly the preoperative and postoperative care with the operative procedure, to give the student a complete concept of patient care.

The frequent use of the imperative mood is for the purpose of brevity, organization, and emphasis. Questions and assignments in each chapter are to aid the student in reviewing the material, in recalling pertinent facts, and in applying the principles to his or her specific situation.

Obviously, if the student starts scrubbing for cases with an older nurse after the first day or two in the operating room and if operating-room theory is given concurrently with the practice, much of the material in this book will have been covered by individual instruction before class discussion.

The authors have attempted to maintain simplicity and brevity and to present a concise outline for preliminary study. They suggest that the student supplement this material by reference reading.

The authors wish to express their grateful appreciation and thanks to those people who by their interest and cooperation supported them:

To Miss Edythe Angell, supervisor of the Operating Rooms at University Hospitals of Cleveland, for helpful suggestions during the preparation of the manuscript and for reading, critically, the entire manuscript. We are gratefully indebted to her because we have learned from her much of what appears in this text.

To Miss Janet McMahon, Educational Director, School of Anesthesia, University Hospitals of Cleveland, for valuable assistance in preparing Chapter 21. Also, to Dr. Edward Depp, anesthesiologist, Euclid-Glenville Hospital, Cleveland, who offered suggestions on this chapter and reviewed it.

To Dr. C.C. Roe Jackson, of the faculty of Western Reserve University School of Medicine, for constructive criticism in reviewing Chapter 17. To Dr. Howard D. Kohn, also of the faculty, who has been most helpful in reading the manuscript and offering suggestions.

To Mrs. Geraldine Mink, librarian, for her assistance; to Mrs. Leona Peck for her patience in typing the manuscript and for her helpful suggestions; to Miss Ruth Elmenthaler and Miss Margaret Sanderson of the operating-room staff for their assistance in making the photographs; and to Mrs. Anita Rogoff for drawing the illustrations.

Mary Louise Kohn, AB, RN, MN (1920-2019)

I first met Mary Louise Kohn, a leader in perioperative nursing education and authorship, several years ago in Dallas at the Association of Operating Room Nurses (AORN) annual congress. I moderated an educational session before a large group of specialty nurses. When the program finished, several participants came out of the audience to discuss the topic and ask questions. Mary Louise, a lovely, petite lady with blonde hair and sparkling blue eyes, introduced herself and complimented my presentation. On October 15, 1992, I had the opportunity to interview Mary Louise. Throughout the interview, her physical presence glowed with professionalism and dignity. The whole room seemed to reflect her persona. She explained how the events of the era in which she lived affected her career path.

Mary Louise came from a highly educated family. Her German father had a Ph.D. and was a Presbyterian minister who taught Hebrew and Greek to scholars of religion and literature. She had several cousins who had Doctorates in various fields. Both of her parents had passed away by the time she was 16 years old, and she lived on a small inheritance left to her by an uncle. She graduated in 1940 from the College of Wooster with a Bachelor of Arts in biology and psychology. She hoped to become a doctor, but money was tight and females were discouraged from entering medicine. She entered nursing so she could earn a living sooner.

During W.W.II, after the bombing of Pearl Harbor on December 7, 1941, only 7,000 Army nurses were on active duty, but within six months the ranks grew to 12,000. Women were rapidly taking a larger role in the war effort and she felt that her participation in civilian nursing was critical to the success of her country. She tried to fill in for the shortages wherever she could, especially for the nurses who were deployed overseas. She wanted to be an Army flight nurse, but her family discouraged her ambitions. She was unable to fulfill that dream and talked about it in a distantly sad way.

She received her Master of Nursing degree from the Francis Payne Bolton School of Nursing (FPB) at Western Reserve University (WRU) in 1943. After graduation, she took a staff nurse position in the operating room (OR) at University Hospitals of Cleveland (UH). She explained that only 35 graduate nurses were available to staff five hospitals for all three shifts.

She met the love of her life, Howard Kohn, MD, during his internship. He joined the Army Medical Corps so Mary Louise joined him at his duty station. They married on the army base in 1944 and lived at their own expense in a rooming house. Mary Louise took a private duty position in the civilian sector because it paid more money, five dollars per day.

Howard was stationed in Atlantic City at the Thomas M. England General Hospital, which consisted of several hotels converted into hospitals for wounded soldiers returning from the front. Mary Louise explained that registered nurses were in demand, so she took a position as Assistant Head Nurse on a 200 patient ward. Only enlisted military nurses could be Head Nurses because the patients were wounded soldiers. Her responsibility included training civilian aides and orderlies, many of who were conscientious objectors or deferrees of the draft. Her workday consisted of 12 hour shifts with one hour for meals.

In 1943, Congress passed the Bolton Act sponsored by Francis Payne Bolton, enacting the U.S. Cadet Nurse Corps, spearheaded by Lucile Petry, to educate registered nurses for duty in the military. All educational expenses and a small stipend were paid for a nursing degree in return for 2 years of service in the Army Nurse Corps if needed. The Cadet Nurse Corps attracted 169,443 women to its service. Male nurses were not actively recruited. By 1944, formal rank as a commissioned officer, usually a Second Lieutenant (2LT) with equal privileges and pay was available to registered nurses. The last Cadet Nurses graduated in 1948.

At the end of the European war in 1945, the number of Army nurses was approximately 27,850. By the end of 1946, only 8,500 nurses remained in the Army Nurse Corps, none were male.

Mary Louise's husband was discharged from the Army in 1946 and decided to specialize in ophthalmology at the Harvard Medical School, graduate program. He completed his training and returned to Cleveland to practice his specialty. Mary Louise became the OR Instructor at the University Hospitals (UH), after serving as head nurse on the surgical floor. UH was affiliated with Western Reserve University (WRU) and the Francis Payne Bolton School of Nursing.

Mary Louise was appointed to the teaching staff of WRU and assisted with the education of the Cadet Nurses. She was highly organized and began to put her original handwritten teaching notes in a retrievable format. Her educational programs and teaching syllabus were of great interest to educators from smaller hospitals in the United States. Many OR educators from other hospitals requested a photocopy of her teaching syllabus so they could standardize their own surgical programs. She found that her teaching material was a valuable tool. The Dean of Nursing at FPB encouraged her to publish because the volume of material was becoming too large to photocopy free of charge. She was approached by several publishers and accepted the offer presented by McGraw-Hill.

In 1951, with the birth of her only daughter, Mary Louise decreased her hours at the hospital and focused on formalizing her written material. She eventually included a co-author, Edna Berry, RN, AD, who was formerly affiliated with UH. Mary Louise was family oriented and found this working arrangement with a co-author to be a help and a hindrance. Edna, who was unmarried, did not have a family so planning writing schedules around a co-author with an infant and a husband was difficult.

The original manuscript was written by hand. Mary Louise did not type and had to hire typists at ten dollars per page to meet deadlines. She diligently had each chapter reviewed by a physician,

and got Edna's agreement before sending any work to print. They contracted artists for line drawings and illustrations and paid to have the book professionally evaluated. There were no professional organizations to lend guidance or standards so they drew from their own resources for the first technique-oriented textbook for OR nurses. The first edition was published in 1955 and contracted for revisions every five years.

During the early sixties, The Association of Operating Room Nurses (AORN) was founded. AORN founders contacted Mary Louise and asked her to be part of the organization as Education Director. She joined the organization, but explained that she could not devote the time needed to become a founder. When AORN created the standards and recommended practices that are the basis of all worldwide perioperative nursing practices, they used *Berry and Kohn's Operating Room Technique* as a reference.

Edna Berry died before the sixth edition was finished. Mary Louise took Lucy Jo Atkinson, RN, MS as co-author for its completion. *Berry and Kohn's Operating Room Technique* had grown into a well-known international OR text. It had been translated into Spanish and Chinese and was the main text of the armed forces surgical training programs. When Mary Louise retired her authorship, Lucy Jo became the solo author of the seventh edition. Mosby purchased the publishing rights for the seventh and subsequent editions of the text from McGraw-Hill. Lucy Jo and Nancymarie Fortunato-Phillips, PhD, MEd, BSN, RNFA, CNOR co-authored the eighth edition and Nancymarie became the solo author for the ninth through thirteenth editions. Nancymarie co-authored the fourteenth edition with Anita Hornacky, RN, BS, CST, CNOR, who will assume solo authorship with the fifteenth edition as part of the Elsevier family of publishing.

Mary Louise lived to be 99 years old and passed away in the spring of 2019. She met with Nancymarie and Anita several times during the production of the thirteenth edition and gave her opinions of the fourteenth edition before she died. Mary Louise and her work as an educator and author was truly the cornerstone of what perioperative nursing is today. Her experience and dedication inspired many perioperative caregivers. She was a wonderful friend and mentor.

Acknowledgments

I want to thank so many people who have made this fourteenth edition possible. First, I want to thank all of the reviewers of the previous editions for their time in review and for their input. The identified needs of this group provide the baselines for the growth and effectiveness of this work. The reviews were very detailed and appropriately critical.

I am so grateful to the many nurses, surgical technologists, and readers of previous editions who wrote to me or called requesting specialty topic coverage in this edition. We welcome feedback at all times and can be contacted by the email address listed at the bottom of this page.

I want to thank our ongoing students in all disciplines (perioperative nursing, registered nurse first assistant, and surgical technology) for asking hard questions and forcing us to step beyond the classroom to satisfy their learning needs. We see them as the future of patient care and the representatives of the high standards described in this text.

I want to thank my perioperative nursing and surgical technologist colleagues for their professionalism and for making the task of revision exciting and fresh. A special thank you to Joe Fortunato, Jr., who created much of the art for this edition and other authorship projects.

I want to thank Sandra Clark, Executive Content Strategist; Danielle Frazier, Senior Content Development Specialist; and Grace Onderlinde, Project Manager, for their support and patience during the production of this edition. Their support made this project possible.

We want to thank Mary Lou Kohn, RN, who trusted us with her wonderful creation. She is the epitome of the perioperative nurse we should strive to be. We put her foremost in mind before we commit any word to paper. We ask ourselves, "How would Mary Lou describe this?" Or, "What would Mary Lou think about adding this?" We do this not only out of reverence for her trust but also because she still exemplifies the highest standards of patient care despite being long retired. Mary Lou is a delightful human being and forever a perioperative nurse.

1 Perioperative Education

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Compare and contrast the art and science of surgery.
- Identify three characteristics of adult learners.
- Name five educational resources available for the learner.
- Define the difference between andragogy and pedagogy.
- Describe how adult learning principles apply to patient teaching.
- Discuss the problems associated with disruptive behavior in the perioperative environment.

KEY TERMS AND DEFINITIONS

Andragogy Teaching and learning processes for mature adult populations.

Behavior Actions or conduct indicative of a mental state or predisposition influenced by emotions, feelings, beliefs, values, morals, and ethics.

Disruptive behavior (bullying) Power imbalance that involves intimidation, oppression, or aggression and results in a counterproductive atmosphere.

Cognition Process of knowing or perceiving, such as learning scientific principles and observing their application.

Competency Creative application of knowledge, skills, and interpersonal abilities in fulfilling functions to provide safe, individualized patient care.

Critical thinking The mental process by which an individual solves problems.

Disease Failure of the body to counteract stimuli or stresses adequately, resulting in a disturbance in function or structure of any part, organ, or system of the body.

Environmental factors Water, air, soil, and food. Contamination and exposure of any of these factors can lead to disease.

Evaluation A process by which the educator measures performance by standardized indicators established by a school, employer, or professional organization.

Knowledge Organized body of factual information.

Learning style Individualized methods used by the learner to understand and retain new information. These may be visual, auditory, tactile, sensory, kinesthetic, or performance-oriented behaviors.

Mentoring A nurturing, flexible relationship between a more experienced person and a less experienced person that involves trust, coaching, advice, guidance, and support. A sharing relationship guided by the needs of the less experienced person.

Objectives Written in behavioral terms, statements that determine the expected outcomes of a behavior or process.

Occupational hazard A workplace hazard that can cause physical, biologic, or chemical injury, leading to disease or death.

Orientation Period during which a student or new employee becomes acquainted with the environment, policies, and procedures of a professional environment.

Pedagogy Teaching and learning processes for immature and/or pediatric populations. A very directed style is used.

Perioperative Total surgical experience that encompasses preoperative, intraoperative, and postoperative phases of patient care.

Preceptor A person who observes, teaches, and evaluates a learner according to a prescribed format of training or orientation.

Psychomotor Pertaining to physical demonstration of mental processes (i.e., applying cognitive learning).

Role model A person who is admired and emulated for good practices in the clinical environment. The relationship between a role model and a learner can be strictly professional without personalized mentoring.

Skill Application of knowledge into observable, measurable, and quantifiable performance.

Surgery Branch of medicine that encompasses preoperative, intraoperative, and postoperative care of patients. The discipline of surgery is both an art and a science.

Surgical conscience Awareness that develops from a knowledge base of the importance of strict adherence to principles of aseptic and sterile techniques.

Surgical procedure Invasive incision into body tissues or a minimally invasive entrance into a body cavity for either therapeutic or diagnostic purposes; protective reflexes or self-care abilities are potentially compromised during such a procedure.

The main focus of this chapter is to establish the baseline or framework for an in-depth study of **perioperative** patient care and support the educational process of the learner. Consideration is given to the perioperative educator, who may not have had a formal education in the teaching of adult learners. Both learners and educators should understand that the same learning and teaching principles apply to patient education. The key terms are commonly used terms that the learner should understand as the basis for learning about and participating in the art and science of **surgery**.

The Art and Science of Surgery

Health is both a personal and an economic asset. Optimal health is the best physiologic and psychological condition an individual can experience. **Disease** is the inability to adequately counteract physiologic stressors that cause disruption of the body's homeostasis. Additional influences, such as congenital anomalies, infection, trauma, **occupational hazard**, or **environmental factors**, interfere with optimal human health and quality of life. As both a science and an art, surgery is the branch of medicine that comprises perioperative patient care encompassing such activities as preoperative preparation, intraoperative judgment and management, and postoperative care of patients. As a discipline, surgery combines physiologic management with an interventional aspect of treatment. The common indications for surgical intervention include correction of defects, alteration of form, restoration of function, diagnosis and/or treatment of diseases, and palliation. Table 1.1 describes some of the most common indications for surgery.

In the 1930s the English physician Lord Berkeley George Moynihan (1865–1936) said, "Surgery has been made safe for the patient; we must now make the patient safe for surgery." Surgical intervention is becoming a safer method of treating physiologic conditions. Most of the former contraindications to surgery that were related to patient age or condition have been eliminated because of better diagnostic methodologies and drug therapies. More individuals are now considered for surgery; however, each patient and each procedure is unique. Perioperative caregivers should not become complacent with routines but should always be prepared for the unexpected. Surgery cannot be considered completely safe all the time, and patient outcomes are not always predictable.

A **surgical procedure** may be invasive, minimally invasive, minimal access, or noninvasive. An invasive or minimal access procedure enters the body either through an opening in the tissues or by a natural body orifice. Noninvasive procedures are frequently diagnostic and do not enter the body. Technology has elevated the practice of surgery to a more precise science that minimizes the "invasiveness" and enhances the functional aspects of the procedure. Recovery or postprocedure time decreases, and the patient is restored to functional capacity faster. Improvements in perioperative patient care technology are attributed to the following:

- Surgical specialization of surgeons and teams
- Sophisticated diagnostic and intraoperative imaging techniques
- Minimally invasive equipment and technology
- Ongoing research and technologic advancements

Surgical procedures are performed in hospitals, in surgeons' offices, or in freestanding surgical facilities. Many patients can safely have a surgical procedure as an outpatient and do not require an overnight stay at the facility. The types of surgical procedures performed on an outpatient basis are determined by the complexity of the procedure and the general health of the individual. Procedures performed on patients who remain overnight in the hospital vary according to the expertise of the surgeons, the health of the patient, and the availability of the equipment.

TABLE 1.1 Common Indications for Surgical Procedures

Indication for Surgical Procedure	Example
Augmentation	Breast implants
Debulking	Decreasing the size of a mass
Incision	Open tissue or structure by sharp dissection
Excision	Remove tissue or structure by sharp dissection
Diagnostics	Biopsy tissue sample
Repair	Closing of a hernia
Removal	Foreign body
Reconstruction	Creation of a new breast
Palliation	Relief of obstruction
Aesthetics	Facelift
Harvest	Autologous skin graft
Procurement	Donor organ
Transplant	Placement of a donor organ or tissue
Bypass/shunt	Vascular rerouting
Drainage/evacuation	Incision into abscess
Stabilization	Repair of a fracture
Parturition	Cesarean section
Termination	Abortion of a pregnancy
Staging	Checking of cancer progression
Extraction	Removal of a tooth
Exploration	Invasive examination
Diversion	Creation of a stoma for urine
Implantation	Inserting a subsurface device
Replantation	Reattaching a body part
Amputation	Removing a large structure
Stenting	Using an implant as a supporting device
Neoconstruction	Face transplant

The purpose of this text is to provide a baseline for learning the professional and technical patient care **knowledge** and **skill** required to provide safe and efficient care for patients in the perioperative environment.

Perioperative Learner

The learner in the perioperative environment may be a medical, nursing, or surgical technology student enrolled in a formal educational program, or the learner may be a newly hired orientee. Medical students have a surgical rotation that includes participation

in surgical procedures. They learn some of the basic principles of surgical technology and sterile technique to ensure the safety and welfare of patients.

Some nursing schools offer basic exposure to perioperative nursing, as a short observation period, part of the core curriculum, or an elective. After graduating from nursing school the nurse needs further education before functioning as a perioperative professional.[1] This education may take place in a postbasic/postgraduate perioperative nursing course offered by a community college or a hospital **orientation** program. Entry-level education for perioperative practice prepares nurses to be generalists. Basic perioperative nursing elective programs focus on the role of the perioperative nurse as both generalist circulator and scrub person. Specialization can follow a period in professional practice in a specific service. The perioperative nurse's role encompasses supervision of unlicensed personnel who scrub in surgery, such as surgical technologists, and requires knowledge of practices and procedures performed under this title.

Surgical technology programs focus primarily on scrubbing in to prepare and maintain the sterile surgical field and handle instruments. Some surgical technology programs offer circulating experiences under the supervision of a registered nurse; however, the role of the circulator requires knowledge and skill not commonly covered in significant depth in shorter training programs. Most surgical technology programs provide scrub experiences in many specialties. After satisfactory completion of the program, many technologists are capable of functioning in the scrub role as a generalist or, in some circumstances, a specialist. Advancing technology indicates the need for specialized competencies for all disciplines of perioperative patient care. Surgeons, perioperative nurses, and surgical technologists should continually strive to learn new procedures and technologies in a team-oriented environment.

Perioperative caregivers new to a particular practice setting should learn the specific performance standards and expectations of that institution. All personnel go through an orientation process to familiarize themselves with the philosophy, goals, policies, procedures, role expectations, and physical facilities specific to their institution. Departmental orientation is specific to the area in which the caregiver is employed.

Many graduates seek employment in the institutions where they performed clinical rotations. This is usually beneficial to the facility and the employee. Some students are hired into apprenticeships before graduation, enabling them to work in the operating room (OR) in a limited capacity in anticipation of a permanent position. Schools that permit students to work while still in the education process should have a policy in place to delineate the student role from the employee role. The policy should be made known in writing to all clinical facilities hosting students and students performing clinical rotations where apprenticeships are offered. The following are considerations in developing a policy for working students:

- Students may not work for compensation during official clinical hours.
- Students may not wear facility name or identification badges while performing clinical rotations as an agent of the school.
- Students may not wear school name or identification badges while performing work for compensation as an agent of the facility.
- Students may not take time off from classroom or clinical rotations to work for compensation.
- Students are not part of the clinical staff during clinical rotation hours.
- Students are to maintain patient confidentiality at all times.
- Students may be screened by the school or facility by routine background checks and drug testing.
- Students should be subject to health screening and vaccinations followed by titers for proof of immunity (i.e., varicella; rubeola; diphtheria, tetanus, pertussis [DTaP]; and hepatitis B). Tuberculosis testing should be performed before clinical rotation.

TABLE 1.2 Characteristics of the Adult Learner Compared with the Child Learner

Adult (Andragogy)	Child (Pedagogy)
Is self-directed	Is task oriented
Uses activities that follow transitions of maturity	Uses activities that follow stages of development
Uses intrinsic thought processes	Uses extrinsic thought processes
Uses problem-solving approach	Uses trial-and-error approach
Values self-esteem	Values self-esteem

All learners in the perioperative environment are adults and perform better if given due respect. This concept applies whether the caregiver is experienced or a novice. Treating an adult learner in a pedagogic manner (pedagogy), as a child is treated, is counterproductive and becomes a barrier to learning. The learner can become resentful and unable to separate feelings of inexperience from feelings of inadequacy. Regardless of the level of learning required, the general characteristics of the adult learner (**andragogy**) as compared with the child learner (**pedagogy**) apply (Table 1.2). These concepts also should be applied to patient education programs.

Not everyone learns at the same speed or assimilates information in the same manner. Theoretic knowledge or a skill learned quickly by one individual may be difficult for another. **Cognition** is premised on the ability to process and retain information. **Learning styles** vary among individuals and are influenced by internal and external factors. Examples of learning-style influences are listed in Box 1.1. Learning styles were described in the early 1990s by Howard Gardner at Harvard University. Understanding the differences in individual learners is the first step to imparting knowledge and skill.[2] Seven learning skills identified by Gardner are summarized as follows with application of teaching methods for perioperative learners:

1. *Visual-spatial:* Very environmentally aware. Learns well by observation, puzzles, graphics, and modeling.
   - The educator can create poster boards with images of instrument pictures and setups. Posters can have backgrounds of blank sterile fields constructed of felt and cardboard

• BOX 1.1 Learning-Style Influences

- Intelligence
- Attentiveness
- Cultural and ethnic background
- Educational preparation
- Motivation to learn
- Concentration and distractibility
- Personality characteristics
- Psychologic strengths or deficiencies
- Social skills, including communication skills
- Manual dexterity
- Physical senses
- Physical health
- Perceptual preferences and sensory partiality (e.g., visual vs. auditory)
- Environment

cut-outs of instruments with Velcro backing for students to place on the surface.

2. *Bodily kinesthetic:* Keen sense of motion and hands-on sense. Communicates well by physical practice.
   - The educator can provide sterile drapes and instrument trays for students' use in preparing sterile fields and setups. The task can be made more challenging by timing the process and creating competition for the best time with the highest degree of accuracy. Teams competing against each other in table setups and draping make the activity fun and exciting.
3. *Musical:* Learns well by listening and the use of multimedia. Frequently learns better with music in the background.
   - The educator (with the help of the students) can enumerate specific steps to a procedure, such as donning the sterile gown and gloves. The steps are recited to a musical beat provided by rhythmic clapping or to an instrumental background tune. Most students recognize simple childhood tunes and can sing or say the steps to the music. Also, modern musical instrumentals are easy to use for this purpose.
4. *Interpersonal:* Group dynamics and study sessions work well for this learner.
   - The educator can assign topics to groups for exploration and development. The students present their findings to the class in a forum setting. Some students may want to simulate procedures for the class.
5. *Intrapersonal:* Learns well through self-study and independence. Highly self-motivated and disciplined.
   - The educator can guide individual students in the creation of personal flashcards or organization of class notes. Students who learn best by self-study generally seek assistance only when further explanation or clarification is needed.
6. *Linguistic:* Very good with language and auditory skill. Learns effectively through lectures and explanation.
   - The educator presents lectures on specific topics and uses multimedia to reinforce the discussion. PowerPoint presentations enhance the lecture and can be printed for the students to use in following along. Embedded video is useful, and links to websites provide variety, such as www.youtube.com.
7. *Logical-mathematical:* Prefers to investigate and solve problems. Conceptual thinking precedes detailing with these learners.
   - The educator can use several testing formats to challenge the learners. Tables set up with instruments for identification by category or classification give students the opportunity to determine how each item is used in a particular specialty. An interesting twist to this method involves intentionally omitting a particularly necessary item from the field; the students have to reconstruct the steps of the procedure to figure out which item is missing.

Each facility should clearly define the role of the perioperative learner of each discipline. Activities of new perioperative nurses and surgical technology students are not the same. The perioperative nurse is involved with more direct patient care and decision making through physical assessment. The student surgical technologist is concerned primarily with preparing and maintaining the sterile field. Both disciplines of learners help prepare for, assist a qualified **preceptor** during, and clean up after surgical procedures, but they are not considered members of the staff complement. Instructional staff should observe for and guard against laziness in the preceptor group. Some preceptors may want to sit back in the pretense of "letting the student take over." In essence this is not an improper approach to precepting, but it can be abused if the preceptor continually leaves the student to flounder or delay the progress of the procedure.

Some preceptors and surgeons may "bully" the students and become impatient because of the students' inexperience. **Disruptive behavior** (**bullying**) is counterproductive. Students should be taught to speak up when necessary, respect the preceptors and surgeons, but not be afraid to ask questions.[3] Most facilities have developed a "zero tolerance" policy concerning interprofessional relationships wherein one person causes another person to feel intimidated or fearful. Some facilities now require a preceptor class to address appropriate behavior, understand student learning styles, and learn what is expected of them and how to help students become successful.

Students should know basic standards and protocol before entering the OR for a clinical rotation. Preceptors may have developed shortcuts with questionable technique not understood by students who are new to the OR environment. Students should not blindly perform tasks directed by preceptors that cause question as to technique or safety without fully understanding what resultant outcome is expected.[4] Educators should discuss the potential for these questionable events and give the student a vehicle for professionally or assertively deferring or opting out of doing something that is nonstandard by the level of education they have experienced in the classroom. This process can be particularly uncomfortable if the student does not feel supported by the educator, who is a mentor in the environment, in doing what has been ingrained as the standard of care. Some examples of this activity include but are not limited to the following (these examples actually happened at a clinical site):

1. *Event:* Preceptor insists on gowning and gloving from the primary sterile field and instructs the student to do so as well. Student deferral vehicle: "My clinical instructor will give me a deficiency grade if I gown and glove from the back table. I am required to gown and glove from a separate surface other than the main field."
2. *Event:* Preceptor is impatient and goes to sit on a stool in the corner because part of the procedure is taking a long time. Student deferral vehicle: "My clinical instructor will give me a deficiency grade if I sit and change the level of sterility of the front of my gown."
3. *Event:* Preceptor instructs the student to offer a towel from the open and biologically contaminated back table to a person who plans to enter the working sterile field. Student deferral vehicle: "My clinical instructor will give me a deficiency grade if I offer a towel from my working back table."

Learners are not expected to assume responsibilities for which they are not fully prepared, but they should be taught to politely speak up when something is not right for the benefit of the team and the patient. Only through continued study and experience can individuals qualify as team members in the perioperative environment.

The new perioperative nurse in a hospital orientation program, who will be functioning in interchangeable scrub and circulating roles, may learn the scrub role first in the learning sequence so as to learn the art of anticipation of surgeon and patient needs during a surgical procedure. This is the closest vantage point by which participation enables the perioperative nurse to be familiarized with the surgical process. An educator, preceptor, or other qualified staff member scrubs in as support and gradually allows the new perioperative nurse to take over more of the work in the sterile field. One of the primary behavioral **objectives** is to gain knowledge and skill in sterile technique. Performing the scrub role allows repetition of tasks performed within the sterile field and better prepares the perioperative nurse to supervise surgical technologists.

The second component of the perioperative nurse's learning sequence is the circulating role. A registered nurse preceptor is

assigned to teach the new nurse the coordination of the scrub and circulating roles. Standard routines are taught under the supervision of an experienced perioperative nurse with comparable knowledge, skill, and educational preparation. Guidance and help from the clinical educator and other experienced staff members help the new perioperative nurse pull it all together. Surgeons and other staff members contribute to the learning process.

Personality traits, such as emotional maturity, social skills, and psychologic characteristics, are continually assessed by the educator.[4] A moody, easily angered, and negative person can be very difficult to deal with as a future team member. The learner who does not possess assertive skills for dealing with stressful events cannot function effectively in a team environment. Subjective responses to all activities should remain on a professional level if the team is to function efficiently. The perioperative nurse in training should be evaluated on a periodic basis to assess for increased **competency** levels.

Perioperative Educator

Experience in the perioperative clinical setting should be planned and supervised by an experienced perioperative nurse educator. The term *educator* is used throughout this text to refer to the person responsible for planning, implementing, and evaluating the learner's experiences in the classroom and clinical perioperative setting. Other teaching personnel at the clinical site include perioperative nurse preceptors.

The educator should consider the effect on the learner who is seeing the perioperative environment for the first time. The OR can appear cold, large, and overwhelming. A tour of the facility before beginning the program can help decrease the learner's anxiety.

A structured curriculum uses behavioral objectives, written guidelines, and relevant assignments for feedback to ensure that learning has occurred. Learner conferences are held at regular intervals to discuss procedures and progress. AORN (The Association of periOperative Registered Nurses) offers perioperative nursing coursework in the AORN Periop 101 and Periop 202 programs purchased by hospitals for training of new perioperative nurses (www.aorn.org/Periop101/).

Didactic presentations should be incorporated into the teaching program to provide information concerning the theory and detail of all performed actions in the perioperative environment. Presentations should be offered by knowledgeable presenters who are well prepared to deliver information to the group. If PowerPoint multimedia are used, the educator should be sure to use accurate and concise terminology when creating the slides. Handouts can be printed in several formats for distribution to the participants to use when following along with the talk or taking notes. Overloading each slide with wordiness and silly images causes confusion and wastes time. The key elements should be simply worded and should not exceed six lines of text per slide. The educator should not read exactly from the slides, but explain while incorporating the concept the slide imparts. Font style should be simple, and font size should be readable even at the back of the classroom. Avoid typing words in all caps. The slide color scheme and design can be selected from predesigned templates or customized per presentation. Colors such as blue and green are easier on the eyes than reds, oranges, and bright yellows. Time between slide changes should permit questions or examples.

Positive reinforcement helps the learner build confidence and competence. The educator should not punish a learner for making honest errors during supervised learning. Degradation and damage to self-esteem are barriers to learning. The learner should not be required to perform any function for which he or she has not had adequate training or guided practice. The educator should maintain a list of procedures in which the learner has participated and has demonstrated increasing levels of competence. Whether the learner is in a school-sponsored OR education program or a departmental orientation program, the duration of the program should be sufficient to afford opportunities for adequate experience to facilitate success. The AORN position statement on basic orientation recommends a period of 40 hours in each specialty as part of the orientation process.

Check-off sheets can help track experiential progress during the education process. Fig. 1.1 shows an example of a basic check-off sheet for the **evaluation** of knowledge and skill in the scrub role. Fig. 1.2 shows an example of a basic check-off sheet for evaluation of knowledge and skill in the circulating nurse's role. This sheet can be modified to apply to specialties as needed. The Association of Surgical Technologists (AST) and AORN have developed skills checklists available through the organizations.

Behavioral Objectives

The learner takes an active role in the teaching/learning process by helping identify behavioral objectives. Effective and organized educational experiences are identified and based on these objectives. The identified behavioral objectives are attained through critical-thinking exercises. Skill in questioning and encouragement in making discoveries allow the learner to use **critical thinking** as a learning tool.

Evaluation of the learner's progress is measured by how successfully the learner has met the behavioral objectives. Behavioral objectives are identified and written in behavioral terms and based on standards of expected performance and accepted standards of patient care. In 1956, Benjamin Bloom described the measurement of cognitive learning. He detailed six levels of learning, ranging from simple recall to advanced abstract thinking.

Bloom's taxonomy provides a framework for structuring cognitive and affective learning. Therefore the concepts to be learned and the behavioral objectives to be met should form the foundation on which all perioperative caregivers build their practice. Each behavioral objective in Box 1.2 is measurable and is evaluated by performance standards.

Elements of Effective Instruction

The organization of the instructional material and the learning experience are further enhanced by the way the program is presented. The elements of effective instruction are summarized as follows:

- Set clear and concise behavioral objectives measurable in cognitive terminology that describes knowledge, comprehension, application, analysis, understanding, and evaluation.
- Establish a learning environment that is controlled by the educator.
- Provide variation in presenting material. Videotapes, DVDs, animated computer programs, podcasts, and photographs can be alternated with lectures and hands-on practice. Handling instruments and supplies in a classroom is less intimidating than handling them in the perioperative environment for the first time.
- Encourage the exchange of questions and answers as an assessment tool. Learners often ask exactly what they need to know. The educator can determine areas of deficient knowledge.
- Reinforce learning. After a skill has been taught in a didactic manner, provide guided practice in the clinical laboratory before the task is actually performed in the perioperative environment. Provide positive support for desired **behaviors**.

Evaluation	Meets Standard	Needs Improvement	Improving Yes or No	Does Not Meet Standard	Comments
Reports for duty in a punctual manner					
Wears OR attire properly: Dons personal protective gear Dons radiation badge as needed					
Performs housekeeping duties: Before first procedure of day Between procedures After last procedure of day					
Sterile supplies: Plans and gathers supplies Checks integrity of packages Checks sterility integrator Checks dates on perishables					
Places items on sterile surface: Opening wrapper(s) Peel packages Solution dispensing					
Scrubs for setup and procedure: Hand and arm scrubbing Hand hygiene with hand antiseptic					
Gowning: Gowns self correctly Gowns others					
Gloves: Closed method Open method Changes contaminated glove Gloves others					
Sterile setup: Drapes table and Mayo stand Positions items in the field					
Accountability: Participates in timeout before incision Labels solutions and drugs Reports amount of use Practices safety Maintains the sterile field Responds appropriately to emergent situations					
Anticipates needs of surgeon: Coordinates with circulator Facilitates the first assistant Passes instrumentation Prepares and applies dressing materials					
Counts: Sponges Sharps Instruments					
Assembles instruments: Attaches knife blades on handles Loads or prepares suture Tests drills and devices Other					
Disassembles the table: Follows proper disposal of items Follows decontamination procedures					
Removes gown and gloves: Gown off first Glove-to-glove/skin-to-skin					

• **Fig. 1.1** Performance appraisal of the scrub role.

Evaluation	Meets Standard	Needs Improvement	Improving Yes or No	Does Not Meet Standard	Comments
Reports for the duty in a punctual manner					
Wears OR attire properly: Dons personal protective gear Dons radiation badge as needed					
Performs housekeeping duties: Before first procedure of day Between procedures After last procedure of day					
Sterile supplies: Plans and gathers supplies Checks integrity of packages Checks sterility integrator Checks dates on perishables					
Dispenses or transfers items to sterile surface as appropriate: Opens wrapper(s) and peel packs Opens closed container Solution dispensing Medication dispensing					
Validates implant parameters and documents in the lot log					
Practices aseptic technique: Dons and removes sterile or nonsterile gloves as appropriate for task Hand hygiene with hand antiseptic					
Gowning and gloving of others: Ties gowns for sterile team members Assists with contaminated glove removal Provides additional gowns and gloves as needed					
Accountability: Gathers and checks solutions and drugs for use on the field Documents amount of usage of drugs and solutions on the field Practices safety for the patient and team Monitors the sterile field and the members of the sterile team					
Anticipates needs of patient, anesthesia provider, surgeon, and other team members: Coordinates with the scrub person Obtains additional supplies and instrumentation as needed					
Provides safe and competent direct patient care: Patient advocate Patient identification Assists the anesthesia provider as needed during induction Validates correct site protocol and time out procedures Patient assessment Responds appropriately to emergent situations Supports psychosocial aspects of care Positioning and prepping as appropriate Monitoring physiologic and psychologic responses as appropriate Cares for specimens Patient teaching					
Counts: Sponges Sharps Instruments Documents any other item added to the field intraoperatively					
Attaches and activates surgical machinery and devices for the sterile field: Electrosurgery (ESU) cables, suction, power cords, and other peripheral equipment Activates, sets, and monitors peripheral equipment					
Supervises and manages the room: Plans and implements direct patient care using the nursing process Directs the activities of learners Communicates procedural progress to the control desk Communicates with family members Manages messages for the surgeon and first assistant Prevents inappropriate traffic through the room Documents procedural activities in patient record Computer literacy Uses patient electronic medical record responsibly Maintains patient confidentiality Manages patient charge items responsibly					

• **Fig. 1.2** Performance appraisal of the circulating nurse's role.

• BOX 1.2 Behavioral Objectives for Perioperative Team Members

- To identify the role and responsibility of each team member
- To define current standard terminology associated with perioperative patient care through use of the perioperative nursing data set (PNDS)
- To compare and contrast knowledge of normal anatomy, physiology, and pathophysiology
- To discuss the interrelationships among physiologic, ethnocultural, and psychosocial factors that affect a patient and family's adaptation to the perioperative experience
- To identify the procedures necessary to prepare each patient as an individual for the intended surgical procedure
- To demonstrate the ability to select appropriate instrumentation, equipment, and supplies according to the individualized plan of care
- To apply the principles of sterilization, disinfection, and aseptic and sterile techniques in the preparation and use of all materials in the perioperative environment to prevent transmission of biologic contamination
- To identify the potential environmental hazards to the patient and team
- To demonstrate knowledge of the basic actions and uses of anesthetic agents, medications, fluid therapies, and electrolytes
- To demonstrate knowledge and skill during the surgical procedure by anticipating the needs of the patient and the team
- To discuss the principles of wound management
- To function as a team member by showing consideration for and cooperation with other perioperative caregivers
- To communicate effectively with personnel on other patient care divisions within the facility
- To develop the ability to perform safely and effectively during stressful situations

Self-assessment tools and performance evaluations provide feedback about the learner's progress.

- Summarize the learner's accomplishments at regular intervals. Reviewing daily activities helps reinforce the learning process by allowing the learner to associate the events of his or her experience with newly acquired knowledge.

The educator should work closely with the perioperative nurse manager. Classroom hours and clinical experience assignments are coordinated to provide the best experience for the learner. The nurse manager offers suggestions and coordination input for the benefit of the learner and staff members. The educator identifies areas of needed experience for the learner. An effort is made to confer and coordinate any changes in the program with all personnel in the department. The educator and the manager collaborate with the assigned preceptors as needed. These strategies foster a friendly and cooperative relationship among learners, educators, management, and preceptor staff.

All perioperative staff members indirectly assist in teaching the learners within the guidelines of the structured learning experience. The learners gain knowledge by observing and working with members of the entire team. Everyone should be familiar with the knowledge level of the learners, the behavioral objectives, and the teaching roles that staff members are expected to assume. Learners also should be responsible for updating the staff about needed experience and their current level of achievement.

Hospitals or facilities offering the clinical perioperative setting for educational programs have policies and procedures that are adaptations of national standards. All personnel, including faculty members and learners, are expected to adhere to their content.

PROS/CONS

Perioperative Educator: Engaging the Learner

Pros

- Health care facilities perform better when employees are engaged with what they are doing. Commitment is linked to job satisfaction and better organizational performances.
- Educators and managers must recognize the current culture of their department and find ways for improvement.
- Health care facilities require education on certain topics as part of employee annual training. These competencies may be required yearly and are documented in the employee record.
- As part of continuing education, a facility may have a perioperative educator or manager who follows a structured curriculum according to the facility guidelines and policies.
- Continuing education credit may be given for completion of a test after an educational presentation.
- Scheduled regular in-services are planned when most employees can be present; this usually occurs during the work day. Employees who are not in attendance may need to reschedule with the educator to cover the missed material.
- Staff involvement during in-services increases when they are recognized, part of decision making, on a unit council, involved in teamwork, involved in training, and recruited to assist.
- A structured presentation keeps the group interested. When knowledge is linked with previous knowledge and preexisting cognitive structure, effective learning occurs.
- People retain information in different ways. Some positive ways to engage staff during an in-service includes vary the tone of voice, include positive body language, practice presentation skills, offer refreshments, tell a story, ask questions, role play, use fewer words, and use technology.
- Understanding information is easier through the use of images, color, audiovisual, demonstration, and active participation.
- Employees may have preclass preparation such as an article or computer module to read, small group discussions, and simulation. Each employee may be required to demonstrate the simulation during the in-service. This helps build confidence and competence through positive reinforcement.
- Use surveys and committees to engage staff; this encourages participation and a chance to be heard.

Cons

- Low morale and poor job satisfaction lead to low participation in educational activities. Workplace culture is hard to change and often ingrained into the culture of the facility.
- Disruptive behavior (bullying) creates bad employee attitudes and needs to be redirected. Redirection may increase in-service participation, positivity, and a better learning environment.
- Learners forget what was taught and done during boring in-services. They get distracted easily. Use emotion because it is a strong memory stimulus and can be more effective than reading data.
- Large groups tend to be less engaging. Break a large group into smaller groups if possible because they are more productive.

Media and Print Learning Resources

Books, journals, videos, DVDs, slides, photographs, computers, and audiovisual materials may supplement the lecture approach to perioperative education. Larger teaching institutions may have live closed-circuit television and interactive telecommunication systems that permit educators and learners to communicate from remote locations. Many audiovisual materials, such as videodiscs, audiotapes, and computer-assisted instruction, are self-contained units for individual study. A bibliography in a text such as this or at the conclusion of a journal article provides references to broaden the learner's database. Accessibility to current medical and scientific literature is without limit. Other sources include websites on the Internet and educational services that provide contact hours online.

The following are useful resources for acquiring and reinforcing knowledge:

1. Library and literature file. Books and current periodicals are available for the learner's reference in the medical library, online, and in learning centers at local colleges.
2. Educational literature, DVDs, and portable storage devices such as a USB flash drive or jump drive are available from surgical supply and instrument manufacturers. Most manufacturers have their product literature and educational material online. All personnel who will be working with the item should review the new equipment literature. In-services are commonly provided by clinical staff associated with the industry. The purchasing agent is a good resource for these types of references.
3. Computer database information systems are available in most facilities or through personal Internet access providers for researching topics of interest for self-study or for supplementing classroom presentations. Computer terminology is defined at www.sharpened.net/glossary for new computer users. Web browsers such as Microsoft Internet Explorer, Mozilla Firefox, Apple Safari, Opera, and Google Chrome are used in searching the World Wide Web (WWW). Most of the search engines have an image-finding capability that allows students to associate the image with a procedure. Many prerecorded surgical procedures can be watched on various websites. Search engines such as Bing and Google are valuable tools for finding special-interest groups and professional medical associations. Most health-related organizations have a website full of information for professionals and patients. AORN Online can be accessed at www.aorn.org. AST has a website at www.ast.org that provides information about surgical technology. Terms associated with the Internet and computer can be found at http://evolve.elsevier.com/BerryKohn.
4. Internet broadcasting in podcast format can be uploaded onto an iPod, MP3, and/or smart device such as a phone, watch, or speaker in audio or video format for remote viewing.
   Netcasts and webinars are online broadcasts for use on smart phones, tablets, PCs, or Macs. Many of the topics are available via the Apple iTunes store. Accounts can be set up with a credit card or PayPal.
   Really Simple Syndication (RSS) feeds are subscription services that provide information via computer and cell phone in the form of e-mail. RSS data is small so it works well with smart phones. A software RSS reader program is necessary to receive and open RSS feeds. The readers are free on the Internet and are part of browser packages such as Internet Explorer or Firefox. Collections of educational medical and nursing RSS feeds are found at www.medworm.com.
5. Specialty online news groups can be subscribed to through computerized e-mail systems. Referred to as *ListServ,* these groups are communication tools for day-to-day discussions with others who have comparable interests. They are available as daily e-mail entries or as a weekly digest. The specialty assemblies at aorn.org have membership blogs where members share ideas. The surgical technology website has educator and student blog sites to discuss topics of interest for surgical technologists.
6. Literary databases are found on select websites and in most libraries. Examples of online literary databases include but are not limited to the following:
   a. Cumulative Index to Nursing and Allied Health Literature (CINAHL) is a widely used index for nursing and allied health. The database includes indexing by subject headings from virtually all English-language nursing journals and allied health literature from January 1983, with bimonthly updates.
   b. Medical Literature Analysis and Retrieval System Online (MEDLINE) is a computer-based reference system available at most libraries in the United States and Canada. Many websites on the Internet offer free MEDLINE access. Biomedical journals, including nursing journals, are referenced. References dating from 1966 at the National Library of Medicine are found at www.nih.gov
   c. Medscape (www.medscape.com) is a free article subscription service online. This site requires registration. The user selects an identification name and password. Many different specialty services are represented in print with continuing education credits.

The array of health-related educational materials is endless. The Internet, which is accessible 24 hours a day, has opened many channels of information throughout the world. Many websites can be accessed in a multilingual mode, including Spanish, German, French, and Japanese. Some websites offer full-text articles that can be uploaded or printed. Some of the articles are in .zip or .pdf format that requires WinZip or Adobe Acrobat Reader to open the file into a readable and/or printable document. WinZip and Acrobat Reader are free programs that can be downloaded and used repeatedly to open zipped or pdf files. Websites such as www.download.com offer links to free file-opening software. These programs are frequently preloaded onto the hard drive of new computer models.

The advancement of computer technology has made computer equipment as small as a wrist watch and devices that easily fit in a pocket or backpack. The average household can now own multiple devices because of their affordability. Tablets and similar devices are good for reading eBooks. Multiple books can be stored on one device.

When researching scientific data on the Internet, it is advisable to review more than one website to support the accuracy of the information. Caution is advised regarding providing personal information such as credit card numbers over the Internet; security may be an issue.

Application of Theory to Practice

Learning is a process of discovery and mastery of skills. Performance-based learning to function competently in an area such as the perioperative environment should take place on three levels: cognitive, **psychomotor**, and affective. The learner should understand the scientific principles (cognitive learning) underlying the technical skills (psychomotor learning) and should

appreciate the necessity of adhering to these principles (affective learning). In simpler terms the learner should know why to do what (cognitive); how (psychomotor); and when, where, and by whom (affective). The learner should always have a rationale for each action. Learners and practicing perioperative caregivers should always know exactly why they are doing what they are doing—not just blindly perform tasks. This approach enables an intelligent modification of the plan of care in the event of an emergency or other untoward situation. In actual practice this knowledge may be critical for patient safety and attainment of favorable outcomes.

Practice will give learners an opportunity to apply their knowledge of the basic sciences. Theory becomes meaningful and valuable only when put to practical use. Some knowledge is gained through observation, but skills are learned through actual hands-on experience in applying the theory learned in the classroom or self-study laboratory.

In the perioperative environment the learner observes living anatomy; its alteration by congenital deformities, disease, or injury; and its restoration or reconstruction. Perioperative experience enables the learner to be a more understanding, observant, and efficient person. In close teamwork with surgeons and anesthesia providers the nurse and the surgical technologist participate in vital resuscitative measures and learn to care for anesthetized, unconscious, and/or critically ill patients. Learning to function in life-threatening situations is critical to the patient's welfare. In addition, the learner discovers that emergencies such as cardiac arrest are easier to prevent than treat. By learning how theory applies to clinical practice, the student gains valuable experience that is applicable to any patient care situation. The learner should strive to attain the following objectives:

- Appreciate what surgical intervention means to each patient.
- Recognize the importance of optimal physical and psychologic preoperative patient preparation.
- Validate the need for constant patient observation intraoperatively.
- Determine the cause of postoperative pain and/or complications.
- Differentiate between seemingly innocuous occurrences and situations that, if left unrecognized and allowed to progress, lead to injury of the patient or a team member or damage to departmental equipment.
- Cope with all situations in a calm, efficient manner, and think clearly and act quickly in an emergency.
- Attend to every detail, observe keenly, and anticipate the needs of the patient and team members.
- Determine the importance of aseptic and sterile techniques, and comprehensively and conscientiously apply knowledge to practice.
- Expect the unexpected. Situations or conditions can change at a moment's notice. The student should use the "what if" philosophy for planning patient care. Thinking ahead and anticipating what to do "if" the patient becomes critical benefit the patient and the team by minimizing the element of surprise when unexpected events occur.

Above all, perioperative experience teaches that no surgical procedure is a minor event to the surgical patient! The only predictable element in the perioperative environment is the potential for an unpredictable occurrence. For practical use, hospitals may classify surgical procedures as major or minor; however, in reality no such distinction exists. Every procedure has a deep personal meaning for each patient and his or her family, and the possibility of an unfavorable outcome can never be completely excluded. All perioperative procedures carry an element of inherent risk. A relatively safe procedure can rapidly become catastrophic, even fatal, if the patient:

- Is unknowingly allergic or sensitive to a chemical, substance, medication, or anesthetic drug
- Develops uncontrollable bleeding
- Has seizures or blackouts
- Experiences cardiac arrest on the OR bed
- Goes into irreversible shock (cardiogenic, hematologic, hypovolemic, neurogenic, toxic, or vasogenic)
- Develops a metabolic event such as malignant hyperthermia, thyroid storm, hyperglycemia, or hypoglycemia

Although every precaution is taken to foresee and prevent adverse reactions, such reactions do occur on occasion. No matter how simple the procedure, an experienced, conscientious team member is always acutely aware of potential problems and gives undivided attention to the patient and procedure at all times.

During the learning experience the learner will participate in or observe the preparation of supplies and equipment and learn their intended use. With practical experience the learner will gain an appreciation for the precision of surgical instrumentation and equipment. Also, in helping to carry out a daily schedule of surgical procedures the learner will become aware of the interdependence of the various departments within the facility and how they work together for the well-being of the patient. One of the most valuable learning experiences in the perioperative environment is the opportunity to see and become a part of real teamwork in action. Chapter 25 explores and explains the coordinated roles of the circulating nurse and the scrub person.

Expected Behaviors of Perioperative Caregivers

Regardless of their respective roles, all perioperative caregivers are expected to be competent and humane. A patient's sense of security is grounded in how he or she perceives the behavior of the team as a whole. This leaves a lasting impression that patients associate with their experiences in the perioperative environment. The behavior of the team reveals self-confidence (or diffidence), interest (or indifference), proficiency (or ineptitude), and authority (or indecision). In addition to possessing technical knowledge and skill, personnel should display appropriate personal attributes and communication skills that inspire confidence and trust in patients and other team members.

Personal Attributes

Personal attributes are manifest in the attitudes displayed by an individual while performing his or her duties. These inherent characteristics contribute to interrelatedness of the team and the final outcome for the patient. Although these concepts are intrinsic to the individual and are certainly open to interpretation, the main premise remains focused on providing safe and efficient patient care through a team effort. Desirable personal attributes are listed in Table 1.3.

Communication

Communication is essential for exchanging information with another person. It is necessary for successful interpersonal relationships and serves to clarify actions. Communication is proactive when an idea or intent is relayed to another person and reactive

TABLE 1.3 Attributes Expected in a Perioperative Caregiver

Desirable Attribute	Measurable Behaviors
Empathy	Develop a sense of what the patient is feeling
Conscientiousness	No compromise in quality of care
Efficiency	Organized and properly prepared; time is not wasted duplicating steps
Sensitivity	Genuine caring and perceptiveness for the patient and the team
Open-mindedness	Accepting of the ideas of others
Flexible and adaptable	Able to cope with changes in routine
Supportive	Nonjudgmental and sincere approach to relationships
Communicative	Exchanges information in a professional manner
Listening	Accepts and receives information in a professional manner
Even-temperedness	Hostility and anger have no place in the perioperative environment
Versatility	Knowledgeable and can troubleshoot
Analytic	Knowing how and why for each task
Creativity	Able to innovate solutions
Sense of humor	Eases tension at appropriate times
Manual dexterity	Good hand-eye coordination
Stamina	Capable of standing for prolonged periods
Good hygiene	Body odors cause discomfort for the team
Ethics	Strong sense of truth, honor, and goodness
Curiosity	Desire to know and learn new things

when a response is received. Communication has taken place when the receiver interprets the message in the manner intended by the sender. Communication is effective only when the patient and caregivers understand one another. A key element is to demonstrate appropriate body language to match the spoken word.

Teamwork

A team is a group of two or more people who recognize common goals and coordinate their efforts to achieve them. Broadly defined, the health care team includes all personnel relating to the patient—those in direct patient contact and those in other departments whose services are essential and contribute indirectly to patient care. Interdependence characterizes a team—without the other members, the goals cannot be met.

The team approach to patient care should be a coordinated effort that is performed with the cooperation of all caregivers. Team members should communicate and should have a shared division of duties to perform specified tasks as a unified body. The failure of any one member to perform his or her role can have a serious effect on the success of the entire team. Performing as a team requires that each member exert an effort to attain the common goals competently and safely. The actions of each team member are important. No one individual can accomplish the goal without the cooperation of the rest of the team.

Pride in professional work, and in the team as a whole, leads to personal satisfaction. High morale is facilitated by adequate staff orientation, staff participation in departmental decision making and problem solving, the receipt of deserved praise, the opportunity for continuing education, and motivation to reach and practice at the highest potential.

The common goal of the perioperative team is the effective delivery of care in a safe, efficient, and timely manner. To function efficiently, team members must communicate effectively. Problems such as a break in aseptic or sterile technique must be identified and corrective actions taken. To fulfill expectations, team members must be aware of each other's needs for information. Efforts of other support services, such as radiology and pathology departments, are coordinated with the needs of the surgeon.

Mutual respect is the foundation of teamwork. It is also a right. Respect is shown through collaboration, cooperation, and truthful communication. Verbal abuse, disruptive behavior, and harassment are out of place in the professional environment. Behavior that inhibits the performance of team members or threatens patient safety should be factually documented and reported to superiors in the chain of command. The Joint Commission (TJC) requires accredited facilities to establish leadership standards that address disruptive and inappropriate behaviors as follows:

1. Defines a code of conduct to distinguish between acceptable and inappropriate behaviors in interpersonal relationships in the perioperative environment
2. Creates and implements a process for managing behaviors that undermine a culture of safety in the perioperative environment

Teamwork requires the commitment and effort of team members to increase productivity, ensure quality performance, and participate in problem solving by communicating and cooperating with one another. A team approach is necessary for patient-centered care. Surgeons, assistants, anesthesia providers, patient care staff, and staff of supporting services should coordinate their efforts. Each discipline contributes to successful outcomes of surgical intervention by working together as a team. The following factors contribute to these successful outcomes:

1. Interdepartmental communication is important for mutual cooperation, consideration, and efficient collaboration.
   a. Personnel on patient care divisions and physicians share pertinent information concerning patients. Collected data are documented, thereby protecting the patient, the patient care personnel, and the facility.
   b. Personnel work together in a congenial atmosphere with respect and appreciation for each other's unique skills and contributions. Team members benefit from the expertise of each other. Teamwork is at its finest in the perioperative environment.
   c. Personnel are considerate of each other and the patient.
      - The surgeon should inform the team of any anticipated potential deviation from his or her regular routine for the scheduled procedure. An advance notice of changes can help avoid delays in obtaining needed equipment.
      - The perioperative team promotes a quiet atmosphere to ensure the surgeon's uninterrupted concentration. Interruptions during the procedure can cause the team to lose concentration and jeopardize the safety of the patient or team members.

- The anesthesia provider and circulating nurse assist each other with certain procedures such as medication administration and intubation.

2. Adequate preparation and familiarity with the surgeon's preferences and the surgical procedure to be performed are fundamental to teamwork. If the perioperative staff members are unfamiliar with the routine and equipment, the patient or a team member may be at risk for injury. An adequately experienced and skilled team is essential for the effective performance of a safe, efficient procedure.
3. The patient has an unconditional right to the team's complete concentration and attention at all times. He or she is a unique individual who is completely dependent on the perioperative caregivers to work as a team.

Although the ideologic differences of personnel may at times be a source of conflict, the care of the patient should be a priority over personality differences. Complex procedures, busy surgery schedules, or shortages of personnel should not interfere with the delivery of efficient, individualized patient care.

Clinical Competence

On the basis of experience and performance, patient care personnel can be categorized as novice, competent, proficient, or expert. The novice lacks experience but is expected to perform to the best of his or her ability with assistance. Most employers provide a formal orientation program for new patient care personnel. During this orientation period, the necessary knowledge, skills, and abilities should be developed to perform at a level of basic competency. As experience is gained, proficiency expands from a minimal competency to an advanced level of expertise. Competent practice requires critical thinking skills and decision-making ability. Statements of clinical competency are established by professional organizations such as AORN and AST. Guidelines are published by each professional organization and made available to practitioners of all disciplines. Competencies are discussed in more detail in Chapter 2.

Realities of Clinical Practice

When a formal educational experience is completed, a learner or orientee is eager to apply his or her skills and knowledge in an employment setting. A transition from dependent learner to independent practitioner evolves over time. The realities of the work environment and the emotional and ethical dilemmas of some situations are experienced as basic competencies are developed. The development of **surgical conscience** evolves as experience is gained. Surgical conscience applies the standards of care to ethical situations and makes decision making more concrete.

It can take 6 months to 1 year to feel confident as a functioning perioperative team member. Many facilities require personnel to take calls for emergencies after business hours; therefore the staff must be competent to fulfill this requirement independent of a preceptor.

Reality Shock

Reality is a sense of actuality, a feeling that this is what the real world is all about. Reality shock sets in as the transition takes place from being a beginning learner to becoming an employed graduate professional nurse or surgical technologist. The familiar educator and peer learners are not always present to give counsel, advice, and moral support. As professional caregivers attempt to adapt to new demands, they need to remember the following:

- Learning does not end with basic education. It is an ongoing process throughout an entire professional career.
- Teaching at various levels is the responsibility of the entire team. New information is developed and shared by the group for the improvement of patient care practices.
- All caregivers were once novices (although some may have forgotten those novice days). They have experienced the feelings and frustrations of being the newest staff member. The experienced caregiver should try to remember these feelings and offer encouragement to new personnel.
- Patience is an asset while developing work habits and establishing working relationships. Expectations of self and of others should be realistic. Feelings of excitement and anticipation and the fear of failure or making mistakes are normal but should be expressed appropriately. Disruptive behavior distracts the attention of the team from the patient.
- Applying the principles and techniques already learned will enable the caregiver to make sound judgments and appropriate decisions in the perioperative environment.
- It is important to ask questions and acknowledge not knowing how to do something. Seeking help promotes professional growth.

Everyone wants and needs to become an accepted member of both social and work groups. The entire perioperative team, including the surgeon and anesthesia provider, is both a social group and a work group. Ambivalent feelings may arise on entering these groups. The pleasures of functioning as a team member may be offset by uncertainty about the ability to perform well. Initial goals will be task- and skill-oriented as learning focuses on policies, procedures, and routines. Eventually insecurity will be replaced with self-confidence. The display of confidence will increase trust, respect, and recognition from others, as well as the personal satisfaction of accomplishment.

Dynamics of the Psychologic Climate: Preceptors, Mentors, and Role Models

Learning to adapt to the variety of tasks and ever-changing demands in the perioperative environment is difficult. Some anxiety is normal, especially in situations in which feelings of insecurity are generated or a sense of intimidation pervades the environment. At times the demands of the job may seem to outweigh the personal resources of the caregiver. Confidence develops as skills are learned.

An understanding of expected performance is perhaps the most important element in the transition from novice to independent practitioner. Personnel in the perioperative environment play vital roles in the beginner's development. There is a distinction among the roles of preceptor, mentor, and **role model**. A preceptor works with orientees and learners according to a prescribed task-oriented lesson plan. The process offers minimal flexibility and little personalization for individual needs. A mentor has more experience with the personnel and the climate of the OR and can provide insight into the social atmosphere of the department.[5] A mentor develops a relatively personalized relationship with less experienced orientees or learners and fosters a sense of nurturance for their growth and assimilation into the department. A beginner should look for a mentor to help bridge the gap

between novice and proficient levels. Beginners should also look for role models—those experienced staff members who are emulated and respected for their clinical competence—and pattern their emerging professional self after the behaviors of the role model. A personal relationship may not evolve with a role model in the same way as with a mentor.

The beginner should stick with the winners—those staff members who are reaping personal rewards and self-satisfaction from their work ethic. Their enthusiasm will be contagious and start the growth of an exciting career. The losers—staff members who have negative attitudes, complain, and do not make an effort to solve problems but instead create them—should be avoided.

Eustress versus Distress

Physical and emotional stresses are part of daily life. Stress is the nonspecific reaction of the body, physiologically and/or psychologically, to any demand. The demand may be pleasant or unpleasant, conscious or unconscious. The intensity of the stressor will dictate adaptation. An individual's perception of a situation will influence the reaction to it.

Stress is not only an essential part of life but also a useful stimulant. Positive stress, referred to as *eustress,* motivates an individual to be productive and efficient. It forces adaptation to the ever-present changes in the perioperative environment. The response should be quick (e.g., when a trauma victim arrives or a patient has a cardiac arrest). To expect the unexpected is part of perioperative patient care. Eustress fosters a sense of achievement, satisfaction, and self-confidence.

Stress that becomes overwhelming and uncomfortable is referred to as *distress*. In the perioperative environment the behavior of others may be perceived as cause for distress. Policies, or a lack of them, can also be a source of distress if they are in conflict with the caregiver's expectations. Through adaptive mechanisms, the caregiver can cope with the tensions, conflicts, and demands of the perioperative environment in either a collaborative or a nonproductive manner. Even though perceived as distress, some conflict is necessary to stimulate a change in work methods and solve organizational problems. Sometimes it takes dissatisfaction with a situation to spark positive change and prevent stagnation.

Patient care personnel become distressed by the conduct of other team members. For example, it is uncomfortable to be harshly criticized by a surgeon in front of peers or patients. However, much that is said is not personally directed. Often the surgeon is reacting to his or her distress regarding unanticipated circumstances presented by the patient, team member, or equipment during the surgical procedure. The reactions of personnel will be influenced by their attitudes, mood, cultural and religious background, values and ethics, experiences, and concerns of the moment. Outbursts of anger are never appropriate in the OR. However, constant frustration and inner conflict create the distresses that can lead to job dissatisfaction. Behaviors that place patients or personnel at risk, such as throwing objects, should be reported to the nurse manager and documented. Many facilities have developed a zero tolerance policy for abusive behavior in the OR.

Stress Reduction

Assertive behavior is a useful tool for conflict resolution. Shared professional communication can keep the tension in the environment at a minimum. The caregiver should keep his or her composure at all times and maintain a professional and assertive (not aggressive) attitude. Personal conflicts between team members should be dealt with privately.

Humor can be an effective method of reducing anxiety. It should be used appropriately to defuse tension. Laughing at oneself helps preserve self-esteem while learning from the experience.

At the end of the work shift the caregiver should evaluate the events of the day, the emotions evoked, and how they were handled. What was done effectively? What coping skills may be needed to improve or enhance positive attitudes and interpersonal relationships in the work environment? Teamwork is essential in the perioperative environment, with every team member obligated to make a positive contribution.

Stress is a reality that need not create a sense of self-defeat. Regardless of the source of stress, the body responds, and the physiologic and psychologic effects can be subtle or intense. The determination of whether a stressor is good or bad depends on an individual's perception of the circumstances. Any event that creates a feeling of impending danger also creates the perception of loss of control. A major factor in stress management is maintaining control, which can be accomplished by learning to tune in to the balance between the body and the mind. The caregiver can learn to be prepared for life's difficulties by understanding how the perception of stress can affect decision making, self-expression, and subsistence in the world.

Listening to the Body

The caregiver should develop a sense for how the body signals exhaustion, hunger, illness, and/or physical pain. The body is a sensory barometer of the environmental effects on the caregiver, and ignoring physical signals decreases the ability of the body to manage stress. Going without sleep or skipping meals creates physical stress that can be avoided. Sleep deprivation caused by long hours on call can be as dangerous as overuse of alcohol or using illegal drugs. The biologic need for sleep cannot be denied and is important for the health and safety of the individual and the others in the environment. Decision making, reaction times, memory, and generalized health are impaired by not getting enough rest. Regular sleep of at least 6 hours per day and rest periods, exercise, adequate dietary practices, and routine health checkups provide a sound basis for care of the body.

Maintaining the Mind

Mental relaxation can help the caregiver manage stress. Using meditation and mental imagery on a regular basis provides a break from stressful routines and allows the mind to fortify itself against the negative perceptions of a situation. Creating time to clear confusing thoughts and align productive thinking enables the body and the mind to support an emotional balance and a sense of well-being. This positive interaction can become an influence in a stressful situation and serve as an example to coworkers.

Foundations of Perioperative Patient Care Standards

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Discuss how standardization influences patient care.
- Describe two professional sources of patient care standards.
- List three main aspects of accountability.
- Identify the components of the nursing process.

KEY TERMS AND DEFINITIONS

Accountability Answering for performance of a service or task.
Accreditation Method of professional evaluation and recognition of an institution for meeting educational, practice, and national standard parameters.
Advocacy Active support of another person.
Benchmark Point of reference that sets the evaluation point of activities.
Competency statement Document based on empirical data that define expected and measurable clinical activities.
Domain Set of knowledge that is specific and clearly identified.
Element Smallest unit of data that is known and can be described and measured.
Guidance statement Document based on empirical data that suggests processes for performance of clinical activities.
Guideline Document or concept based on empirical data that guides clinical activities.
Licensure Approval for practice granted by a governmental agency for a predetermined period, after which the approval process is repeated.
Nomenclature Specialized set of terms.
Nursing diagnosis Identification of patient problem, need, or health consideration, which may be actual or at risk; based on human response patterns according to NANDA International.
Nursing process Organizational framework for planning patient care; this involves assessment, nursing diagnosis, outcome identification, planning, implementation, and evaluation of the plan.
Obligation Duty or promise.
Outcome Effect of an intervention.
PNDS Perioperative nursing data set. Standardized perioperative nursing language.
Position statement Document that describes a particular belief.
Profession Vocation in a specialty requiring specialized education and knowledge.
Recommended practice Activities believed to be the optimal level of professional practice that are achievable.
Responsibility Social, moral, or legal duty.
Rights Power or possession of privilege.
Standard Authoritative statement that describes accountability, values, and priorities.
Taxonomy Orderly classification based on interrelationships.

This chapter establishes the basis for perioperative patient care. The opening section gives a glimpse of historic patient care and progresses to modern perioperative practice.

Surgical Conscience

The essential elements of perioperative practice are caring, conscience, discipline, and technique. Optimal patient care requires an inherent surgical conscience, selflessness, self-discipline, and the application of principles of asepsis and sterile technique. All are inseparably related.

Florence Nightingale is credited with developing the environmental theory of patient care on which all perioperative patient care is based (Box 2.1). According to her theory, the caregiver is accountable for creating and maintaining the best possible environmental conditions to assist natural healing. She emphasized the need for prevention through education and teamwork. In her eyes the team consisted of not only the caregivers, but also the patient and family. She often approached her legislators with suggestions for bills and laws designed to protect patients and caregivers. Her numerous letters and writings chronicle her work.

The concept of a surgical conscience is simply a surgical Golden Rule: *Do unto the patient as you would have others do unto you* (Box 2.2). The caregiver should consider each patient as himself or herself or as a loved one. Once an individual develops a surgical conscience, it remains inherent thereafter. Nightingale summarized what is, in essence, its meaning, when she said, "The nurse should keep a high sense of duty in her own mind, must aim at perfection in her care, and must be consistent always in herself."

Patient Rights

As a consumer the patient purchases services to fulfill health care needs and is entitled to certain **rights**. Access to health care is recognized as a right, not a privilege, of every human being.

• BOX 2.1 Nightingale's Environmental Theory

Physical Environment
- Sanitation
- Ventilation
- Lighting
- Noise
- Odors
- Temperature

Psychologic Environment
- Communication
- Advice
- Variety
- Scientific knowledge base
- Creativity
- Spirituality

Social Environment
- Mortality data
- Prevention of disease
- Education of caregiver
- Nursing as distinct from medicine
- Accountability
- Responsibility

• BOX 2.2 Elements of Surgical Conscience

- A sense of moral obligation and responsibility
- Self-regulation and control
- Honesty and integrity in professional practice
- Personal commitment
- Ethical value system
- Admit and remedy errors
- Sincere desire to do the right thing

Patient Advocacy

In **advocacy**, a patient advocate recognizes the patient's and the family's need for information and assistance in coping with the surgical experience, regardless of the setting. As an advocate the perioperative nurse can provide information discovered during patient assessment that identifies specific needs or health concerns requiring action. Advance preparation can help the patient and family anticipate events. Assistance in coping acknowledges the anxieties and fears of the patient and family, regardless of how minimally invasive the procedure may seem. No procedure is minor to the patient! Each patient reacts differently. The patient senses some relief in knowing that the caregiver has taken the time to identify needs specific to his or her care. The patient advocate is a caregiver who acts in the following ways:

1. Establishes rapport with the patient, family, or significant others in a manner that conveys genuine concern and sincere caring
2. Encourages the patient and family or significant others to express feelings and ask questions
3. Helps relieve anxiety and apprehension by providing appropriate factual information regarding what to expect
4. Helps the patient to make informed decisions throughout the perioperative experience
5. Acts as a patient representative by communicating pertinent information to other team members
6. Oversees all activities throughout the perioperative experience to ensure the safety and welfare of the patient
7. Keeps the family informed of significant events throughout the perioperative experience
8. Protects the patient's rights by compliance with advance directives for care (living will, durable power of attorney, or both). Additional information about advance directives and durable power of attorney can be found in Chapter 3.

Accountability

Accountability means answering to someone for an obligatory action. As both learners and caregivers, perioperative nurses and surgical technologists are accountable to the following people and entities:

- Patients receiving services
- Employer
- Educational institution providing learning experiences
- Profession or vocation to uphold established standards of practice
- Self and other team members

A lack of accountability for behavior in the perioperative environment may result in patient injury or dissatisfaction with care. Health care providers have a legal and moral **obligation** to identify and correct situations that threaten a patient's safety and well-being. Most incidents that could endanger the patient lead to preventable legal actions. Prevention focuses on the responsible performance of duty and continual performance improvement. The provision of safe care of the patient also protects caregivers and the health care facility from liability. In addition, it upholds the reputation of the professions by maintaining the confidence of the consumer public. Failure of a caregiver to maintain accountability constitutes negligence. If negligence is established, any caregiver can be held liable for his or her own acts of omission or commission. Each person is responsible for his or her own negligent acts.

Standardization of Patient Care

Importance of Standardization

Perioperative patient care personnel should be able to cope with all situations and give patients the best of their skills and knowledge. Although the use of different techniques may achieve the same results, each hospital establishes policies and procedures for all personnel to follow based on **standards**, **recommended practices**, and **guidelines** developed by professional organizations and predicated on scientific research. These written policies, procedures, and guidelines help prevent confusion and foster coordination of activities. The guidelines, or **guidance statements**, are intended to demonstrate a way to incorporate recommended practices in everyday patient care. Uniformity and standardization of procedures help personnel develop skill and efficiency for the following reasons:

- The main purpose is to ensure the safety and welfare of the patient and personnel.
- It is easier for the perioperative educator and preceptors to teach learners consistent methods of patient care.
- Learning is easier if everyone performs procedures in the same way.
- Deviations show a need for evaluation of the procedures or the staff. Do the procedures need revision?
- Consistent procedures provide an efficient check during preparation for any surgical procedure.
- One person can take over for another at any time during the surgical procedure, if necessary, and know exactly where to find instruments and supplies.
- Routine procedures establish habits that increase speed in thought and action. Doing work in a certain way promotes a high level of proficiency.
- Knowing the standards allows intelligent decision making when a patient's condition requires modification of a routine.

Professional Sources of Standards

Standards of care are defined as those acts that a reasonably prudent person with comparable training and experience would perform under the same or similar circumstances. Professional standards delineate activities related to performance, performance improvement, continuing education, ethical behavior, **responsibility**, and accountability.

Standards established by regulatory agencies are governed by laws. Standards established by professional associations are voluntary. Standards of practice for perioperative patient care include professional and regulated standards. Several sources of perioperative patient care standards are identified in the following list:

1. Standards of Perioperative Nursing. These standards, which originated as American Nurses Association (ANA) standards of OR practice in 1975, were approved by ANA and AORN (Association of periOperative Registered Nurses) and originally published in 1981. Reviews and revisions are done annually as needed.

   These five sets of standards for an optimal level of perioperative nursing practice are published annually in the *AORN Guidelines for Perioperative Practice* (formerly AORN Standards and Recommended Practices). The scaffold of the standards is premised in patient care quality and is primarily trifold—Structure, Process, and **Outcome**. These three components provide a means for the perioperative nurse to analyze and interpret care. Reviews and revisions are done yearly as needed.

   a. *Standards of Perioperative Administrative Nursing Practice.* These structural standards provide a framework for establishing administrative and organizational practices in a variety of settings.
   b. *Standards of Perioperative Clinical Practice.* These process standards are based on problem-solving techniques using principles and theories of biophysical and behavioral sciences. They describe how the nursing process is used in the perioperative setting. The Perioperative Nursing Data Set (**PNDS**) provides a means to measure and collect performance improvement data.
   c. *Standards of Perioperative Professional Practice.* These process standards describe a competent level of behavior for the professional role of the perioperative nurse. The activities relate to quality practice evaluation, continuing education, collegial relations, collaboration, ethical conduct, and use of resources, evidence-based research, and leadership.
   d. *Quality and Performance Improvement Standards for Perioperative Nursing.* These process standards to assist in the development of methods to measure, assess, and improve patient care.
   e. *Perioperative Patient Outcomes: Standards of Perioperative Care.* These outcome standards reflect desired observable patient outcomes during preoperative, intraoperative, and postoperative phases of patient care. They focus on patient and family responses to intervention during surgical, diagnostic, or therapeutic intervention. Each outcome has a unique identifier in the PNDS.
2. The Operating Room Nurses Association of Canada (ORNAC, www.ornac.ca) has published the ORNAC Standards, Guidelines, and Position Statements for Perioperative Registered Nurses (formerly Recommended Standards for Operating Room Nursing Practice and Quality Assurance Audit.)
3. Association of Surgical Technologists Standards of Practice (AST, www.ast.org). These process standards provide guidelines for safe and effective patient care in appropriate preoperative, intraoperative, and postoperative practice settings. They include interpersonal skills, environmental safety, and application of principles of surgical technology.
4. The Joint Commission (TJC) standards (www.jointcommission.org). These standards, published in the Accreditation Manual for Hospitals, are functional, performance-based standards that focus on actual clinical care provided directly to patients and on management of the health care organization providing services. They relate to efficiency, effectiveness, safety, and timeliness; appropriateness, continuity, and availability of care; and patient satisfaction. TJC evaluates compliance with these standards and reviews clinical outcomes of care provided as fundamental criteria for **accreditation**. Selective clinical indicators serve as outcome measurements for the processes of patient care. Additional information about error reporting and monitoring of patient care standards is found in Chapter 3.
   - TJC established National Patient Safety Goals: The goals are up-dated as needed. Some of the goals include:
   - Improve the accuracy of patient identification by using at least two forms of patient identification.
   - Improve the effectiveness between caregivers by using standardized patient "hand-over" or "hand-off" reporting (change from one caregiver to another), verbal reflection, avoiding abbreviations and symbols, and ensuring timely communications.
   - Improve the safety of using medications by identifying potential "sound-alike" or "look-alike" drugs in the facility,

labeling all drug containers and delivery devices on and off the field, decrease the risk of anticoagulation error.
- Reduce the risk for health care–associated infections by meticulous hand hygiene and by recording and reporting as a sentinel event any unanticipated death or loss of function associated with sepsis or health care–acquired infection.
- Accurately and completely reconcile medications across the continuum of care by comparing patient current medication regimen with medication orders during care in the facility. Patient and subsequent caregivers in and out of the facility are provided a complete list of current medications on discharge.
- Reduce the patient's risk for harm from falls by implementing a program of safe patient positioning and transport in the OR. Fall prevention programs should have an evaluation process.
- Encourage the patient's participation in the safe delivery of care by defining and communicating the steps of care and encouraging the patient and family to ask questions and voice concerns for safe care.
- Identification of potential safety risks in the patient population relevant to patients with emotional or behavioral disorders by prevention of self-harm or suicide.
- Improve recognition and response to changes in the patient's condition by ongoing assessment and immediate access to specially trained individuals when a patient's condition has changed.

5. National Fire Protection Association (NFPA) standards (www.nfpa.org). NFPA 99 includes the codes and standards for health care facilities. These standards apply to environmental safety to reduce, to the extent possible, hazards to patients, personnel and visitors.
6. Association for the Advancement of Medical Instrumentation (AAMI) device standards (www.aami.org). These standards provide the industry with reference documents on accepted levels of device safety and performance and test methods to determine conformance. AAMI standards also have been established for sterilization, electrical safety, and patient monitoring for health care providers in relation to evaluation, maintenance, and use of medical devices and instrumentation.
7. Clinically based risk-control standards. These standards are written by medical specialty groups and professional liability underwriters. They establish appropriate **benchmarks** of acceptable practices and outcomes specifically for controlling liability losses. They may be incorporated into the health care facility's risk management program.

Standards from Regulatory Bodies

The standards set by these organizations are enforceable by law, as follows:

1. Federal Medicare Act and all subsequent amendments to this Social Security Act (www.cms.gov). This legislation incorporates the provision that institutions participating in Medicare must maintain the level of patient care recognized as the norm. Specific requirements are included.
   a. Health Insurance Portability and Accountability Act (HIPAA) (www.cms.gov). The Department of Health and Human Services (HHS) set national standards for electronic health care transactions and national identifiers for providers, health plans, and employers. It also addresses the security and privacy of health data. Many facilities require the employees to sign a confidentiality agreement upon hire. Schools of nursing and surgical technology, clinical sites, and patient care training sites require students to sign confidentiality agreements. Some schools prohibit tape recording in class because of patient and facility confidentiality issues.
   b. Medicare's "No Pay List." Accuracy of documentation of conditions present on admission as differentiated from conditions acquired during hospitalization determines facility reimbursement for patient care. Claims for payment that have no documentation about conditions "present on admission" are immediately rejected without reimbursement. More information can be found at (www.cms.gov). As of October 2008, the Centers for Medicare & Medicaid Services (CMS) decided not to reimburse facilities for acquired conditions. As of 2018, CMS will not reimburse the facility for the following conditions:
      1) Pressure ulcers
      2) Falls or trauma
      3) Vascular catheter–associated infection
      4) Retained foreign objects from surgery
      5) Certain surgical site infections (mediastinitis after cardiac surgery, bariatric gastrointestinal procedure, and orthopedic procedures of spine, neck, shoulder, or elbow)
      6) Air embolus
      7) Blood incompatibility
      8) Uncontrolled blood sugar
      9) Deep vein thrombosis (DVT) and pulmonary embolus (PE) after knee or hip joint arthroplasty
      10) Urinary catheter–associated infection
      11) Wrong site surgery
      12) Wrong patient surgery
      13) Wrong surgery performed on a patient
      14) Iatrogenic pneumothorax, venous catheterization
   c. National Quality Forum (NQF). Serious reportable events mirror the CMS "No Pay List" and the up-dated 2018 serious reportable events document can be viewed online at www.qualityforum.org
      The NFQ document details include, but are not limited to, the following events:
      1) Surgical events such as wrong site or wrong patient surgery
      2) Device or biologic material–associated deaths (equipment and medication contamination)
      3) Patient protection event such as patient suicide
      4) Care management event such as wrong drug or blood administration
      5) Environmental event such as electrocution or falls
      6) Criminal event such as assault or abduction
2. American National Standards Institute (ANSI) standards (www.ansi.org). These standards concern exposures to toxic materials and safe use of equipment such as lasers.
3. U.S. Food and Drug Administration (FDA) performance standards (www.fda.gov). Federal Medical Device Amendments regulate the manufacture, labeling, sale, and use of implantable medical devices and many products used in or on patients. The FDA also controls treatment protocols for use of drugs and regulates the reprocessing of medical instrumentation. The manufacturer's lot number and product description of implanted devices are required documentation in the patient's chart.
4. Agency for Health Care Research and Quality (AHRQ) clinical practice guidelines (www.ahrq.gov). These standards

include indicators for performance measurement. They are based on research and professional judgment regarding effectiveness and appropriateness of medical care, including safety, efficacy, and effectiveness of technology. This agency was created in provisions of the Consolidated Omnibus Budget Reconciliation Act of 1989.

5. Occupational Safety and Health Administration (OSHA) standards (www.osha.gov). These legally enforceable standards include permissible levels of toxic substances in the environment. Although explicitly developed to protect employees, patients receive secondary benefits from control of hazards in the environment.

Sources of Standardization Data within the Health Care Facility

Each patient care facility uses several sources from which to derive standardization data. Efficient use of time and resources is the end result. Establishing protocols and performance expectations that are specific to the needs of the facility benefits the patient, the caregiver, and the facility. Many of the following documents may be found on the facilities' intranet for employee use.

1. *Facility-specific patient care standards.* The patient care services department establishes standards for appropriate patient care based on the standards developed by the ANA. Optimal standards of nursing practice guide the provision of patient care throughout the institution. Written policies and procedures reflect these standards. Institutional standards are based on standards established at national levels by TJC, AORN, ANA, and other nursing organizations and governmental agencies. Nurses should work within the limitations of the nurse practice act of the state in which they are licensed and practice. **Licensure** is a legal requirement to practice nursing. Copies of facility-specific documents are available for review from the nursing or hospital administration.
2. *Hospital policy and procedure manual.* This manual contains basic and general administrative and patient care policies that apply to all hospital personnel. A copy is retained on each patient care unit and in all departments of the hospital.
3. *Safety plan manual.* The potential hazards and identifiable situations that may cause injury to a caregiver or patient are described in the manual provided by the hospital safety committee. Plans for fire or disaster drills and evacuation routes are outlined.
4. *Safety data sheets (SDS).* Also known as *material safety data sheets (MSDS).* These detailed sheets describe chemicals used in the workplace and actions to take if they are spilled into the environment. Specific cleanup and disposal methods are outlined. Most facilities require a yearly review of the SDS process. Individual SDS for specific chemicals are online at www.msds.com.
5. *Disaster plan manual.* This manual outlines the plans for both internal and external disasters. Both internal and external disasters require rapid activation of all services within the hospital. Personnel who are off duty will be called to the facility and assigned as needed. Command centers and communications will be critical stations for the entire facility to follow and respond. Triage protocol will be followed carefully as defined by the facility.
   a. An internal disaster is an event that happens within the facility (e.g., an explosion, a fire) and requires employee assistance for control of the situation and evacuation of personnel and patients. An evacuation plan should be part of this planning structure because in-process surgeries cannot be abruptly halted and simply carried out of the building.
   b. An external disaster is an event that happens outside the confines of the facility (e.g., the World Trade Center terrorist actions of September 11, 2001, or an active shooter at a public venue). An external disaster could also be a natural phenomenon such as an earthquake or an accident (e.g., a train derailment).
   c. A combined internal-external disaster such as Hurricane Katrina is complex and may have multiple stages of resolution. Extremes of patient casualties may be brought in only to find the facility is to capacity in census. In some circumstances the facility may be out of communication with surrounding communities because of power failure or flooding and cannot easily reroute patients to a safe receiving hospital.
6. *Infection control manual.* This manual contains the policies and procedures designed to minimize the risk for infection and control the spread of disease within the health care facility. It includes state, local, federal, and professional standards for the protection of the patient and the caregiver.
7. *Perioperative policy and procedure manual.* This manual, usually a hardcover ringed binder, contains the policies pertaining solely to the administration and operation of the perioperative environment or online in the hospital's intranet. A copy is accessible for reference in the manager's office, at the control desk, or in both places. The primary purpose of the perioperative policy and procedure manual is to detail why and how procedures should be specifically performed within the perioperative environment. It includes both supportive activities and practices that involve direct perioperative patient care.
8. *Orientation manual.* This manual is designed to acquaint personnel with the environment, policies, and procedures specific to performance and the position descriptions of all personnel in the department.
9. *Instrument book.* The individual instruments and trays required for each surgical procedure are listed in a central processing computer or in a separate book kept in the instrument processing area. Photographs or catalog illustrations help instrumentation personnel identify the vast number of instruments and how they are compiled into sets. Flashcards and educational instrument textbooks are commercially available. A search engine with an image finder (e.g., Google or Bing) may be used to find specific instruments. Most instrument companies have online catalogs.
10. *Surgeon's preference cards/case cart sheet.* A preference card is maintained in a computerized database or written note card for each surgical procedure that each surgeon performs. The surgeon's specific preferences and any variance from the procedures in the procedure book are listed on these cards. The cards are revised as procedures and personal preferences for new technology change. A set of these cards is kept readily available in a central file or in a computer under the surgeon's name, and they are pulled for each day's surgical procedures. In preparing for each surgical procedure, nurses and surgical technologists consult both these cards and the procedure book. A surgical central supply department may use these cards to pack a case cart for each individual procedure. Box 2.3 shows sample case cart sheet components incorporating the surgeon's preference card.

• BOX 2.3 Sample Case Cart Sheet Components with Surgeon's Preferences[a]

Surgeon:
Dr. Jared
Gloves:
Size 8
Positioning:
Supine
Instruments:
Soft tissue set
Special requests:
Music on low
Procedure:
Excision lipoma right anterior thigh
Prep:
One-step iodophor
Medications:
1% lidocaine plain
Sterile saline 1000 mL
Suture:
3-0 Vicryl PS1
Disposable supplies:
Extra 4 × 4 sponges available
Patient:
Martin Alexander
Patient data (e.g., age, sex, allergies):
26 years old, male, no allergies
Drapes:
General custom pack
2 gowns
Sponges:
2 packs Raytec
Notes:
Call family when procedure completed

[a]*Components of computer-generated case cart procedure supply sheet. These sheets are generated at the time the procedure is scheduled using standardized surgeon's preference cards and patient-specific needs. Items listed under each heading are examples only.*

11. *Directories.* Alphabetic listings of the location of supplies and equipment are maintained for the instrument room, general workroom, sterile supply room, and general perioperative storage areas. Regardless of where the storage areas are located, personnel should know the location of supplies and equipment. Directories save time in trying to locate items.

Recommended Practices

Recommended practices are optimum behavioral objectives for caregivers. They may not always be achievable, as standards are, because of limitations in a particular practice setting. Recommended practices state what ideally can be done.

AORN guidelines for perioperative nursing concern sterile and aseptic techniques, and other technical aspects of professional practice are directed toward providing safety in the perioperative environment. They are premised in principles of microbiology, scientific literature, validated research, evidence-based practice, and experts' opinions. Although compliance is voluntary, individual commitment, professional conscience, and the practice setting should guide perioperative caregivers in using these recommended practices. They represent an optimal level of practice and are achievable.

Guidelines and recommended practices of other agencies, including AAMI, the Centers for Disease Control and Prevention (CDC), the National Institute for Occupational Safety and Health (NIOSH), OSHA, and the Environmental Protection Agency (EPA), also are used for environmental, patient, and personnel safety.

Policies and Procedures

Policies and procedures reflect variations in institutional environments and clinical situations. They are established to protect employees, learners, and patients. They establish the facility's standard of care. Policies should be consistent with regulatory and professional standards of practice. Procedures define scope, purposes, and instructions to be carried out and by whom. They should be clearly written, current, dated, and reviewed periodically. Although policies and procedures vary from one institution to another, they provide guidelines for patient care and safety in that specific physical facility. Learning and following policies and procedures are protective measures against potentially litigious actions.

Many facilities document in the employee's personnel file that policies and procedures were reviewed during orientation to the employment setting. Employees are often asked to sign a notation verifying knowledge of a new or revised policy or procedure after its introduction. Some policies and procedures apply to all employees; others refer to a specific department. Because of the potential legal implications, adherence to all policies and procedures is mandatory. Personnel are evaluated on their ability to follow policy and perform procedures correctly. The following examples should be included in the perioperative department manual. These procedures are incorporated into discussions in subsequent chapters.

Universal Protocol

Universal Protocol is a standardized means for keeping a patient safe in surgery. The World Health Organization (WHO) created a basic surgical safety checklist under the guidance of Dr. Atul Gawande and a select team of anesthesiologists, surgeons, and registered nurses. The purpose of the checklist is to globally reduce surgical harms to patients in a manner that can be applied universally in high- and low-income countries. Initial multinational studies of the checklist use demonstrated a one-third reduction in surgical mortality and morbidity.

The initial items require oral confirmation at three critical points during perioperative patient care that include (1) the "sign in" before induction of anesthesia, (2) "time out" before skin incision, and (3) "sign out" before the patient leaves the OR. The universal checklist provides a means for documentation of each step of care for patients undergoing invasive and noninvasive surgical procedures. AORN incorporated TJC's 2010 Patient Safety Goals and Universal Protocol into the WHO Surgical Safety Checklist to create a Comprehensive Surgical Checklist. Up-dates to the checklist were added and can be found on the June 2016 Comprehensive Surgical Checklist at www.aorn.org (Fig. 2.1).

Identifying the Patient

When a patient enters the facility a plastic identification wristband is put on the patient in the admitting area. Care is taken to place the wristband in a location that does not interfere with the surgical site. To verify accuracy the patient should be asked for his or her birth date and to spell his or her name and pronounce it. The circulating nurse and anesthesia provider check the wristband with the patient and surgeon, the patient's chart, and the surgical schedule. The surgeon should visit with the patient before an anesthetic is administered. A parent, legal guardian, or individual with power of attorney can complete this identification process. TJC indicates that at least two methods should be used to identify a patient as part of the patient safety goals.

Identifying the Surgical Site

The surgical site indicated by the consent form should be verified between the circulating nurse and the patient. Universal methods of surgical site verification include asking the patient to describe what he or she understands about the planned procedure. If the procedure is on a particular side of the body, the patient should be asked to point to and clarify the site. The surgeon should mark

the site with his or her initials in indelible ink that does not wash off during intraoperative skin preparation. Marking with an X is inappropriate and may be misunderstood.

Before making the incision the entire team pauses for a "time out" as the surgical site listed on the consent form is read aloud. The entire team confirms that this is correct information for the patient and that any scans or x-rays reflecting the same body part are displayed in the correct orientation. Allergies, sensitivities, and administered medications are confirmed at this time. During the "time out" process, the availability of the correct implants or special equipment is confirmed (Box 2.4).

The surgical site marking and identification process should be standardized within the facility and written into policy to avoid wrong site procedures. The time out process should be documented in the patient's record by the circulating nurse. More information can be found at www.aorn.org in the official statements section and on the TJC website at www.jointcommission.org. TJC has described factors that contribute to wrong site, wrong patient, and wrong procedure surgery. They are as follows:

- Emergencies
- Morbid obesity
- Physical deformity
- Unusual equipment or setup of the OR
- Multiple surgeons
- Multiple procedures
- Unmarked patients
- Unverified patients
- No checklist
- No assessment
- Staffing issues
- Distractions and disharmony among staff members
- Lack of information about the patient
- Organizational culture of the facility

• BOX 2.4 "Time Out" for Prevention of Wrong Site Surgery

- Correct position?
- Correct site?
- Correct procedure?
- Correct equipment?
- Correct images? (scans or x-rays in proper orientation)
- Correct implants? (as appropriate)

Protecting Personal Property

Personnel in preoperative areas are responsible for removing valuables and prostheses before patients go to the OR. The circulating

nurse is responsible for double-checking each patient and removing unnecessary items brought to the OR. Personal items such as religious medals, hearing aid(s), spectacles, dentures, and eye prostheses are commonly permitted to remain with the patient who is having local or regional anesthesia. The circulating nurse should inform the anesthesia provider and the surgeon of the presence of such items and document them on the patient's chart. Artificial extremities, undergarments, wigs, hairpins, wristwatches, and rings should be removed. Jewelry could get lost, or a ring might become stuck on the patient's finger as a result of postoperative swelling. In addition to the danger of losing or damaging these items, some could cause pressure areas on the anesthetized patient's body.

Any item that is removed should be placed in a rigid container and labeled with the patient's name and identification number. The patient's personal property should not be wrapped in a paper or linen towel that could inadvertently be discarded in a trash receptacle or laundry hamper. The container may be retained by the circulating nurse during the surgical procedure and sent with the patient to the postoperative area. Alternatively, the circulating nurse may immediately ask a nursing assistant to return the container to the patient care unit. This person should obtain a receipt for the patient's personal property from the person receiving it. The receipt is given to the circulating nurse to put in the patient's chart along with a notation of the transaction in the nurses' notes. Patients value their property. A caregiver can be held liable for lost or damaged personal property.

Observing the Patient

Unattended patients may fall from a stretcher or the OR bed. Falls are one of the most frequent causes of avoidable injuries. Side rails, restraints, and safety straps should be used to protect all patients, children as well as adults. A small child could reach and insert a tiny finger into an electrical socket. Patients should be observed at all times in the perioperative environment.

Positioning the Patient

Care is taken when moving all patients to and from the OR bed. The patient should be positioned to ensure adequate exposure of the surgical site for the surgeon but not compromise any body system. The anesthesia provider should determine the physiologic safety of the patient's body systems. Cardiopulmonary functioning should not be impaired. Adequate support of joints and limbs should be provided during movement into the desired position. Pressure areas should be adequately protected to prevent neurovascular damage.

The plan of care should include appropriate numbers of personnel for safe patient movement. Patients who are incapable of assisting with physical motion require a minimum of four people to ensure a safe move from one surface to another. There should be at least one person on either side of the patient, one at the foot, and one at the head to monitor the patient's airway and physiologic response. The person guiding the patient's head, usually the anesthesia provider, should be the one who counts "one—two—three" to pace the synchronized movement from one surface to another.

The surgeon determines the appropriate surgical position in consultation with the anesthesia provider. The circulating nurse and first assistant help position the patient. A stretcher is kept nearby at all times if a patient is placed in a prone position or any position other than supine. In the event of an emergency the patient will need to be placed in a supine position for treatment such as cardiopulmonary resuscitation (CPR).

Many patients receive a general anesthetic or heavy sedation and are therefore unconscious or not in control of their protective reflexes. Constant vigilance is essential to safeguard patients who are vulnerable and unable to protect themselves. Liability on the part of the team would be difficult to dispute. Everyone in the perioperative environment has a duty to monitor and protect the patient at all times without exception.

Aseptic and Sterile Techniques

Infection is a serious postoperative complication that may become life-threatening for the patient. Perioperative patient care team members must know and apply the principles of aseptic and sterile techniques at all times. Established procedures for aseptic technique, sterilization, and disinfection should be followed meticulously. An emergency situation in which asepsis becomes a secondary concern is a rare occurrence. Asepsis should not be compromised for the sake of convenience of the caregiver. Each team member should consider how personal preferences for care of self or a loved one should be applied to the care of patients.

Postoperative wound infection can originate in the OR from a break in technique by any team member. Inappropriate reuse of disposable items may be indefensible, as can use of an unsterile endoscope introduced into a sterile body cavity. An unsterile scope can disrupt the mucous membrane and come into contact with the patient's vascular system. No area of the body is considered "dirty." Any area of the body is at risk when the vascular system is entered and should be worthy of sterile instrumentation. Microorganisms can be transferred via any access portal to the vascular system, including, but not limited to the mouth, urethra, penis, vagina, rectum, and ear. Strict asepsis and sterile technique prevent many postoperative complications. The following principle applies: When in doubt about something's sterility, consider it unsterile, hence the phrase, "When in doubt, throw it out."

Accountability of Accurate Counts

The primary responsibility for accounting for all sponges, sharps, and instruments before, during, and after every surgical procedure rests with the circulating nurse and scrub person. Laziness and a cavalier attitude surround the statement, "the incision is too small to lose anything." Do not be fooled by this cavalier statement. It can happen when least expected. There are several reasons to count and be accountable for items used in a surgical procedure. Examples include the following reasons for accountability:

1. Patients have retained items from a surgical procedure regardless of the size or location of the surgical site. This is a serious safety breach that is inexcusable.
2. Instruments are costly and should not "vanish into thin air." It is a shame that some hospitals x-ray all the trash and have metal detectors on the doors of the OR. Instruments stuck in washing machines cause damage to the mechanisms. Accountability significantly decreases this loss.
3. Many instruments and devices have sharp tips or cutting surfaces. If an instrument is in the trash or laundry it can become a source of injury to unsuspecting housekeepers or laundry workers. Gloves worn for cleaning do not protect from sharp objects. This can result in prolonged illness and inability to work.

Any item put into the patient should be documented as part of the count and reconciled at the end of the procedure. The counts should proceed in an established manner each time. The surgeon and first assistant facilitate the count of the items on the surgical field before closure; however, it is not their job to perform the actual counts. Because accountability for sponges, sharps, and instruments is recognized as essential to safe practice and the

standard of care, omission of appropriate counts or a facility's lack of established procedures for counting and accountability could result in a serious injury to a patient and threat of liability for the facility. There is no excuse for any retained foreign object if the entire team follows the systems for accountability.

The circulating nurse should document in writing the outcome of the final counts as correct or incorrect and any unusual incidents concerning them, including the need for an x-ray to look for a lost item. If an x-ray is taken, the name of the radiologist and the findings also should be documented. An incident report should be filed on all counts that remain unresolved. It is not necessary to indicate the actual number of sponges or needles used on the OR record. The documentation of correct or incorrect counts is sufficient. Any questionable count should be documented as resolved or unresolved and to whom the event was reported.

PROS/CONS

Counting and Accountability

Pros

- Every health care organization should define a standardized count procedure that fits their facility. Count sheets may be used as part of the standardized count procedure, but it is up to each facility to determine the appropriate practices to implement.
- The circulating nurse and scrub person should do a count before any procedure in which any item from the sterile field could be retained.
- Some facilities have policies in which the only counted items are those that are small enough to be lost in a wound. Instruments may not be counted for tiny incisions.
- Specific cases such as trauma may be exempt from the counting process because the priority is to save the patient's life.
- Documentation must state the reason for aborting the count in cases in which the count was void. An x-ray may be done after the procedure to determine whether any item was retained.
- Facility standardization and counting protocols are put in place to protect the patient and surgical staff.

Cons

- Some organizations do not specify that everything needs to be counted for every procedure. Every facility is responsible for their own policies and procedures determining what items need to be counted in every case.
- Counting is a time-consuming part of the surgical process because it is done before the procedure, during the procedure, before closing the wound, and after the procedure (final count).
- Some cases, such as orthopedic surgeries, have many trays with small parts that are designed to size custom implants. Because there are so many pieces they are not counted based on the rationale that they will not be removed from their tray.
- Accountability is the responsibility of the surgical team. Lack of accountability can result in patient injury or poor surgical outcome.
- Deviations in the standard counting policies can result in a "never event," which is a retained surgical item. Risk factors that contribute to retained items may include error in the count, unexpected change in procedure, high body mass index, distractions, and change of staff.

Facility policy and procedure should determine the disposition of any tally sheets used in the counting process. The tally sheets are merely worksheets and have no particular value to the permanent record. Some facilities use a wipe-off grease board to tally sponge, needle, and instrument counts. Additional information about the processes and rationale for counting and being accountable is described in Chapter 25.

Using Equipment

All instruments, equipment, and appliances should be used and tested according to the recommendations and instructions of the manufacturer. Safety devices such as personal protective attire or smoke evacuation apparatus should be employed as necessary. Electrical and laser equipment also should pass inspection by the biomedical engineering department and be tagged with a dated preventive maintenance sticker. Electrical equipment should be properly grounded to prevent electrical shock and burns. Equipment or devices that are known or suspected to be faulty are not used.

The facility should conduct appropriate training and competency reviews for all equipment used in patient care. Personnel who set up and operate facility-owned equipment may be found negligent if a patient is injured. Great care is critical to prevent injury when using all equipment in the perioperative environment. It is inappropriate to operate equipment or machinery for which the employee has had no training. All personnel should have adequate training on all equipment they are expected to operate during patient care in the OR. Records of such training should be on file within the department.

Preventing Skin Injury

Skin injury may be caused by an electrical or thermal device, chemical agent, sharp objects, or mechanical pressure. Pressure necrosis is possible after any procedure and especially after procedures lasting more than 2 hours. Patients who have been in holding areas or emergency departments may have pressure injury in process before arriving at the OR. The circulating nurse should assess the patient for skin injury.

A burn may occur from the use of a hot instrument taken directly out of the autoclave, such as a mouth gag or a large retractor. The best practice is to avoid immediate-use sterilization (IUSS) and obtain a wrapped, processed instrument from the instrument room. If immediate sterilization must be used, the scrub person should immerse the hot instrument in a basin of cool, sterile water before handing it to the surgeon. The hot item should not be placed in a damp towel and placed on the patient's skin; the heat from the item will transfer through the towel and cause a burn. Prolonged contact of even moderate temperatures can cause tissue damage. The patient under anesthesia has no protective reflexes to warn of an impending injury. Thermal injury can happen when any device or solution heated beyond 110° F (44° C) comes into contact with a patient's tissues.

A patient may be burned during use of the electrosurgical unit (ESU). Inadequate skin contact or improper placement of the patient return electrode can cause a deep tissue burn that will not manifest immediately in the OR by a superficial reaction. Redness of the skin on removal of the patient return electrode may be caused by the adhesive rather than a burn. In a thermal injury the deep tissue necroses and sloughs from the bottom up, leaving a full-thickness wound that may be insensate because of nerve damage. The tip of the ESU pencil, endoscopic instrument, or suction

cautery probe remains hot after it is applied to tissues for hemostasis. Unintended burns may occur if the hot tip touches other body parts or it is activated against a metal retractor or instrument. Use of a dry sponge against an activated tip causes ignition and fire.

Alcohol and other flammable solutions such as some one-step alcohol-based prep chemicals can ignite, causing flash fires if the solutions are pooled under the patient or allowed to saturate drapes, especially in the presence of oxygen. Vapors, fumes, or oxygen can accumulate under drapes and ignite if exposed to the ESU pencil. A thermal burn also can occur from other types of electrical and laser equipment that are improperly used or maintained. The caregiver should be aware that the effects of some types of lasers on tissue are not readily visible until tissue necrosis takes place several days postoperatively.

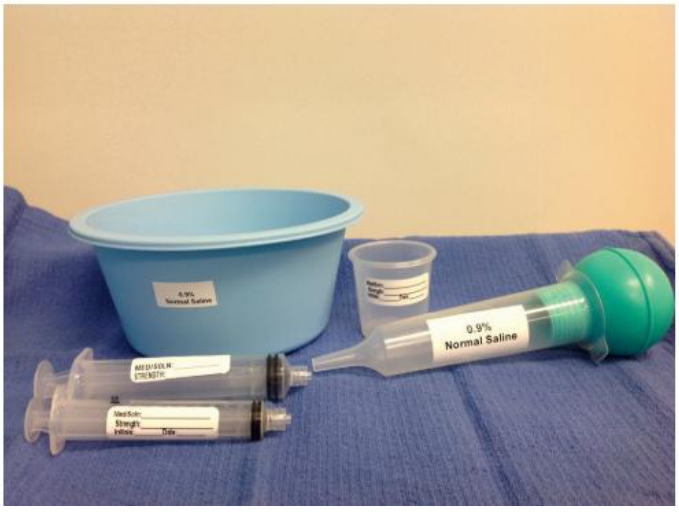
Administering Drugs

Any drug or solution used in the surgical site, such as an antibiotic or local anesthetic, is recorded in the perioperative note by the circulating nurse and surgeon. The drug is checked by a registered nurse and the scrub person before it is transferred to the sterile field. The sterile medication cup and syringes (if used) are clearly labeled by the scrub person on the field immediately after the drug is dispensed (Fig. 2.2). The scrub person frequently has more than one drug on the instrument table, and confusion could result if the drugs are not properly marked. The scrub person repeats the name of the drug to the surgeon when passing it. Medications and medication handling are described in more detail in Chapters 23 and 25.

The scrub person should not "spear" a vial held by the circulating nurse, because that action places the circulating nurse's hand at risk for a needlestick injury. The drug should be drawn into a syringe by the circulating nurse and dispensed into the sterile medicine cup after removing the needle used to penetrate the vial. Dispensing with the needle in place can cause aerosolization of the drug, potentially causing airborne exposure of a sensitive person.

AORN has developed a medication toolkit for preventing medication errors. Contact AORN at www.aorn.org for more information about receiving this packet. Consider the "seven rights" of medication administration:

- Right patient
- Right drug
- Right dose
- Right reason
- Right time
- Right route
- Right documentation



• **Fig. 2.2** Labeled basin with solution and labeled delivery device.

Monitoring the Patient

The standard of care indicates that a registered nurse is responsible for monitoring the cardiac and respiratory status of a patient receiving local anesthetic, with or without intravenous (IV) conscious sedation, if an anesthesia provider is not present. The nurse is expected to interpret the monitoring equipment, assess the patient, and initiate interventions promptly if the patient has an untoward reaction. Policies and procedures are delineated by each facility for care of the patient receiving local anesthetic. The nurse who is monitoring the patient should not be assigned circulating duties that would distract attention from the patient. Nurses who monitor patients under moderate sedation should be advanced cardiac life support (ACLS) certified. Patient monitoring is described in more detail in Chapter 27.

Preparing Specimens

With very few exceptions, tissue and objects removed from a patient are sent to the pathology department. The loss of a tissue biopsy specimen could necessitate a second surgical procedure to obtain another one. Incorrectly labeled specimens could result in a mistaken diagnosis, with possible critical implications for two patients. The loss of a specimen could prevent determination of a diagnosis and subsequent initiation of definitive therapy. The pathology report becomes part of the patient's permanent record as added documentation of the diagnosis. Specimens from opposite sides of the body should be sent in separate marked containers.

Care for foreign bodies according to the policy of the facility. They may have legal significance and frequently are claimed by police, especially if the foreign body is a bullet or something implicated in a crime. A receipt from the person taking them protects personnel and the facility. Chain of custody is a serious subject, and these items are accounted for at all times.

Specimen handling can be hazardous for personnel. Best practices indicate that a sterile container and lid of the appropriate size on the sterile field is the safest way to prevent biologic exposure of other team members. The scrub person should contain the specimen completely before handing the container off to the circulating nurse, who is wearing protective gloves. Dropping a specimen into a cup being held by another is placing that person at risk for exposure. This is avoidable. Specific information about specimen preparation is found in Chapter 22.

Patient Teaching

The patient and/or significant others need to be informed about treatment options and their roles in the process. The patient has the right to make decisions and contribute to the development of the plan of care. The perioperative nurse can assist with preoperative teaching of deep-breathing exercises for postoperative recovery. Information should be provided verbally and in writing. The patient and/or significant others should respond appropriately in such a way as to signify understanding of the information. This is particularly important for ambulatory surgery patients who will go home under the care of others. Patient

teaching and demonstration of understanding is documented in the chart. More information about patient teaching is located in Chapter 21.

Professionalism

Professionals act responsibly in accord with their commitment to public trust and service. Simply stated, the word **profession** implies a combination and coordination of knowledge, skills, and ideals that are communicated through activities based in higher education. The characteristics of a profession include the following:

- It defines its own purposes and code of ethics.
- It sets its own standards and conducts its own affairs; it is self-regulated and has autonomy.
- Through research, it identifies and develops its own body of knowledge unique to its role.
- It requires critical thinking skills in clinical judgment, as well as problem-solving and decision-making skills in the application of knowledge.
- It engages in self-evaluation and peer review to control and alter its practices and accountabilities.

Professional Perioperative Nursing

Professional nursing is dedicated to the promotion of optimal health for all human beings in their various environments. AORN is the leading organization for perioperative nursing and sets the standard for professionalism. In the support of professional perioperative nursing in a wide variety of specialties, AORN has formed specialty assemblies for specialized practice areas and professional interests. The specialty assemblies do not have regular meetings, but offer online and newsletter participation. Several times a year the specialty assemblies offer workshops. Assembly meetings are held at the annual AORN Congress. An abbreviated internal specialty assembly governance structure provides a chairman and other elected officials. A perioperative nurse may belong to as many assemblies as desired.

Nursing in general is both a humanistic art and an applied science. The art of professional nursing practice involves nursing diagnoses and the treatment of human responses to health and illness in all patient care settings. The science behind the paradigm of nursing is based on theories about the nature of humankind, health, and disease. Nursing education prepares nurses to translate the art and science of nursing into relevant knowledge and skill. Professional nursing education is built on a solid base of general education in liberal arts, humanities, and natural and behavioral sciences. AORN **Position Statements** reflect that, in the future, minimal entry level into perioperative nursing should be the baccalaureate degree.

A wise physician once said that the physician's role is to cure sometimes, to relieve often, and to comfort always. The same can be said for the perioperative nurse, who is a registered nurse who embodies all that "nurse" has traditionally meant to a patient—provider of safety and comfort, supporter, and confidante. The patient's safety and welfare are entrusted to the perioperative OR nurse from the moment of arrival in the perioperative environment until departure and the transfer of responsibility for care to another professional health care team member. The perioperative nurse is legally accountable for the delivery of care to patients in the perioperative environment, including interventions that assist the patient in a conscious or unconscious state. The primary emphasis of the nurse's responsibility is to the patient. The perioperative nurse identifies the physiologic, psychologic, and sociologic needs of the patient; develops and implements an individualized plan of care that coordinates interventions; and evaluates outcomes of the patient's perioperative experience. The nurse is accountable and responsible for delegated patient care.

Patient-Nurse Relationship

To practice in a technologically complex environment, perioperative nurses must be flexible and their skills must be diverse. Their roles incorporate both the technical and the behavioral components of professional nursing. Competent fulfillment of the perioperative nursing role is based on the knowledge and application of the principles of biologic, physiologic, behavioral, and social sciences. Perioperative nurses develop nursing diagnoses based on patients' problems, needs, and health status. This is essential information in the identification of expected outcomes and in the formulation of a perioperative plan of care.

The perioperative nurse shares a special humanized experience with the patient at a time of great stress and need in his or her life. This relationship encompasses feelings, attitudes, and behaviors, with mutual trust and understanding as vital components. Effective interaction encompasses concern for the unique personhood of both the patient and the nurse. The length of time spent with the patient is not as important as the quality of the interaction. The level of the interaction may directly affect the patient's perception of the delivery of care in the perioperative environment.

To achieve and maintain a viable cooperative relationship, the patient should be able to sense that the nurse unconditionally cares about his or her well-being. The nurse should remain aware that personal interaction is often predicated on culture, attitudes, beliefs, and experiences. Knowledge of the effect of care on the patient's outcome enhances the attainment of the desired result.

Perioperative nursing care is a specialized combination of individualized and standardized care. Individualized care, the art of nursing, demonstrates genuine concern for the patient as a person and is not purely technical. Standardized care, the science of nursing, is derived from a body of scientific knowledge that has been developed through research and clinical practice.

Evidence-Based Practice

The medical model has used tradition or habit to determine the foundations of practice. In the 1980s, medicine adopted an evidence-based framework premised in research as a foundation for patient care practices. Nursing has questioned the best methods for performing patient care and has sought confirmation of the rationale that supports nursing actions. The development of a systematic process involves research that yields evidence of best practices. The essential elements involve obtaining and evaluating evidence and considerations for implementing newly established evidence in practice.

Caregivers should always question why they are doing a particular action and if it is truly effective. Behaviors should continually be evaluated for usefulness as opposed to ritualism. Many practices may no longer be necessary and are not supported by evidence. The following questions should be systematically reviewed when researching for evidence-based practice:

- Which practice area requires evidence?
- What comprises evidence?
- How can evidence be found?
- What is the value of individual increments of evidence?

- Can the increments of evidence be combined into a unit of practice?
- Can the unit of practice be implemented in patient care?

To set up a research project or a systematic review, the following should be well established:

- Who will make up the population to be studied?
- Which intervention will be studied?
- How does one intervention compare with another?
- Which outcomes are preferred?
- Has an investigational review board approved the research project?

Nursing Process

Perioperative patient care requires developing a plan of care and identifying expected outcomes through the **nursing process** (Box 2.5). The nursing process is a systematic approach to nursing practice using problem-solving techniques. This six-part process provides a systematic foundation for assessing the patient, establishing a **nursing diagnosis**, identifying desired outcomes, planning interventions, implementing care, and evaluating the success of the plan. Human response patterns to health and illness are vital elements in establishing a nursing diagnosis (Box 2.6).

Integration of the Nursing Process into Perioperative Patient Care

The six components of the nursing process are integrated into the three phases of the patient's perioperative experience: the preoperative phase, the intraoperative phase, and the postoperative phase. Throughout the entire perioperative period the patient is continually assessed, the plan of care is modified, implementation is effected, and the cycle is evaluated for the attainment of outcomes. The perioperative nurse is responsible for continually assessing the patient by observing and acknowledging parameters identified in Box 2.7. The system and the structure had been traditionally complex until specific data elements of perioperative patient care were clearly stated in a standardized manner.

• BOX 2.6 Human Response Patterns According to NANDA International

- Exchanging
- Communicating
- Relating
- Valuing
- Choosing
- Moving
- Perceiving
- Knowing
- Feeling

• BOX 2.7 Assessment Parameters Monitored Throughout Perioperative Care by the Circulating Nurse

- Physiologic
- Medical diagnosis
- Surgical site and procedure
- Results of diagnostic studies
- Laboratory tests
- Review of systems
- Mobility, range of motion
- Prosthetics (internal or external)
- Sensory impairments
- Allergies
- Skin condition
- Nutritional and metabolic status
- Height and weight
- Vital signs
- Elimination pattern (e.g., continence)
- Sleep, rest, exercise patterns
- Medications
- Substance abuse
- Psychosocial
- Cognition (e.g., mental status)
- Cultural and religious beliefs
- Perception of procedure
- Expectations of care
- Knowledge base (e.g., informed consent)
- Readiness to learn
- Ability to understand and retain teaching
- Stress level (e.g., anxiety, fears)
- Coping mechanisms
- Support from family or significant others
- Attitude and motivation (e.g., health management)
- Affective responses (e.g., ability to express feelings)
- Speech characteristics (e.g., language)
- Nonverbal behavior

AORN responded to this dilemma and has identified a Perioperative Patient Focused Model that consists of three primary areas of nursing concern: nursing diagnosis, nursing interventions, and patient outcomes. These areas are reflected in the model as

• BOX 2.5 The Nursing Process

Assessment

- Identify the actual or potential problems, needs, and health status considerations through appraisal of the physiologic, psychosocial, objective, subjective, cultural, and ethnic data related to the patient as an individual. Assessment is based on functional health patterns.
- Document assessment data.

Nursing Diagnosis

- Formulate prioritized actual or potential nursing diagnoses unique to the patient. Human response patterns guide the development of nursing diagnoses.

Identification of Outcomes

- Develop measurable and attainable expected outcomes and mutual goals in collaboration with the patient, significant others, and other health care providers.
- Identify realistic time frames in which fulfillment may be accomplished.

Planning

- Establish and prioritize a working set of interventions for the actual problems, needs, and health status considerations.
- Establish a contingency plan for the potential problems, needs, and health status considerations that may become actual during the course of the perioperative experience.
- Include the patient's input for the construction of the individualized plan.
- Document the plan of care in a retrievable manner.

Implementation

- Share the plan with the perioperative team for continuity of care.
- Activate the interventions in a systematic order of priority.
- Discontinue any intervention that is ineffective.
- Document the implementation of the interventions and their effectiveness.

Evaluation

- Determine the effectiveness of the plan as the expected outcomes and mutual goals are met.
- Reformulate the plan and implement new interventions as necessary.
- Document the effectiveness of the plan of care in an ongoing, systematic manner.

domains that describe the perioperative patient's interaction with the health care system, particularly surgery. The primary domains concerning perioperative nurses and their patients are patient safety, physiologic responses, and behavioral responses (1) concerning the patient and the system and (2) concerning the nurse, ethics, and the patient's rights and the health care system.

Perioperative Nursing Data Set (PNDS)

AORN developed the perioperative-specific nursing vocabulary that defines and describes the perioperative patient's experiences from preadmission to discharge from care. The standardized language of data elements identifies specific common components that are distinctly part of perioperative patient care. Electronic health records (EHRs) represent perioperative nursing care in a unified language that provides feedback in an evidence-based format. The AORN SYNTEGRITY framework was developed to provide a consistent integration of perioperative documentation incorporating PNDS into the perioperative record for minimization of discrepancies and evidence of standards compliance (Fig. 2.3). The PNDS is set into tables used by perioperative information systems. Tables of PNDS values connect assessment and nursing diagnoses, intervention, and outcome data directly to the individual patient via standardized documentation by EHR or paper documentation.

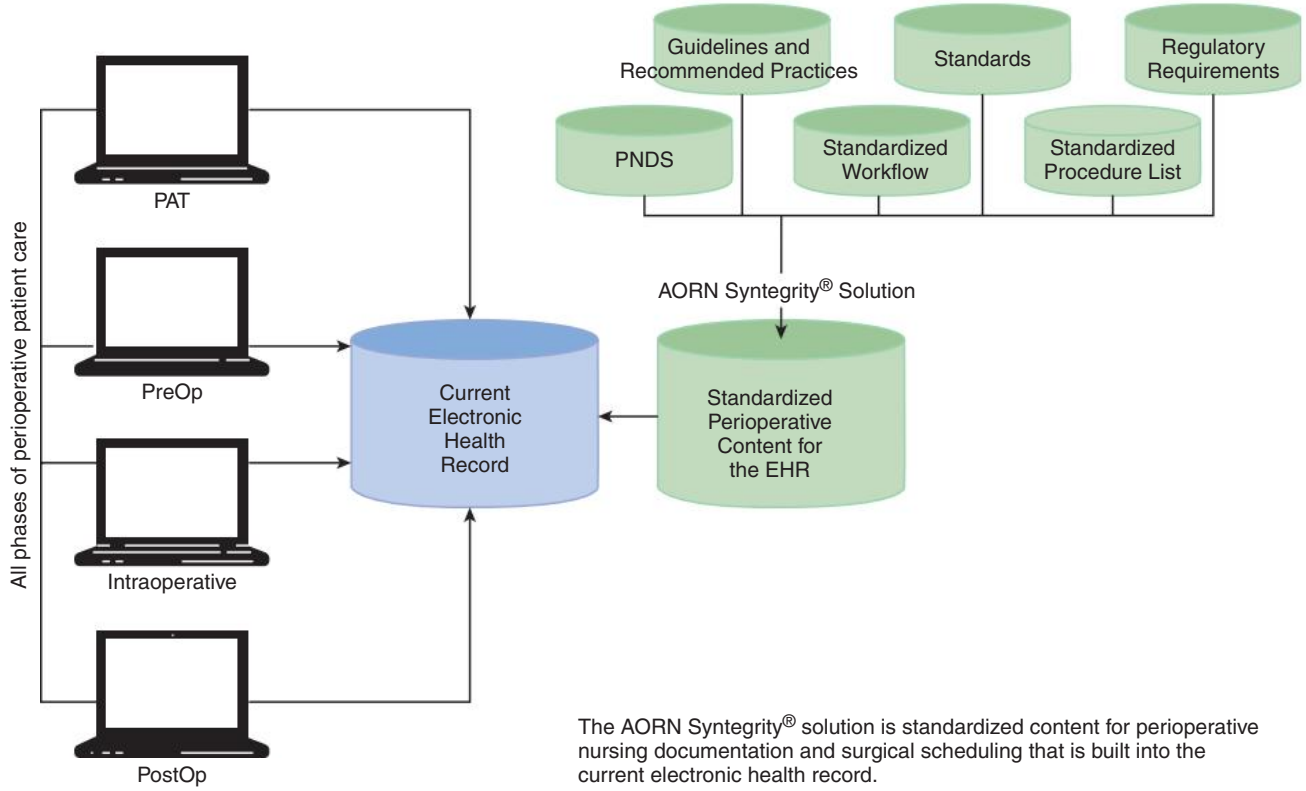
A data **element** is the smallest unit of descriptive information available that retains its meaning. It allows the reader to conceptualize without added descriptors. The Perioperative Nursing Data Set (PNDS) published by AORN includes 93 perioperative nursing diagnoses, 151 perioperative nursing interventions, and 39 patient outcomes. The PNDS is described in four domains specific to the perioperative nursing process. These are as follows:

- Domain 1: (D1) Safety
- Domain 2: (D2) Physiologic responses
- Domain 3-A: (D3-A) Behavioral responses of patient and family: Knowledge
- Domain 3-B: (D3-B) Behavioral responses of patient and family: Rights and ethics
- Domain 4: (D4) Health system

The PNDS is important for capturing data in a systematic way that can be retrieved, measured, and evaluated by an information system. Nursing diagnoses have been connected with implementation of nursing interventions and with specific outcomes to further validate the use of a standardized perioperative language. The standardized language has a letter and a number that are specific to the nursing activity it describes within the particular domain as described. For example:

- A: Assessment
- Im: Implementation
- E: Evaluation
- O: Outcome

The PNDS was officially recognized by the ANA's Committee on Nursing Practice Information in 1999. The clinical relevance of the PNDS is specific to perioperative patient care and provides a standardized language to validate the value of the role of the professional perioperative nurse. The PNDS is a clinically validated nursing language that is useful for clinical practice, education, and



• **Fig. 2.3** AORN SYNTEGRITY Standardized Perioperative Framework. Nurses enter their documentation, and AORN SYNTEGRITY framework provides a guide through a standardized language, PNDS, with your current information system. (Reprinted with permission from AORN. research. According to AORN, the advantages of PNDS usage include but are not limited to the following:

- Providing a framework to standardize documentation (i.e., AORN SYNTEGRITY)
- Providing a universal language for perioperative nursing practice and education
- Assisting in the measurement and evaluation of patient care outcomes
- Providing a foundation for perioperative nursing research and evaluation of patient outcomes
- Informing decisions about the relationship of staffing to patient outcomes
- Providing data about the contributions of nurses to patient outcomes in the perioperative arena
- Data can be gathered and tallied in a mechanized format and are compatible with computerized information systems.

AORN's SYNTEGRITY Perioperative Documentation Solution is compatible with most EHRs and can be found at Syntegrity@aorn.org. Consult AORN online at www.aorn.org for additional information about the PNDS or SYNTEGRITY Perioperative Documentation Solution system. Other nursing organizations with recognized forms of standardized language are listed online at www.nursingworld.org.

Preoperative Phase

The preoperative phase of the patient's surgical experience begins when the decision is made to undergo surgical intervention, and it ends when the patient is transferred to the OR bed in the OR. During this phase the perioperative nurse performs the assessment, determines the nursing diagnoses, identifies potential outcomes, and develops a plan of care. The nurse assesses the patient to identify any actual or potential physiologic, psychosocial, and spiritual needs, problems, or other health status considerations. In collaboration with the patient and/or significant others the nurse then determines the nursing diagnoses and identifies the expected outcomes of the perioperative experience. The perioperative nurse plans, prioritizes, and initiates the patient care necessary for the attainment of the desired outcomes.

Intraoperative Phase

The intraoperative phase begins with placement of the patient on the OR bed and continues until the patient is admitted to a postprocedure or postoperative area, such as the postanesthesia care unit (PACU). Implementation of the plan and evaluation of care continue during this phase. The perioperative nurse either personally carries out the plan of care or supervises others in carrying out the plan with skill, safety, efficiency, and effectiveness. Modification of the plan may be necessary during the procedure.

Postoperative Phase

The postoperative phase begins with admission of the patient to a postprocedure or postanesthesia area (PACU) or an intensive care unit (ICU). Patients admitted to the facility on an ambulatory 1-day-stay basis may return to the ambulatory unit. As indicated by his or her condition the patient will transfer from the immediate postoperative patient care division for progressive stages of self-care on a surgical unit before being discharged from the hospital. The postoperative phase ends when the surgeon discontinues follow-up care. Evaluation, the sixth component of the nursing process, is completed during this phase.

Standards of Perioperative Nursing Practice

A standard is an authoritative statement established and published by a profession and by which the performance of practice can be measured. The standards of nursing practice establish parameters and competency levels against which the practice of the profession is compared.

The ANA Standards of Clinical Nursing Practice reflect the nursing process and state the interventions to be performed. These standards are a description of a competent level of practice common to all nurses and form the foundation of all decision making in the provision of care to all patients. The interpretive statements that accompany each standard provide definitions of terms along with the interventions and guidelines necessary to achieve these standards. Criteria for the achievement of each standard are also stated and remain consistent with current nursing practice.

Nursing practice is based on theory and evidence-based practice. Nursing is constantly evolving with the development of new technology and research. The standards are written in behavioral terms so nurses can measure to what degree each standard has been met.

The *Standards of Perioperative Clinical Practice,* originally published in 1981, were revised in 2009 by the AORN Board of Directors. The standards are updated annually as necessary to keep pace with changes to validate current practices. The nursing activities inherent in each standard are incorporated in the nursing process during the three phases of surgical care.

Standard I: Assessment

The perioperative nurse collects patient health data from which the nursing diagnoses are derived. Data collection is continual and ongoing. It may be gathered in the preoperative holding area, on the patient care unit, in the clinic, or by a telephone call to the patient at home. Information can be obtained from the patient's chart, by consultation with other members of the health care team (e.g., unit nurses, surgeon, anesthesia provider), through interviews with the patient and/or family or significant others, and by observation and physical assessment. Data collection is a progressive and orderly process of gathering meaningful information pertinent to the planned surgical intervention. It includes but is not limited to the following parameters:

- Current medical diagnosis and therapy
- Diagnostic studies and laboratory test results
- Physical status and physiologic responses, including allergies and sensory or physical deficits
- Psychosocial status, including education level
- Spiritual needs, ethnic and cultural background, and lifestyle
- Previous responses to illness, hospitalization, and surgery
- Patient's understanding, perceptions, and expectations of the procedure

Pertinent data collected through physiologic and psychosocial assessment are documented. Box 2.7 lists the perioperative assessment parameters. The basic elements of a nursing assessment are described in the sections that follow.

- *Subjective data:* Include the patient's perceptions and expectations of the procedure and may be recorded in the form of a direct quote.
- *Objective data:* Include the nurse's observations of the patient and the interpretation of baseline data.

Physiologic Assessment

The perioperative nurse performs a physical assessment of the patient. Techniques include inspection/observation, auscultation, percussion, palpation, and olfaction. The assessment of major body systems establishes the baseline health status of the patient. It provides a basis for planning appropriate patient care and provides a database for postoperative evaluation.

The perioperative nurse should be familiar with laboratory test norms so that critical deviations can be identified in all phases of perioperative care. Other important parameters for planning perioperative care include knowledge of allergies, skin integrity, sensory or physical limitations, prosthetic devices, nutritional/metabolic status, and chronic illness. The routine use of medications can affect or interact with anesthetic medications and postoperative recovery. A patient who smokes and who will have general anesthesia needs to be taught coughing and deep-breathing exercises. The patient who is dependent on alcohol or other drugs can suffer postoperative physiologic and psychologic manifestations of withdrawal. A chemically dependent person who is recovering from an addiction may refuse preoperative sedation and postoperative narcotics for pain.

Psychosocial Assessment

The perioperative nurse performs a psychosocial assessment. Illness makes a person vulnerable, and individuals vary in their ability to cope with stressful situations. Culture, religion, and socioeconomic factors have an effect on a patient's interpretation of illness and response to the interaction with the perioperative environment. Anticipatory apprehension, although normal to some degree, may diminish critical-thinking and decision-making abilities. Stress may initiate an exaggerated response of normal coping mechanisms for self-protection. Establishing a preoperative psychosocial baseline facilitates prompt recognition of maladaptation to a perioperative event.

Documentation

Pertinent information should be recorded in the patient's chart or EHR for use by the perioperative team. Data collection sets the baseline for ongoing care in the perioperative environment and into the remote postoperative care period.

Computer information systems can be used to establish a computerized patient database. Many facilities have incorporated the Internet to permit the patient access to his or her own medical record with a personalized logon and password. Use of the PNDS allows the nurse to use standardized terminology that in turn permits data collection about patient care. This is the foundation of evidence-based practice. A copy of the patient care plan can be viewed in the patient's record. The nurse should review the patient care plan and date and sign it for the permanent record.

Standard II: Diagnosis

The perioperative nurse analyzes the assessment data in determining the nursing diagnoses. Nursing diagnoses are conclusions based on analysis and interpretation of the human response patterns revealed by the assessment data. These are concise written statements about a patient's actual or potential problems, needs, or health status considerations amenable to nursing intervention.

A medical diagnosis defines problems on the basis of a patient's pathologic condition(s). NANDA International (NANDA-I) has developed a list of nursing diagnoses available at www.nanda.org. This list, known as a **taxonomy**, classifies human response patterns and standardizes the **nomenclature** for describing them. It includes definitions and defining characteristics for each diagnosis and leads the nurse to generate assessment data that link to outcomes. The PNDS has 93 nursing diagnoses specific to perioperative patients. A NANDA-I nursing diagnosis has three components:

1. *Defining characteristics.* Human responses to altered body processes and other contributing factors describe the acuity of an actual or potential health status deviation. The nurse identifies the characteristics for which nursing interventions can legally be used to maintain current health status or to reduce, eliminate, or prevent its alteration. These interventions are based on human response patterns:
   a. *Problem.* Any health care condition that requires diagnostic, therapeutic, or educational action. Problems can be active (requiring immediate action) or inactive (having been solved). Problem-oriented medical records are built on this premise. An ongoing list is maintained in a database and is used throughout the managed care environment.
   b. *Need.* A lack of something essential for the maintenance of health that may be met through the plan of care. Needs may be actual (in existence at the time of assessment) or potential (anticipated to become actual during the length of stay [e.g., deficient knowledge]). Many of these needs are met through the intervention component of the plan of care.
   c. *Health status considerations.* A personal habit, lifestyle, or influencing agent that if uncontrolled can lead to a decline in physiologic or psychologic well-being (e.g., occupational hazards, exposure to chemical agent or smoke, substance abuse).
2. *Signs (objective) and symptoms (subjective).* Data obtained during the assessment identify the defining characteristics of the patient's actual or potential health problems. The patient's functional health patterns are assessed (Box 2.8). Gordon has suggested that there are 11 functional health patterns that should be assessed. The domains include physiologic, psychologic, and sociologic aspects of observed behavior.
3. *Etiology/related factors.* The causes of problems may be related to physiologic, psychosocial, spiritual, environmental, or other factors contributing to the patient's health status. These causes define relevant risk factors to be considered in planning patient care.

Documentation

Use of the PNDS terminology helps perioperative nurses establish standard communication when documenting nursing diagnoses. A common language facilitates continuity of patient care.

Standard III: Outcome Identification

The perioperative nurse identifies expected outcomes unique to the patient. Each outcome can be affected by nursing care (also

- Coping/stress tolerance
- Value/belief

Modified from Gordon M: Manual of nursing diagnosis, 1997-1998, St. Louis, 1997, Mosby.

referred to as "nurse sensitive"[*]) and is specific to the individual, the family, and the community. The Nursing Outcomes Classification (NOC) taxonomy is built on five levels: domains, classes, outcomes, indicators, and measures.[a] The standardized terminology gives quantifiable language to the statement of outcomes and has numeric codes that can be used in nursing informatics systems. Each outcome is evidence based and researched using qualitative and quantitative methods.

The nurse measures the patient's responses and uses a five-point Likert scale to tally the score. A numeric baseline range is documented, and the numeric target outcome is identified. This method permits the use of the data in an information system and empiric research. Over 540 outcomes are closely linked and integral with 235 NANDA-I nursing diagnoses[b] and can be used across the care continuum in all branches of nursing, including the perioperative care areas.

Expected perioperative outcomes are the desired and obtainable patient objectives after a surgical intervention. These outcomes occur within specified time frames and have specific criteria for evaluation, as demonstrated in the 39 identified PNDS patient outcomes. They direct patient care to modify or maintain the patient's baseline functional physical capabilities and behavioral patterns. The patient's rights and preferences are the cornerstones for expected outcomes. They should be realistic, attainable, and consistent with medical regimen and patient outcome standards for perioperative nursing.

Documentation

The results of care should be documented in standardized language. Examples of PNDS outcomes are prefixed with the letter "O" and the nomenclature and number from the PNDS list. Select examples of PNDS documentation include the following:

- O30: The patient's neurologic status is consistent with or improved from baseline levels established preoperatively.
- O14: The patient's respiratory status is consistent with or improved from baseline levels established preoperatively.
- O13: The patient's fluid and electrolyte balance is consistent with or improved from baseline levels established preoperatively.

Standard IV: Planning

The perioperative nurse develops a plan of care that prescribes interventions to attain the expected outcomes. Based on the assessment data, nursing diagnoses, and identified expected outcomes, the perioperative nurse devises a plan of care. The plan should include a provision for all phases of patient care in the perioperative environment. Strategic concepts to consider in planning perioperative patient care include but are not limited to the following:

- Participation of the patient and/or significant others in formulation of the plan
- Medical diagnosis and effect of surgical intervention on the patient's physiology
- Psychosocial and spiritual needs of the patient and his or her significant others
- Environmental safety, comfort, and well-being
- Provision of supplies, equipment, and technical expertise
- Current best nursing practices

The plan of care should reflect current standards, facilitate the prescribed medical care, and work toward the attainment of desired outcomes. The scope of the plan is determined by assessment data. Any unusual data are considered for individualized patient care. Alternative options or interventions, not just routine procedures, are a necessary part of the plan. Regardless of format, the plan of care specifies the following parameters:

- Patient care necessary to achieve expected outcomes
- Interventional priorities and sequence of care
- Availability of resources needed to implement the plan
- How, where, and by whom the care will be delivered
- Specific modifications for individualized aspects of care
- Methods for evaluating the effectiveness of the plan

Documentation

Standardized patient care plans may be developed for patient populations undergoing like procedures, with space provided to note any unique or unusual patient assessment data. These care plans can be organized on preprinted forms to include the usual nursing diagnoses and expected outcomes and may include, but are not limited to, the following:

- The patient will demonstrate understanding of the procedure.
- The patient will be injury free.
- The patient will remain normothermic.
- The patient will be infection free.
- The patient's skin will remain intact.
- The patient will remain physiologically stable.
- The patient will demonstrate psychologic comfort.
- The patient will return to normal activities of daily living.

The format of the record may include checklists and spaces for specific patient data. This record accompanies the patient throughout the perioperative environment and serves as a guide for the perioperative team. Use of a standardized language, such as the PNDS, is beneficial for precise communication. Dissemination of the plan to all personnel involved in providing care to the patient is essential for continuity of care. The plan is modified as indicated by ongoing evaluation data.

Standard V: Implementation

The perioperative nurse implements the direct and indirect interventions identified in the plan of care. A taxonomy of nursing interventions known as the Nursing Intervention Classification (NIC) is the basis for the standardization of terminology.[c] The NIC is linked to NANDA-I and describes more than 550 evidence-based interventions that are grouped into classes. The seven domains of the NIC are Physiologic: Basic, Physiological: Complex, Behavioral, Safety, Family, Health, and Community. The standardized terminology of the NIC gives quantifiable language to the nursing interventions and has numeric codes that can be used in nursing informatics systems.

The plan of care is implemented throughout the perioperative care period by the entire team. Scientific principles provide the basis for patient care interventions that are consistent with the plan for continuity of patient care in the perioperative environment. They are performed with safety, skill, efficiency, and effectiveness.

[a]Terminology used in *Nursing Outcomes Classification (NOC),* ed 5, St. Louis, 2013, Elsevier.

[b]See www.nanda.org/nanda international nursing diagnoses: definitions and classification, 2018-2020. Accessed December 18, 2018.

[c]Blulecheck G, Butcher H, Dochteman JM, Wagner C: *Nursing Intervention Classification (NIC),* ed 7, St. Louis, 2013, Elsevier.

The patient's welfare and individual needs are paramount in every facet of activity and must not be compromised. Seemingly routine details are significant. For example, taking a defective instrument out of circulation may prevent injury to the patient or team member. All preoperative preparations within the perioperative environment provide for the physical safety of the patient and team in an aseptic, controlled manner. The circulating nurse also provides emotional support to the patient before transfer to the OR bed and during induction of anesthesia.

This text focuses primarily on direct and indirect interventions that perioperative and perianesthesia nurses and surgical technologists perform to ensure achievement of expected patient outcomes. Implementation of safe and efficient patient care requires the application of technical and professional knowledge, sound clinical judgment, and a surgical conscience on the part of all team members. Nurses have a responsibility to monitor constantly the physiologic and psychologic responses of patients to care. They control environmental factors that affect outcomes of surgical intervention.

Documentation

All patient care interventions (both routine and individualized), observations of patient responses, and the resultant outcomes delineated in the patient care plan are documented as evidence of the care given. This written documentation becomes part of the patient's permanent record. The circulating nurse accountable for the patient's care is responsible for the documentation either in writing or through the EHR. The person completing the documentation should sign with a complete name and title. Interventions contributing to patient comfort and safety are identified. Activities other than direct patient care that are not recorded elsewhere and may affect patient outcomes are included (e.g., how tissue specimens were handled).

Writing nurses' notes or progress notes on the patient's chart or completing an accurate intraoperative observation checklist provides a profile of what has happened to the patient. The notes should contain what happened and why. Intraoperative records not only have legal value but also are valuable to the postoperative care team. The PNDS provides standardized language to describe 151 nursing interventions that are designated by the letter "I" and the nomenclature and number from the list. Select PNDS intervention examples include the following:

- I4: Administers care to wound site
- I5: Administers electrolyte therapy as prescribed
- I3: Administers care to invasive device sites
- I37: Evaluates for signs and symptoms of electrical injury
- I84: Manages specimen handling and disposition

Standard VI: Evaluation

The perioperative nurse evaluates the patient's progress toward the attainment of outcomes with an actual outcome statement, as described in the PNDS. Evaluation is a continual process of reassessing the patient and his or her responses to implementation of the plan of care. Perioperative caregivers accommodate a variety of intense situations within a short time. The perioperative team is always on the alert for, and prepared to respond to, the unexpected. The flexibility of the team is manifest in the quick modifications to the plan of care during emergency situations.

All components of the nursing process are performed concurrently during the intraoperative phase as changes occur in the patient's internal and external environments. The patient is observed during the surgical procedure and evaluated for responses to all interventions.

Determination of patient responses and the realization of expected outcomes can be verified by direct observation of and/or conversation with the patient. The perioperative nurse observes the patient's responses to interventions during the immediate preoperative and intraoperative phases of care in the perioperative environment. The perioperative nurse may accompany the patient to the PACU or postprocedure area to determine the level of attainment of expected outcomes. The "hand-over" or "hand-off" report should be standardized between the perioperative nurse and the postanesthesia nurse. For the purposes of this text, the term *hand-over* is used to describe the exchange of patient information between professional caregivers. Ideally the perioperative nurse visits the patient postoperatively on the patient care division or phones an ambulatory patient at home within 24 to 48 hours after discharge to complete the assessment of outcomes.

Documentation

The patient's permanent record should reflect the ongoing evaluation of perioperative nursing care and its outcomes. This includes a comparison of expected outcomes to the degree of outcome attainment as determined by the patient's responses to nursing interventions. Documentation using a standardized language provides legal evidence of results of the plan of care and revisions to the plan after reassessment of the patient. Examples of PNDS in action include, but are not limited to, the following PNDS numbered nursing diagnoses and outcome statements:

- O31: Patient demonstrates knowledge of the expected responses to the procedure.
- O11: Patient has wound/tissue perfusion consistent with or improved from baseline levels established preoperatively.
- O12: Patient is at or returning to normothermia at the conclusion of the immediate postoperative period.
- O2: Patient is free from injury from extraneous objects.

Clinical Competency of the Perioperative Nurse

Using the framework of the nursing process, AORN published **Competency Statements** in Perioperative Nursing in 1986 and revises them periodically. These broadly written statements of expected competencies can be used to develop position descriptions, generate performance appraisals, and organize orientation and staff development activities. They serve as guidelines for the skills a nurse should reasonably expect to achieve to function as a competent perioperative nurse in the perioperative environment. These statements incorporate the many principles, procedures, and practices elaborated throughout this text for competent care of the surgical patient, as follows:

- Assess the physiologic health status of the patient.
- Assess the psychosocial health status of the patient and family.
- Formulate nursing diagnoses based on health status data.
- Establish the patient's expected outcomes based on nursing diagnoses.
- Develop a plan of care that identifies patient care interventions to achieve expected outcomes.
- Implement patient care interventions according to the plan of care.
- Evaluate the attainment of expected outcomes and effectiveness of patient care.

- Participate in both patient and family teaching.
- Create and maintain a sterile field.
- Provide equipment and supplies based on patient needs.
- Perform sponge, sharps, and instrument counts.
- Administer drugs and solutions as prescribed.
- Physiologically monitor the patient during the surgical procedure and throughout the perioperative experience.
- Monitor and control the environment.
- Respect the patient's rights.
- Demonstrate accountability.

Scope of Perioperative Nursing Practice

Perioperative nurses care for patients throughout the continuum of the perioperative intervention. The patient's needs are unique during this phase of care and require specific activities particular to the realm of perioperative nursing. The professional nurses render direct care or oversee the implementation of the plan of care through specialized activities that include, but are not limited to, the following:

- Educate staff and peers
- Emotionally support and reassure the patient and his or her family
- Serve as patient advocate
- Control environment
- Provide resources
- Maintain asepsis
- Monitor physiologic and psychologic status
- Manage aggregate patient needs
- Supervise ancillary personnel
- Validate and explore current and prospective practices
- Integrate and coordinate care across all disciplines
- Collaborate and consult

These activities are incorporated into the scope of perioperative practice by managers, educators, practitioners, and researchers. These practices take place in hospitals, clinics, educational facilities, physicians' offices, provider organizations, and industry.

Surgical Technology

The activities of registered professional nurses are supplemented and complemented by the services of allied technical health care personnel. The term *allied health care personnel* refers to individuals who have been trained in a health care–related science and have responsibility for the delivery of health care–related services but who are not graduates of schools of medicine, osteopathy, dentistry, podiatry, or nursing. Approximately two thirds of the health care workforce are designated as allied health professionals. Educational preparation may be offered in colleges, vocational-technical schools, hospital-based programs, or military service schools. Technologists, technicians, and therapists in more than 130 occupational categories work collaboratively with and under the direction of physicians and registered nurses.

The surgical technologist, or ST, is a member of the direct patient care team and works intraoperatively with the surgeon and anesthesia provider under the direction of the circulating nurse. This team is referred to as the *perioperative team.* The surgical technologist prepares instruments, supplies, and equipment to maintain a safe and therapeutic surgical environment for the patient. The surgical technologist performs specific techniques and functions designed to exclude pathogenic microorganisms from the surgical wound.

An accredited surgical technology program includes courses in anatomy and physiology, pathology, and microbiology as prerequisites to courses that involve the theory and application of technology during surgical procedures and for care of the perioperative environment. Other courses in the curriculum, such as pharmacology, help explain the underlying basis for the technical tasks to be performed. Courses in psychology, ethics, and interpersonal communication are fundamental to an appreciation of the humanities.

AST, National Board of Surgical Technology and Surgical Assisting (NBSTSA), Accreditation Review Council on Education in Surgical technology and Surgical Assisting (ARC-STSA), Commission on Accreditation of Allied Health Education Programs (CAAHEP), and Accrediting Bureau of Health Education Schools (ABHES) recommend that an associate degree is the preferred educational level for entry into practice and that certification should be a condition of employment.

NBSTSA offers a national certification examination for individuals who meet the graduation requirements from an accredited program. After graduation from an accredited program, an application for testing may be submitting for approval. Upon passing the examination, the credential: Certified Surgical Technologist (CST) may be used. As of 2020,the certification cycle is 2 years and the credential renewed by continuing education hours or retaking the examination. Continuing education credits must be specific to Surgical Technology and may be obtained from AST.

The NBSTSA 2-year recertification cycle by continuing education requires:

- 30 Continuing education credits for a CST
- 38 Continuing education credits for a CSFA
- The renewal fee is reduced to reflect the 2 year cycle

Guidelines for Surgical Technologists

AST has developed position statements and guidelines based on evidence that provide a description of professional topics and guidelines that demonstrate best practices. The quality of the surgical technologist's practice is judged by these guidelines. The authoritative position and practice statements include those in the following section.

Teamwork I

Teamwork is essential for perioperative patient care and is contingent on interpersonal skills. Communication is critical to the positive attainment of expected outcomes of care. All team members should work together for the common good of the patient. For the benefit of the patient and the delivery of quality care, interpersonal skills are demonstrated in all interactions with the health care team, the patient and family, superiors, and peers. Personal integrity and surgical conscience are integrated into every aspect of professional behavior.

Preparation II

Preoperative planning and preparation for surgical intervention are individualized to meet the needs of each patient and his or her surgeon. The surgical technologist collaborates with the professional registered nurse in the collection of data for use in the preparation of equipment and supplies needed for the surgical procedure. The implementation of patient care identified in the plan of care is performed under the supervision of a professional registered nurse.

The preparation of the perioperative environment and all supplies and equipment will ensure environmental safety for patients and personnel. The application of the plan of care includes wearing appropriate attire, anticipating the needs of the patient and perioperative team, maintaining a safe work area, observing aseptic technique, and following all policies and procedures of the institution.

Surgical Expertise

Application of basic and current knowledge is necessary for a proficient performance of assigned functions. The surgical technologist should maintain a current knowledge base of procedures, equipment and supplies, emergency protocol for various situations, and changes in scientific technology pertinent to his or her performance description objectives. It is the responsibility of the surgical technologist to augment his or her knowledge base by studying recent literature, attending inservice and continuing education programs, and pursuing new learning experiences.

Ethics

Each patient's rights to privacy, dignity, safety, and comfort are respected and protected. Each member of the OR team has a moral and ethical duty to uphold strict observance of the patient's rights. The surgical technologist, like all members of the health care team, is expected to perform as a patient advocate in all situations. This is an accountability subject and should be part of each aspect of patient care.

Aseptic Technique

Every patient is entitled to the same application of aseptic technique within the physical facilities. Implementation of the individualized plan of care for every patient includes the application of aseptic or sterile technique at all times by all members of the health care team. All patients are given the same dedication in their care.

Clinical Competency of the Surgical Technologist

The performance description developed by AST identifies performance objectives against which the surgical technologist may measure his or her level of competency. According to AST, the surgical technologist can aspire to three levels based on education, experience, and time in service. Each level requires the surgical technologist to be certified and employed in the OR. The employment setting can be a clinic, private practice, or facility, such as a hospital. These levels could be used to structure seniority, promotions, and salaries. The CST levels are as follows:

Level I CST

- Entry level as certified or a qualified applicant
- Graduated from an accredited program with a minimum of 120 cases in the scrub role
- Performs as first scrub in all assigned specialty cases

Level I Competencies

- Demonstrates knowledge and practice of basic patient care concepts
- Demonstrates the application of the principles of asepsis in a knowledgeable manner that provides for optimal patient care in the OR
- Demonstrates basic surgical case preparation skills
- Demonstrates the ability to perform in the role of first scrub on all basic surgical cases
- Demonstrates responsible behavior as a health care professional

Level II CST (Advanced)

- Current CST
- A minimum of 1 year of full-time employment
- Documentation of continuing education credits

Level II Competencies

- Demonstrates all competencies required for CST level I
- Demonstrates advanced knowledge and practice of patient care techniques
- Demonstrates advanced knowledge of aseptic and surgical technique
- Demonstrates advanced knowledge and practice of circulating skills and tasks
- Demonstrates knowledge related to OR emergency situations
- Demonstrates advanced organizational skills
- Demonstrates advanced knowledge in one or two specialty areas
- Demonstrates a professional attitude

Level III CST (Specialist)

- Current CST
- Associate's degree in surgical technology or related field, established work history
- Documentation of continuing education credits in a specialty or management area

Level III Competencies

- Demonstrates all competencies required for CST level II
- Demonstrates superior knowledge and practice of patient care techniques and instrumentation
- Demonstrates superior knowledge of aseptic and surgical technique
- Demonstrates advanced knowledge and practice of circulating skills and tasks
- Demonstrates advanced knowledge related to OR emergency situations
- Demonstrates advanced organizational skills
- Demonstrates superior knowledge in one or two specialty areas
- Demonstrates a professional attitude
- Demonstrates leadership abilities
- Fulfills the role of a preceptor or mentor
- Involved in committee meetings and decision making

Continual Performance Evaluation and Improvement

Nursing research and experience have shown that quality cannot be ensured, only monitored, and performance can be improved. TJC has adopted a definition of quality as "continual improvement" in patient care services to increase the probability of expected patient outcomes and reduce the probability of undesired outcomes. Outcomes can be defined, monitored, and measured. Patient satisfaction is one outcome measurement that is critical in evaluating quality of performance. Satisfied patients are more cooperative and receptive to therapy and teaching.

Each patient deserves the best possible care. Without the structure provided by the nursing process, health care services would be fragmented and accountability for the quality of services rendered would be made difficult. Society demands the accountability of those who provide patient care services. Patients are protected by laws, standards, and recommended practices. Performance of care should comply with established policies and procedures of the hospital or ambulatory care facility and with professional standards of practice.

Performance Improvement Studies

Most studies are designed to measure compliance with current policies and procedures and identify the need for change in practice guidelines or education of staff. Both strengths and weaknesses in performance are identified. Ultimately the purpose is to correct deficiencies and deviations from expected standards. Important aspects that have an effect on the quality of patient care are identified, and a measurable indicator is established for each aspect. Data sources and methods of data collection should be appropriate for each indicator. Sample size and the frequency of data collection should be sufficient to identify trends or patterns in the delivery of care. A sample size of 5% of the monitored patient population selected for study or 25 patients or events, whichever is greater, is usually adequate to obtain reliable data.

Data are collected either concurrently or retrospectively and are organized for evaluation. A concurrent study begins with a current manifestation and links this effect to occurrences at the same time (i.e., is related to care in progress). This type of study focuses on a systematic series of actions that brings about an outcome. Through concurrent observation, the implementation component of the nursing process can be monitored during perioperative patient care to determine whether interventions are consistent with established standards for care and recommended practices. The interventions performed should protect the welfare and safety of the patient and should meet his or her identified physiologic and psychologic needs. The environment, including equipment or supplies used in the room, can be evaluated at this time.

A retrospective study focuses on the end result of patient care or on a measurable change in the actual state of the patient's health as a result of care received. This evaluation of outcomes usually occurs through review of patient records. The study begins with a current manifestation and links this effect to some occurrence in the past (i.e., care previously given). Complications attributable to care in the perioperative environment may be identified (e.g., nerve palsy from poor positioning, infiltration of an IV infusion, postoperative wound infection). The source of these complications may be difficult to identify unless every detail of actual care given and any unusual occurrences are recorded in the patient's record. Accurate and complete documentation is therefore essential for meaningful retrospective studies.

Any method that systematically monitors and evaluates the quality of patient care can enable perioperative nurses and surgical technologists to take corrective action for improvement of performance. Quality improvement studies also assist in the coordination of plans for patient care with surgeons; improve communications with other departments; identify needs for revision of policies and procedures; and reassess equipment, personnel, and other aspects of patient care.

Benchmarking

Benchmarking is a term that is used to continually monitor progress of a competitor to discover methods for performance improvement and how to implement them. According to TJC, when processes within the same facility are measured against each other, this is referred to as *internal benchmarking.* Measuring performance against an outside competitor is referred to as *competitive benchmarking.* If another industry's activities are used as the comparison, the reference is then made to *functional benchmarking.*

When practices are benchmarked, the current level of attainment is clearly identifiable and higher performance attributes can be viewed as the next step in professionalism.

Peer Review

Peer review differs from other quality improvement programs in that it looks at the strengths and weaknesses of an individual practitioner's performance rather than appraises the quality of care rendered by a group of professionals to a group of patients. An associate with the same role expectations and performance description examines and evaluates the clinical practice of a peer. The individual is evaluated by written standards of performance, and the review should offer constructive criticism of the performance observed. Through this framework, caregivers gain feedback for personal improvement or confirmation of personal achievement related to their effectiveness of professional, technical, and interpersonal skills in providing patient care.

Legal, Regulatory, and Ethical Issues

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Define negligence as it applies to caregivers.
- Discuss informed consent.
- Describe the importance of patient care documentation.
- List several methods of documentation of patient care.
- Identify three potential events that could lead to litigation.
- Describe the role of The Joint Commission in the promotion of patient safety.

KEY TERMS AND DEFINITIONS

Advance directive Document that indicates wishes concerning health care and usually designates someone to make decisions if the patient is unable to do so for self.
Autonomy Self-government or independence.
Causation Action directly or indirectly causing an injury.
Consent Voluntary, autonomous permission to proceed with an agreed-on course of action.
Damages Compensation awarded to make restitution for an injury or a wrong.
Defendant Person named as the object of a lawsuit.
Deposition Statement given under oath that is a documentation of fact used in a court of law.
Iatrogenic Injury or illness caused by professional intervention of a health care provider.
Indicator A measured increment of performance, process, system, or outcome.
Liability Legally responsible for personal actions.
Malpractice Substandard delivery of care that results in harm.
Near miss An event or situation that just by chance did not cause patient injury. A very close call.
Negligence Careless performance of duty.
Plaintiff Person who initiates a lawsuit.
Proximate cause An act of commission or omission by one or more persons that caused a consequence to another.
Root cause analysis The baseline reason for the occurrence of failure in a process or system.
Sentinel event An unexpected occurrence that involves physiologic or psychologic injury or death. This occurrence signals the need for appropriate reporting and documentation, immediate investigation, and response.
Systems approach A global attitude of improvement and safety that encompasses involvement of individuals and the organization at all levels. Adverse events are attributed not only to individuals but also failure of the interaction of the individual and the organization.
Tort Wrong committed by one person against another; civil action.

Competent patient care is the best way to avoid a **malpractice** or **negligence** claim. Unfortunately, even under the best of circumstances, a patient may be injured and recover monetary **damages** as compensation. Understanding how a **liability** action starts and how it proceeds is important in the effort to avoid the many pitfalls that can lead to being named and successfully sued in a lawsuit.

Caregivers should consider that liability is not the only rationale behind competent care. The main focus should be the desired outcome for the patient and the exemplary delivery of care. Performing in a particular manner merely to avoid being sued is not an ethical practice.

Legal Issues

Inherent in professional practice is the duty to safeguard the safety and rights of patients. The patient is at risk for harm during any surgical procedure. These factors also may present health care providers with ethical dilemmas complicated by legal issues.

Respect for the patient's **autonomy** and the patient's right to make informed decisions about his or her own health care should be considered and balanced by the professional obligations of beneficence (the duty to benefit) and nonmaleficence (not to harm).

Any caregiver can be named in a lawsuit. Being named in a suit does not mean that you have been successfully sued and does not always mean you are liable for anything. Attorneys frequently name everyone involved with the patient in the suit as part of the fact-finding process for building the lawsuit. When in doubt about personal competency for a new or unfamiliar procedure or piece of equipment, seek guidance from the clinical educator or immediate supervisor.

Regardless of who is in charge of the team, each team member is responsible for his or her own actions. When performing duties within the scope of practice and according to facility policy and procedure, the risk for being successfully sued in a malpractice or negligence suit is very limited. Honest mistakes can result in patient injury. If a suit is brought to court, a jury can evaluate a reasonable set of circumstances, facts, and testimony to render a verdict in favor of the caregiver. The **plaintiff** does not always win. If the verdict is found in favor of the plaintiff, the damages awarded may be for compensatory award. Many states have set limits on the amount of money that can be awarded by the court.

The quality of health care is assessed through the outcome of services rendered. If the outcome is unacceptable, patients tend to take grievances to court. The severity of an injury usually determines whether a claim of merit will arise, but other contributing factors include a breakdown of rapport between the patient and the health care team members and unrealistic expectations about the outcome of care.

Causes for litigation lie in patients' and their families' belief that physicians and/or health care organizations have not provided appropriate diagnosis, treatment, or results. Although the physician is professionally responsible for patient care, other patient care personnel act as part of the health care team, carrying responsibility for their own actions. Medical and surgical sales personnel and suppliers of equipment and drugs also are indirectly involved in treatment and may be held responsible for product liability.

Liability

To be liable is to be legally bound and responsible for personal actions that adversely affect another person. Every patient care provider should always perform duties in accordance with standards and practice guidelines established by federal statutes, state practice acts, professional organizations, and regulatory agencies and those that are common practice throughout the community. Deviation from these standards and practices that cause injury to a patient can result in liability for negligence or malpractice. For this type of civil suit to be successful for the plaintiff, he or she has to prove that negligent care or malpractice caused the injury.

Negligence is the failure to use the care or skills that any caregiver in the same or a similar situation would be expected to use. These acts of omission or commission that cause damage to a patient may give rise to **tort** action, which is a civil lawsuit.

Malpractice is any professional misconduct, unreasonable lack of skill or judgment, or illegal or immoral conduct. Malpractice and negligence claims usually are settled in a civil court; however, depending on the severity of the injury and the extent of the misconduct, they may be taken to criminal court. From the legal point of view of damages or fault, professional negligence is often synonymous with malpractice in a tort action. The following factors contributing to a successful lawsuit on behalf of the plaintiff have been called the "four Ds of malpractice":

1. Duty to deliver a standard of care directly proportional to the degree of specialty training received
2. Deviation from that duty by omission or commission
3. Direct **causation** of a personal injury or damage because of deviation of duty
4. Damages to a patient or personal property caused by the deviation from the standard of care

Statutory laws (laws by legislation) and common laws (laws based on court decisions) differ from state to state. Courts differ at times in their interpretation of laws. Any caregiver who is in some way thought to be responsible for injury to a patient may be sued. The nurse manager or clinical educator responsible for assigning duties to this individual may be included in the suit if delegation and supervision are in question.

Caregivers, such as nurses, technologists, and technicians, are considered employees of the health care facility. The facility is almost always named in the suit as ultimately responsible for hiring, monitoring credentials, evaluating, and disciplining their employees.

The court may rule that a learner or an experienced practitioner is liable for his or her own acts. A learner may be held responsible for independent actions in proportion to the amount and type of instruction received and judged by the standard of other learners in training. An instructor can be named with the learner as partially liable.

Medical care and professional liability have become institutional problems. The primary cause of professional liability claims is **iatrogenic** medical injury—an injury or other adverse outcome sustained by a patient as a result of treatment. Many incidents in the perioperative environment have been causes for a lawsuit.

Liability Prevention for the Facility and the Team

Complex technologies, acuity of hospitalized patients' conditions, short-stay procedures, diverse roles of providers, inadequacy of staffing numbers, and other factors present challenges in managing risks for liability. Many surgeons restrict their practices to avoid patients who have complex diseases or who are at high risk for uncertain outcomes. Others practice defensive medicine, ordering tests principally to protect themselves against possible litigation. Because lawyers have become increasingly sophisticated in representing injured patients, all health care providers need to take measures to protect themselves from litigation. A preventive strategy includes the following:

- Become active within the professional organizations associated with setting the standards for practice. Most organizations provide up-to-date education and resources for improvement of practice. Have a voice in shaping the future of the profession.
- Remain current with continuing education. Become certified, and maintain the credential.
- Establish positive rapport with patients. Patients are less likely to sue if they perceive that they were treated with respect, dignity, and sincere concern. Patients have the right to accurate information and good communication.
- Comply with the legal statutes of the state and standards of accrediting agencies, professional associations, and the health care facility policies.
- Adhere to the policies and procedures of the facility. Seek a position on the policy and procedure committee to have a say in the formation and revision of facility practices.

- Document assessments, interventions, and evaluations of patient care outcomes. Each patient care activity is an **indicator** of competent care and should be documented. Leave a paper trail that is easy to follow for the reconstruction of the event in question.
- Prevent injuries by adhering to policies and procedures. Shortcuts can be hazardous to the patient and team members.
- If an injury occurs, control further injury or damage by reporting problems and taking corrective action immediately.
- Maintain good communications with other team members.
- In addition to these strategies, the facility as the employer and the caregiver as the employee should take steps to avoid liability. The facility protects the patient, its personnel, and itself by maintaining safe and well-defined policies and procedures based on national standards and recommended practices.

Liability Insurance

Formerly it was thought that patients did not sue nurses and other patient care providers because they had no large assets. Unfortunately, this is no longer true. Increased autonomy increases the risk for liability. Perioperative nurses make independent nursing decisions based on their assessments, and they can perform and/or delegate certain patient care interventions without a physician's order. No matter how careful the caregiver is, mistakes can happen. An unintentional wrong may cause injury to a patient.

Most facilities carry insurance that covers incidents that result in harm to a patient when policies and procedures are followed; however, they may not cover the employee who fails to follow the established protocol. In some instances the facility's insurance may not adequately cover all of the expenses associated with a lawsuit, such as a private attorney, time in **deposition**, and lost wages during suspensions and trial.

The caregiver who accidentally caused the injury may be named in the suit as an individual or as a codefendant. Carrying personal liability insurance protects against a possible discrepancy with the facility's insurance coverage and provides the employee with the opportunity for representation by a personal attorney.

A professional liability policy can be individualized to meet the practice of the insured. The policy costs are tax deductible, and the protection of personal assets and wages may well be worth the price of the coverage. Professional associations recommend individual professional liability insurance and frequently offer discounts to members.

Borrowed Servant Rule

In the past the surgeon was considered the captain of the ship in the perioperative environment and was liable for the negligent acts of servants. In the early 1940s and 1950s, courts held that this doctrine, based on the master–borrowed servant relationship, was applicable by the mere presence of the surgeon. Once having entered the operating room (OR), the surgeon was considered to have complete control over other team members. But courts now recognize that the surgeon does not have complete control over the acts of the perioperative patient care team at all times.

Each member of the team has significant performance autonomy. The surgeon usually is not held responsible when a perioperative caregiver fails to carry out a routine procedure as expected. Courts have decided that certain procedures do not need to be personally performed by the surgeon, such as counts or mixing medications on the sterile field. According to the borrowed servant rule, the surgeon is liable for acts of team members only when he or she has the right to control and supervise the way in which a perioperative caregiver performs the specific task. A good example of this is counting sponges, sharps, and instruments. The facility, not the surgeon, establishes the mechanism by which the employee team accounts for items used during a procedure. The surgeon does share some liability if he or she prohibits or prevents the team from accomplishing this task. If this is the case, the circulating nurse should clearly document the surgeon's refusal to permit counting in the medical record and report to the immediate supervisor.

Independent Contractor

The employer may be held responsible for employees under the master–servant rule. However, the current trend is to hold an individual responsible for his or her own acts under the principle of the independent contractor. For example, a private scrub person, biomedical technologist, or first assistant may contract with several surgeons to provide services on a fee-for-service basis. These individuals are not directly employed by the facility but are usually credentialed and given permission to work with the surgeon by the medical staff department. Some questions may arise concerning the level of responsibility of the facility for credentialing someone who is accused of substandard practice. The facility will be named in the suit initially but may be dropped at a later date. A detailed contract explaining all responsibilities and duties should be written and signed by all contracting personnel.

The Joint Commission (TJC) determined that the facility that permits independent contractors, such as private first assistants, interns, residents, or other privately engaged personnel, is responsible for specific standards associated with accountability. Current standards are as follows:

- The contractor must be appropriately credentialed for the role.
- The contractor must be competent.
- The contractor must be providing care under the direct supervision of a licensed practitioner.
- The contractor may perform duties only within the scope of his or her intended role.
- The contractor must adhere to the policies and procedures of the facility.
- The contractor must be oriented to the facility's emergency evacuation procedures.
- The contractor must be current in immunizations and health screenings.
- The contractor must display appropriate identification at all times.
- The contractor must comply with all background checks, possibly including fingerprinting and drug testing.

Doctrine of the Reasonable Man

A patient has the right to expect that all patient care personnel will use knowledge, skill, and judgment in performing duties that meet standards exercised by other reasonably prudent professionals involved in similar circumstances.

Whenever a mishap occurs in patient care, the cause of the event is compared with local and national standards of care. Experts are consulted by attorneys, and the mishap is studied. The results should show whether the same event performed by someone else of the same or similar education and role would have had the same result under the same or similar circumstances. This is how the courts determine the reasonableness of a caregiver's

actions. An example of this might be how drugs are administered. The average nurse in average circumstances would check and recheck to be sure the right patient gets the right drug. A careless nurse might omit checking the patient's identification and administer the wrong drug. This would be considered unreasonable and would be a source of liability.

Doctrine of *Res Ipsa Loquitur*

Translated from Latin, *res ipsa loquitur* means "the thing speaks for itself." Under this doctrine, the courts allow the patient's injury to stand as inference of negligence. The **defendant** has to prove that he or she did not act negligently. Before this doctrine can be applied, three conditions must exist:

1. The type of injury would not ordinarily occur without a negligent act.
2. The injury was caused by the conduct or instrumentality within the exclusive control of the person or persons being sued.
3. The injured person could not have contributed to negligence or voluntarily assumed risk.

This doctrine applies to injuries sustained by the patient while in the perioperative environment, such as a retained foreign object (e.g., sponge, towel, needle, or other instrument/item), a fall, or a burn. The defendant must prove that a breach did not occur and that he or she was not negligent.

Doctrine of *Respondeat Superior*

An employer may be liable for an employee's negligent conduct under the *respondeat superior* master–servant employment relationship. This implies that the master will answer for the acts of a servant. If a patient is injured as a result of an employee's negligent act within the scope of that employment, the employer is responsible to the injured patient. The patient may name both the facility and the employee in a civil suit, but the employee may be dropped from the suit if he or she was following facility policy and procedure and acting within the appropriate scope of practice.

A facility may have outdated practices or unsafe procedures. One example might be the labeling of drugs on the sterile field. Instead of requiring the name and dose of the drug to be written on the sterile container and the syringe, the facility may permit the scrub person to place the cap of the syringe into the medicine cup containing local anesthetic to signify the contents of both the syringe and cup. This is a practice that was in effect in some facilities up to a few years ago. It is clearly an unsafe practice to require a scrub person to manage drugs on the sterile field in this manner. The facility would be found liable for this action if it required the employee to perform at this unacceptable level.

Doctrine of Corporate Negligence

Under the corporate negligence doctrine, the facility may be liable not for the negligence of employees but for its own negligence in failing to ensure that an acceptable level of care is provided. The facility has a duty to provide services and is responsible for the following:

- Screening and verifying qualifications of all staff members, including medical staff, according to standards established by TJC
- Monitoring and reviewing performance and competency of staff members through established personnel appraisal and peer review procedures
- Maintaining a competent staff of physicians and other caregivers
- Revoking practice privileges of a physician and other caregivers when the administrators know or should have known that the individual is incompetent or impaired

Corporate negligence includes the use of personnel who are inadequately trained for the position they hold. The Alabama Supreme Court found HealthTrust, Inc. liable for permitting a surgical technologist to perform in the role of first assistant at Crestwood Hospital in 1997 *(Cantrell v. Crestwood).* The surgical technologist was holding a retractor during an open hip procedure on a pediatric patient and permanently injured the sciatic nerve. Her leg is disfigured, and she has undergone multiple failed surgeries to restore function. The surgeon was not found liable for the acts of the facility's employee.

Extension Doctrine

If the surgeon goes beyond the limits to which the patient consented, liability for assault and battery may be charged. This doctrine implies that the patient's explicit **consent** for a surgical procedure serves as an implicit consent for any or all procedures deemed necessary to cope with unpredictable situations that jeopardize the patient's health. By medical necessity and sound judgment, the surgeon may perform a different or an additional surgical procedure when unexpected conditions are encountered during the course of an authorized surgical procedure (e.g., finding an abscess near the target organ or finding a tumor extended into adjacent structures).

The surgeon may extend the surgical procedure to correct or remove any abnormal or pathologic condition under the extension doctrine. The court will determine whether the patient consented to a specific procedure or generally to surgical treatment of a health problem. The surgeon may not routinely remove the appendix or gallbladder during a tubal ligation.

Assault and Battery

In legal terms, assault is an unlawful threat to harm another physically. Battery is the carrying out of bodily harm, as by touching without authorization or consent. Lack of informed consent to perform a procedure is an important aspect of an assault-and-battery charge. Informed consent must be obtained by the physician and consent to perform a procedure must be given voluntarily with full understanding of implications by the patient. The purposes of a written, signed, and witnessed consent are to protect the surgeon, anesthesia provider, perioperative team members, and facility from claims of unauthorized procedures and to protect the patient from unsanctioned procedures. Consents are discussed in detail later in this chapter.

Invasion of Privacy

The patient's right to privacy exists by statutory or common law. The patient's chart, medical record, DVD, videotapes, x-rays, and photographs are considered confidential information for use by physicians and other health care personnel directly concerned with that patient's care. The patient should give written consent for videotaping or photographing his or her surgical procedure for medical education or research. The patient has the right to refuse photographic consent.

The patient has the right to expect that all communications and records pertaining to individualized care will be treated as

confidential and will not be misused. This includes the right to privacy during interview, examination, and treatment. The surgery schedule bearing the names of the patients should not be posted in a location where the public or other patients can read it.

Some patients, such as celebrities, may request to be admitted with an alias. Care is taken when identifying these patients so they will not be confused with other patients and receive the wrong procedure. Community hospitals may be admitting people from the surrounding neighborhood. The caregiver may be in a position to learn private information about a neighbor. Maintaining the confidentiality of patient information is imperative. Every health care worker has a moral obligation to hold in confidence any personal or family affairs learned from patients. Many facilities have implemented confidentiality agreements with all health care personnel on the premises. Health care personnel must sign and date the agreement and understand that it is a legal binding document. Violations can lead to punishment or termination of employment. Schools for surgical personnel require students to sign confidentiality agreements before going to a clinical site.

Health Insurance Portability and Accountability Act

The Health Insurance Portability and Accountability Act (HIPAA) was originally published in the *Federal Register* in 2003 and was updated in 2009 and 2013. This act provides for confidentiality of health data involved in research or transmitted and stored by electronic or any other means. The release or disclosure of this protected health information (PHI) requires patient authorization. HIPAA covers far more than PHI—it covers fingerprints, voice prints, and photographic images. Specific information can be found at www.hhs.gov/hipaa.

In 2009, HIPAA added the Health Information Technology for Economic and Clinical Health Act (HITECH). With increased electronic health record (EHR) sharing of medical information between health care providers and facilities, security and privacy measures needed strengthening and are enforced through the HITECH Act. The Omnibus Act of 2013 added four new additional rules to HIPAA that strengthened privacy laws to protect health information from unauthorized use or sale.

When a victim of crime or a perpetrator is in a health care facility, both have the right to privacy. Caregivers may not speak to news media or any other person concerning either individual. If a crime is discovered by a caregiver, the information must be reported to an appropriate supervisor. At no time is a caregiver to make a promise of secrecy to a suspected perpetrator.

The use of social media, such as Twitter, Facebook, and Instagram to discuss patient information is a violation of patient confidentiality.[1] Accessing patient records without authorization is grounds for dismissal from employment. Both of these activities are violations of HIPAA and are punishable by law.

Abandonment

Abandonment consists of leaving the patient for any reason when the patient's condition is contingent on the presence of the caregiver. If the caregiver leaves the room knowing there is a potential need for care during his or her absence, even under the order of a physician, the caregiver is liable for his or her own actions.

In *Czubinsky v. Doctor's Hospital,* the surgeon ordered the circulating nurse to leave the room to help him start another procedure. During the circulating nurse's absence, the patient had a cardiac arrest. The only team members on hand were the anesthesia provider and the surgical technologist. At the trial, the circulating nurse admitted to knowing that it was wrong to leave the patient because of his condition but left because of the surgeon's insistence. The expert witness testified that the circulating nurse should not have been ordered away from the patient to work in another room. The court decided that if adequate help for resuscitation had been available in the OR during the patient's crisis he would not have suffered permanent brain damage, which occurred because of this breach of duty. According to the court, the circulating nurse had a duty to remain with the patient.

If an event necessitates leaving a patient, it is important to transfer care to another caregiver of equal status and function. In uncontrollable circumstances, the perioperative manager should be consulted immediately. The patient must not be left unattended. No one, not even a physician, may release a caregiver from a responsibility to a patient. A child or disoriented patient left alone or unguarded in a holding area, for example, may sustain injury by an electric shock from a nearby outlet or by some other hazard within reach. The circulating nurse may be considered negligent by reason of abandonment for failure to monitor a patient in the OR. The circulating nurse should be in attendance during induction of and emergence from anesthesia and throughout the surgical procedure to assist as needed.

The Joint Commission and Sentinel Events

Professional accountability requires professionals to monitor performance as it applies to patient outcomes. The identification of an undesired outcome may be the result of direct or indirect actions of the caregiver. Such an outcome is referred to as a **sentinel event**—an unexpected event that involves a risk for or the occurrence of death or serious physical or psychologic injury. Serious injury specifically includes loss of limb or function. The term *sentinel* was selected to represent the concept because the seriousness of the event requires immediate investigation and response. These events have a significant effect on patient outcomes; they should be evaluated for root cause and a plan to prevent its occurrence should be prepared.

Root Cause Analysis

TJC developed and approved a list of sentinel events that should be voluntarily reported and other events that need not be reported (Box 3.1). The TJC publication *Framework for Root Cause Analysis and Corrective Actions* has been made available to institutions as a guideline for investigating the causes of sentinel events. The objective is to improve the system that has permitted the error to occur. The guidelines include a fill-in-the-blank questionnaire to help track the cause of the event.

The guidelines suggested by TJC allow each facility flexibility in determining the root causes for events specific to the environment. Using flowcharts, the facility can identify one or more of these root causes in identification of the problem or **proximate cause** of the error. Each facility is encouraged but not required to report sentinel events to TJC. Other sources, such as the patient, a family member, or the media, may generate a report and can find the forms on-line on TJC's website. If TJC becomes aware of an event, the facility is required to perform a **root cause analysis** and action plan or other approved protocol within 45 days of the occurrence. A TJC glossary of sentinel event terminology is available at www.jointcommission.org.

• BOX 3.1 Reportable and Nonreportable Sentinel Events Identified by The Joint Commission

Reportable

- Any event that results in the loss of life or limb (e.g., death, paralysis, coma) associated with a medication error
- Suicide of a patient within 72 hours of being in an around-the-clock care setting
- Elopement or unauthorized departure of an individual from an around-the-clock care facility that results in suicide or homicide or permanent loss of function
- Abduction from a care facility
- Rape
- Discharge of an infant to the wrong family
- Hemolytic transfusion reaction involving the administration of blood or blood products having major blood group incompatibilities
- Surgery on the wrong patient or the wrong body part
- Intrapartum maternal death related to the birth process
- A perinatal death unrelated to a congenital condition in an infant weighing more than 2500 g
- Assault, homicide, or other crime resulting in patient death or a major permanent loss of function
- A fall that results in death or major permanent loss of function as a direct result of the injuries sustained
- Hemolytic transfusion reaction involving incompatible blood
- A retained foreign object from surgery

Nonreportable

- Any **near miss**
- Full return of limb or bodily function by discharge or within 2 weeks of the initial loss of function
- Medication errors that do not result in death or the permanent loss of function
- Any sentinel event that has not affected the recipient of care
- A death or injury that follows discharge against medical advice (AMA)
- Unsuccessful suicide attempts
- Unintentionally retained foreign body without permanent loss of function
- Minor hemolysis with no clinical sequelae

Adapted from The Joint Commission: Accreditation Committee examples of voluntary reportable sentinel events, 2019.

Institutional Reporting of Sentinel Events

The Patient Safety and Quality Improvement Act of 2005[a] encourages a culture of safety in the health care system. TJC indicates that mistakes are minimized by designing a systems approach that anticipate and possibly prevent human error.[b] Each procedure has inherent safety risks that are not always apparent. These tend to surface when procedural guidelines are not established or not effective.

The 2005 act references data that show the incidence of reporting to be more accurate when done on a voluntary basis rather than when reporting is mandatory. Health care facilities have requested protection for reporting information because to rework the system the faults need to be known. This is the main way of studying problems and finding solutions for improved performance. Many states have adopted the National Quality Forum's (NQF) list of adverse events as the foundation for mandatory adverse event reporting.[c]

In 2004, Minnesota was the first state to adopt the adverse events list as mandatory to report. In the first year of mandatory reporting, surgical adverse events were the highest reported of all the categories by early 2006. Other states have followed by implementing reporting systems and including additional categories of adverse events that are mandatory to report. For additional information about the NQF adverse event list, go to www.qualityforum.org.

National Patient Safety Goals

Universal Protocol is incorporated into the National Patient Safety Goals (NPSGs) implemented in July 2010 by TJC (Fig. 3.1). The up-dated TJC accreditation statements incorporate NPSGs' language to prevent wrong patient, wrong site, and wrong surgery events as part of Universal Protocol. The complete list of 2019 NPSGs can be viewed at www.jointcommission.org.

Universal Protocol adherence is expected wherever patient care is provided. Examples of accredited facilities accountable for meeting the NPSGs include the following:

- Ambulatory health care facilities
- Critical access hospitals
- Hospital systems
- Office-based surgeries

Patient safety is a serious concern when the patient's protective reflexes and cognition are impaired by preoperative medications and/or anesthetics. The focus of the applicable patient safety goals includes but is not limited to the following points:

- Adequate patient identification
- Accurate marking for surgical procedures
- Eliminating medication errors
- Improving communication between caregivers
- Preventing health care–associated infections
- Preventing injury from falls and pressure points
- Safe and appropriate use of machinery alarms (e.g., electrosurgery, cardiac monitors)
- Identification of patient safety risks

"Never Events" and Reimbursement for Hospitals and Health Care Facilities

The Centers for Medicare & Medicaid Services (CMS) took action in 2009 to improve patient care and decrease errors and injury by denying payment for medical errors that result in serious harm or death for patients. The CMS no longer reimburses for care rendered to patients to remedy the consequences of errors. The CMS generated a list of nonreimbursable conditions, or a "No Pay List," for the following injuries acquired during care:

- Air embolism
- Blood incompatibility
- Catheter-associated urinary tract infection
- Poor control of blood sugar
- Deep vein thrombosis or pulmonary emboli after total knee or total hip surgery
- Falls or trauma while in care
- Removal of a retained object from surgery
- Pressure injury
- Surgical site infection after certain orthopedic or bariatric surgery
- Surgical site infection after coronary artery bypass surgery
- Catheter-associated vascular (bloodborne) infection

Details concerning statistics and trends in CMS programs and rulings can be found at www.cms.gov.

SpeakUP™

The Universal Protocol

for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery™

Guidance for health care professionals

Conduct a pre-procedure verification process

Address missing information or discrepancies before starting the procedure.

- Verify the correct procedure, for the correct patient, at the correct site.
- When possible, involve the patient in the verification process.
- Identify the items that must be available for the procedure.
- Use a standardized list to verify the availability of items for the procedure. (It is not necessary to document that the list was used for each patient.) At a minimum, these items include:
  - ☐ relevant documentation
    Examples: history and physical, signed consent form, preanesthesia assessment
  - ☐ labeled diagnostic and radiology test results that are properly displayed
    Examples: radiology images and scans, pathology reports, biopsy reports
  - ☐ any required blood products, implants, devices, special equipment
- Match the items that are to be available in the procedure area to the patient.

Mark the procedure site

At a minimum, mark the site when there is more than one possible location for the procedure and when performing the procedure in a different location could harm the patient.

- The site does not need to be marked for bilateral structures.
  Examples: tonsils, ovaries
- For spinal procedures: Mark the general spinal region on the skin. Special intraoperative imaging techniques may be used to locate and mark the exact vertebral level.
- Mark the site before the procedure is performed.
- If possible, involve the patient in the site marking process.
- The site is marked by a licensed independent practitioner who is ultimately accountable for the procedure and will be present when the procedure is performed.*
- Ultimately, the licensed independent practitioner is accountable for the procedure – even when delegating site marking.
  * In limited circumstances, site marking may be delegated to some medical residents, physician assistants (P.A.), or advanced practice registered nurses (A.P.R.N.).
- The mark is unambiguous and is used consistently throughout the organization.
- The mark is made at or near the procedure site.
- The mark is sufficiently permanent to be visible after skin preparation and draping.
- Adhesive markers are not the sole means of marking the site.
- For patients who refuse site marking or when it is technically or anatomically impossible or impractical to mark the site (see examples below): Use your organization's written, alternative process to ensure that the correct site is operated on. Examples of situations that involve alternative processes:
  - ☐ mucosal surfaces or perineum
  - ☐ minimal access procedures treating a lateralized internal organ, whether percutaneous or through a natural orifice
  - ☐ interventional procedure cases for which the catheter or instrument insertion site is not predetermined
    Examples: cardiac catheterization, pacemaker insertion
  - ☐ teeth
  - ☐ premature infants, for whom the mark may cause a permanent tattoo

Perform a time-out

The procedure is not started until all questions or concerns are resolved.

- Conduct a time-out immediately before starting the invasive procedure or making the incision.
- A designated member of the team starts the time-out.
- The time-out is standardized.
- The time-out involves the immediate members of the procedure team: the individual performing the procedure, anesthesia providers, circulating nurse, operating room technician, and other active participants who will be participating in the procedure from the beginning.
- All relevant members of the procedure team actively communicate during the time-out.
- During the time-out, the team members agree, at a minimum, on the following:
  - ☐ correct patient identity
  - ☐ correct site
  - ☐ procedure to be done
- When the same patient has two or more procedures: If the person performing the procedure changes, another time-out needs to be performed before starting each procedure.
- Document the completion of the time-out. The organization determines the amount and type of documentation.

The Joint Commission

This document has been adapted from the full Universal Protocol. For specific requirements of the Universal Protocol, see The Joint Commission standards.

• **Fig. 3.1** The Joint Commission poster for the Universal Protocol. (From The Joint Commission: Speak up initiatives, available at www.jointcommission.org.)

Consent

General Consent

Most facilities require the patient or his or her legal guardian to sign a general consent form on admission. This form authorizes the attending physician and the staff to render standard day-to-day treatment or to perform generalized treatments and care as the physician deems advisable. This general consent is relied on only for activities performed in routine care. Physicians and nurses should be knowledgeable about the statements on the form used in their facility.

Each facility should have policies and procedures in place about the authorization of general consent. Many facilities require the patient or appropriate guardian to sign the general consent document in the admission department before admission to the facility. This is facilitated by the admissions clerk, who is a nonmedical person. This in no way equals informed consent. Box 3.2 compares content examples of general consent to treat versus informed consent.

Informed Consent

State statutes differ in their interpretation of the doctrine of informed consent, but all recognize the physician's duty to inform the patient of the risks, benefits, and alternatives of a procedure and to obtain consent before treatment. Failure to do so may be considered a breach of duty. *Informed consent is a process—not a paper document that is signed.* Explanations of the procedure, risks, benefits, and alternative therapy are made verbally to the patient's level of understanding.[2] Some facilities have a special form that is used during this process. A surgeon or anesthesia provider may be held liable for negligence if the patient can prove failure to disclose significant information that would have influenced a reasonable person's decision to consent. Informed consent is a protective act for the patient and the treating physician and should be documented appropriately. The circulating nurse, as patient advocate, should ensure that an accurate and complete informed consent process has taken place before permitting the patient to be transferred to the OR.[2]

The anesthesia provider also has a responsibility to inform the patient of any potential for unfavorable reactions to any medication or anesthetic agent that may be given during the surgical procedure. The risks of anesthesia should be explained without causing the patient undue stress. If the surgeon intends or wants to perform a procedure not specified on the consent form, the circulating nurse has the responsibility to inform the surgeon and/or proper administrative authority of the discrepancy.

The surgeon may be approved by the U.S. Food and Drug Administration (FDA) as a clinical investigator or by the Department of Health and Human Services (HHS) as a researcher for the controlled experimental use of new drugs, chemical agents, or medical devices. Written consent based on an informed decision to participate in the research should be obtained from the patient before any investigational item, drug, or procedure begins. The surgeon completes an investigator's report that is returned to the supplier of the drug or device and eventually filed with the FDA (www.fda.gov). The patient is free to refuse or withdraw at any time from research performed under the auspices of the HHS. All parties involved with the procedure are bound by HIPAA and the confidentiality implied therein. More information can be found on the HHS website (www.hhs.gov).

Informed Consent for a Surgical Procedure

According to the American College of Surgeons, a reasonable approach to informed consent should involve answering the following patient questions:

- What do you plan to do to me?
- Why do you want to do this procedure?
- Are there any alternatives to this plan?
- What things should I worry about?
- What are the greatest risks or the worst thing that could happen?

The patient has the right to waive an explanation of the nature and consequences of the procedure and has the right to refuse treatment. When a patient signs a consent agreement, consent is given only for the specific procedure indicated on the form. Additional procedures should be listed and signed separately—not added after the patient has already signed the form. Contents documented about informed consent should include but are not limited to the following:

- Who will be performing the procedure, including any residents, interns, or first assistants
- Each surgical procedure to be performed, including secondary procedures
- Any procedure for which an anesthetic is administered
- Procedures involving entrance into the body via an incision, puncture, or natural orifice
- Any hazardous therapy, such as irradiation or chemotherapy
- Other persons attending the performance of the procedure, such as students, sales personnel, or other observers
- Video recording or photography and the disposition of the recorded/photographed images

Responsibility for Informed Consent before a Surgical Procedure

The surgeon is responsible for obtaining informed consent from the patient, which should include the risks, benefits, and possible

• BOX 3.2 Examples and Comparison of Consent Form Contents

General Consent to Treat

Admission to facility
Time and date admitted
Admissions clerk name
Mode of admission
Treating/admitting physician
Person responsible for payment
Contact persons for emergency
Basic care assumptions (such as dietary orders, activity orders, testing, examination by physician)

Informed Consent

Name of patient and legal guardian as appropriate
Name of facility
Specific procedures and who explained them
Specific practitioners and their roles
Risks of the procedure
Alternatives to treatment
Signatures: patient or legal guardian, surgeon(s), and the witness to the signatures
Date and time the process took place

Data from Centers for Medicare & Medicaid Services, 2018, available at www.cms.gov.

complications of all proposed surgical procedures. The explanation should include a discussion of the removal and disposition of body parts, the potential for disfigurement or disability, and what the patient may expect in the postoperative period. The preoperative discussion also should include advice to the patient regarding medications, diet, bathing, smoking, and other factors that might affect outcome and rehabilitation.

The surgeon has the ultimate responsibility for obtaining informed consent for the procedure and should document this activity in the patient's permanent record according to facility policy and procedure. The patient or appropriate guardian may be required to sign this record in the presence of a witness. All consent documents become a permanent part of the patient's medical record and accompany him or her throughout the perioperative environment. When checking the patient's identity and chart on arrival in the OR, it is the duty of the circulating nurse and the anesthesia provider to be certain of the following:

- The appropriate consents are on the chart and are properly completed, dated, and signed.
- The information on the form is correct concerning the patient, procedure, and personnel performing the procedure.

Validation of Consent

The patient should personally sign the consent unless he or she is a minor, is unconscious or mentally incompetent, or is in a life-threatening situation. The next of kin, legal guardian, or other authorized person should sign for these patients. The physician gives explanations to the parent of a minor or to the legal guardian of an incompetent adult.

A consent document should contain the patient's name in full, the surgeon's name, the specific procedure to be performed, the signatures of the patient and authorized witness(es), and the date of signatures. A signed consent is regarded as legally valid for as long as the patient still consents to the same procedure. Institutional policy may vary.

The patient giving consent for treatment should be of legal age and mentally competent. Except in life-threatening emergency situations, the patient should sign the consent form before premedication is given and before going to the OR or other procedural/interventional area. This may be done in the surgeon's office, in the facility's admitting office, or on the patient care unit; it is done freely without coercion. If the patient is the following:

- A minor, a parent or legal guardian should sign.
- An emancipated minor, married, or independently earning a living, he or she may sign.
- A minor who is the parent of an infant or child who is having a procedure, he or she may sign for his or her own child.
- Illiterate, he or she may sign with an X, after which the witness writes, "Patient's mark." Because illiteracy implies the inability to read and write, the patient should indicate an understanding of a verbal explanation.
- Unconscious, a responsible relative or guardian should sign.
- Mentally incompetent, the legal guardian—who may be either an individual or an agency—should sign. A court order may be necessary to legalize the procedure in the absence of the legal guardian.
- An adult or an emancipated minor who is mentally incapacitated by alcohol or other chemical substance, the spouse or responsible relative of legal age may sign when the urgency of the procedure does not allow time for the patient to regain mental competence.

Consent documents vary. Policies related to informed consent are developed by the medical staff and governing body in accordance with legal requirements. All personnel involved in the care of patients should be familiar with these policies.

Witnessing a Consent

A witness verifies that the consent was signed without coercion after the surgeon explained the details of the procedure. The patient's or guardian's signature should be witnessed by one or more authorized people. The witnesses may be physicians, nurses, other facility employees, or family members as established by policy. Checking or witnessing the signature of the patient or other authorized person does not constitute validation of informed consent. The witness assumes no liability or responsibility for the patient's understanding. The witness signing a consent document attests only to the following:

- Identification of the patient or legal substitute
- Voluntary signature, without coercion
- Mental state of signatory (i.e., not coerced, sedated, or confused) at the time of signing

Consent in Emergency Situations

In a life-threatening emergency, the consent to treat and stabilize is not essential. Although every effort should be made to obtain consent, the patient's physical condition takes precedence over a procedure permit. The patient's state of consciousness may prevent him or her from verbalizing or signing a permit for treatment. Permission for a lifesaving procedure, especially for a minor, may be accepted from a legal guardian or responsible relative by telephone, fax, or other written communication. If it is obtained by telephone, two nurses should monitor the call and sign the form, which is signed later by the parent or legal guardian on arrival at the facility.

Right to Refuse a Surgical Procedure

The patient should reconcile the advantages and disadvantages of the surgical intervention. Each patient is entitled to receive sufficient information from which to intelligently base a decision regarding whether to proceed. The patient has the right to decide what will or will not be done to him or her. Only after making this decision is the patient asked to sign a written consent for a surgical procedure.

The patient has a right to withdraw written consent at any time before the surgical procedure. The surgeon is notified, and the patient is not taken into the OR. The circulating nurse documents the situation in the patient's record. The surgeon should explain the medical consequences of refusing the surgical procedure. If therapeutically valid, alternative methods of medical management should be offered. The surgical procedure is postponed until the patient makes a final decision. The procedure may be canceled.

The surgeon should document the patient's refusal for surgical treatment. For legal protection, the surgeon should also obtain from the patient, parent, or legal guardian a written refusal for the procedure or other treatment. The physician is required to inform the patient of the consequences of refusing diagnostic tests or therapeutic procedures.

Second Opinion

If the surgeon or patient has doubts about the necessity of a procedure, another opinion should be sought from a qualified specialist in the appropriate field of surgery. Consultation is a

common and desirable part of good surgical practice. A second opinion may be required by third-party payers (i.e., insurance carriers) or managed care services. This is particularly indicated if the surgical procedure involves extended disability. Policy may require special consultation or consent for procedures resulting in reproductive sterilization or a pregnancy termination.

Advance Directives

The Patient Self-Determination Act enacted by the U.S. Congress in December 1991 ensures the patient the opportunity to participate in decision making before a procedure.[d] The law requires that patients be informed of their rights to make their own decisions regarding their health care. This act applies to hospitals, nursing homes, home health care agencies, hospice programs, and health maintenance organizations. It does not apply to freestanding ambulatory or office settings. In 2016 CMS issued a final rule allowing advanced care planning conversations and counseling to be reimbursed under the physician fee schedule.

Each patient has the right to determine the care received and participate in the selection of delivery methods. The caregiver has the obligation to respect the patient's wishes regarding that care. This right extends to the issue of refusing treatment. Policies should be in place to provide for making patients aware of their right of self-determination.

The term **advance directive** encompasses durable power of attorney and living wills. The living will concept allows the patient to refuse treatment or nonessential measures to prolong life in a hopeless situation. A *durable power of attorney* document designates the person authorized to make decisions in the event that the patient is incapacitated. It allows the wishes of patients concerning their care needs to be met if they become impaired and cannot make decisions. The durable power of attorney does not apply to pediatric patients or to incompetent adults who are already under legal guardianship. These patients already have decision makers available to decide treatment options.

On admission to the facility, the patient is asked whether he or she has an advance directive or durable power of attorney. A federal regulation requires that the institution be aware of whether such a document exists and enact it in the event of impaired cognitive function of the patient. The perioperative team should be made aware of its existence. A copy, not the original, is placed in the patient's record. Advance directives may also indicate the patient's preferences concerning organ donation. The family is still asked for consent before any procurement occurs after the patient's death. In some states, the family has the right to refuse procurement regardless of the patient's last wishes.

Documentation of Perioperative Patient Care

Verbal communication between patients and health care providers does not constitute legal documentation of care. Entries in the record by nurses and physicians provide a history of the patient's clinical course and responses to treatment. The record serves to identify what was done. The broad assumption is that if something is not documented, it was not done. The record serves as a means of communication among providers for continuity of care. Policies and procedures should be in place for documentation. Each patient care facility is responsible for the following:

- Establishing, evaluating, and enforcing policies and procedures for patient care documentation
- Interpreting and outlining standards for care documentation in accordance with accreditation guidelines
- Protecting the privacy of patients by preventing unauthorized access and use of documented patient care data and reports
- Creating forms and charting formats for personnel to use in hard copy documentation
- Selecting protocol for computerized archives of patient care records and reports
- Providing a timely mechanism for retrieval of archived patient care records and reports for reference in a timely manner for routine or emergency care

All interactions with patients should be documented in the patient's medical record in the appropriate format. Regardless of the format or the media used for the patient's record, all entries should be:

- Documented on the appropriate form (e.g., code sheet, perioperative record, medication sheet, progress note).
- Written legibly in ink without erasures. The charting procedure may be specific (e.g., all entries are to be made in black ink if paper charting is used).
- Stated factually. Documentation of objective data and services rendered should be very specific. Observations and actions should be stated definitively, objectively, and concisely. Record what is seen, heard, felt, or smelled (i.e., the facts without judgment or opinion). Write quotes of the patient's subjective expression.
- Stated in understandable terminology. Abbreviations may be permissible only for very commonly accepted medical terms (e.g., T&A, D&C, TUR). Most institutions provide a standard list of their accepted medical abbreviations for charting purposes.
- Dated (month, day, year), including the time (AM/PM) the note is written and the time action was performed as appropriate for significant events or changes in the patient's condition. Late entries are documented as per facility policy. Computerized entries are date stamped.
- Signed with the full legal signature, title, and status of the writer, either in permanent ink or electronically.
- Corrected if an error is made. The date, time, and initials of the person making a correction should be noted next to the correction. A single line should be drawn through incorrect information on a paper document without obliterating it (the mistake should not be scribbled out or erased), and the correct information should then be entered. Correction fluid is not acceptable. If an entire page must be recopied, the original is attached to the new copy and not destroyed.

Additional documentation in the patient's record should include the following:

- Execution of the physician's orders and the patient's responses
- Any teaching of the patient or family, including how he, she, or they indicated understanding
- Any unusual event, such as a fall, spontaneous change in condition, or injury
- All visitors, especially physicians
- Any notification of physicians or supervisors

[d]Patient Self-Determination Act, Public Law 101-508, *Fed Reg* 57, March 6, 1992.

The perioperative nurse should be alert to signs that a patient does not clearly understand what is going to happen as a result of surgical intervention. This should be documented and brought to the attention of the surgeon. Significant observations should be recorded in the chart. For example, if a patient verbally withdraws consent for a surgical procedure or expresses a fear of death in the OR, the perioperative nurse is responsible for communicating this information to the surgeon and anesthesia provider and for recording the patient's statement.

Benefits of Documentation to the Facility

There are many reasons for accurate documentation other than those for legal application. Some facilities use the data for strategic planning and growth of the organization. Benefits of accurate documentation to the facility include but are not limited to the following:

- Legal permanent record
- Billing and reimbursement
- Performance improvement
- Measurement of clinical pathways
- Budget and financial planning
- Staffing ratios
- Research protocol
- Utilization review
- Risk management
- Patient acuity and census

Standards and Methods for Documentation of Patient Care

The standards for patient care documentation are established by the American Nurses Association (ANA) and TJC. The standard of care requires that patient care documentation reflect the application of the nursing process (assessment, nursing diagnosis, outcome identification, planning, intervention, and evaluation) during the entire length of stay, according to the ANA and TJC. The use of the perioperative nursing data set (PNDS) is the method of choice for perioperative patient care documentation. The PNDS provides a standardized universal language for patient care documentation and is used by many surgical computer information system manufacturers.

Charting Modalities

Many ways of recording patient care information have been used over the years. Changes in technology have created more methods of recording patient care. Examples of documentation methods include the following

- *Narrative charting.* Expository writing about significant events using third-person commentary, quotes, and standard abbreviations. Entries are sequential, timed, dated, and signed.
- *Block charting.* Short commentary on activity that resembles narrative charting covering a longer period of several hours or days. Entries are sequential, timed, dated, and signed. Some facilities use a checklist format.
- *Focus charting.* Specific documentation directed at a designated aspect of the patient's needs, status, or health considerations.
- *Subjective-objective charting (subjective-objective assessment plan [SOAP]).* Multidisciplinary approach to documenting care according to cues given by a patient with a specific set of signs and symptoms. This approach uses direct quotes and assessment data.
- *Problem-oriented charting (problem-oriented medical record [POMR]).* Approach using a problem list as the working element from which care is planned. Working from the list, patient priorities are investigated, diagnosed, treated, minimized, solved, or remain ongoing. As problems are solved, they are stricken from the list.
- *Computer-generated charting.* Use of standardized care plans formulated in the computer and modified for the individual patient. The computer time and date stamps the plan as it is printed for the hard copy record. This form of charting requires the caregiver's signature.
- *Computer information systems, check-off forms, and flow sheets.* Commonly used as shortcuts for record keeping. Unfortunately, it is easy to rely on the standardized data on these preprinted records and inadvertently omit potentially important individualized information. Most computerized patient records have secondary documentation fields to complete for individualized data capture.

Computerized Documentation

Many facilities have been using computers for patient admitting, billing, scheduling, and human resource information for several decades. Within the past decade, patient data have been recorded and stored electronically at the patient care unit level. Referred to as *electronic health records* (EHRs) or *electronic medical records* (EMRs), the documentation is transmitted electronically to multiple sites, including the OR, surgeon's offices, patient care areas, and other health care facilities around the world. Only select personnel are permitted to access this information and must log on using employee identification and passwords to enter the computer system.[3] Documenting under another individual's name and password is against facility policy. Passwords are changed at routine intervals. Retrievable data recorded and accumulated in these electronic files include patient care information, laboratory results, surgical reports, admission and discharge summaries, and many highly sensitive details about a patient's financial status. Many larger multihospital systems, such as the Cleveland Clinic, have used the Internet to permit multiple record access points for office-based physicians, surgeons, and the patient. All authorized users have access to reports and health data as soon as they are entered into the system.

Nurses charged with the responsibility of accessing and contributing to computerized patient data should be aware that security and confidentiality must be protected. Failing to maintain the secrecy of passwords and failing to log off after use are common problems identified with unauthorized access. Some systems have a built-in log-off feature if the workstation is left idle for a prolonged period. If this happens, the user has to reenter the system by logging back on.

Perioperative Documentation

Specific care given in the perioperative environment should be documented on the patient's chart. Most facilities use a preprinted form with a standardized plan of care. Space is provided to add individualized patient needs and to document additional interventions. Data included in the record come from several patient care areas.

PROS/CONS

Computerized Documentation

Pros

- Terminology is standardized.
- Abbreviations are standardized.
- Useful for accumulation of data from many sources.
- Data retrieval is easier and efficient.
- Information is legible and in standard terminology.
- Uses standardized formats, flowcharts, and graphs.
- All entries and printing are time and date stamped.
- Can minimize errors if orders are entered online instead of handwritten.
- Data can be transferred electronically between physician's office and care facility.
- Record updating is more timely and ongoing.
- Can save time, space, and resources.
- Easier to retrieve archived charts from previous admissions.
- Health care organizations with multiple remote sites can transfer patient data online.

Cons

- Can be confusing for inexperienced users.
- Failure to log off can leave the system available to unauthorized use.
- Can be out of service for undetermined periods.
- Needs periodic maintenance and software updates.
- Backups of files are needed in case of failure.
- Paper records must be kept when the system is down.
- Impersonal interaction between patient and caregivers.
- Preoutlined care plans are less individualized.
- Hardware and software can be costly to install.
- Potential for breach of security if files are transferred online.
- Charting can be easily recorded under the wrong patient.
- Detailed information may be left out because the user only clicks on items from a checklist that applies to the patient.

A comprehensive checklist is included with the chart to assist the circulating nurse to determine whether all of the data initiating Universal Protocol are included on the chart (see Fig. 3.1). Expected outcomes should be specified (e.g., the patient is free from injury). The circulating nurse should document specific activities performed to achieve the expected outcomes. The permanent perioperative record should include but not be limited to the following:

- Preoperative history and physical (H&P) examination, laboratory reports, consent form(s), and other documents in the chart per policy. Any area on the patient's body with redness or injury before hands-on care begins must be documented as "present on admission."
- Patient identification and verification of the surgical site, intended surgical procedure, allergies, and nothing-by-mouth (NPO) status.
- Significant intraoperative times, such as arrival in and departure from the OR, anesthesia start and finish, and incision and closure.
- Patient's condition on transfer to and from the OR, as well as the method of transport to and from the OR, and by whom. Any change in the patient's skin integrity, such as redness or injury should be documented as "not present on admission."
- Level of consciousness or anxiety manifested by objective observation.
- Patient position, and types of restraints and supports used for maintaining the patient's position on the OR bed and for protecting pressure areas, and by whom.
- Personal property disposition, such as religious articles, hearing aid, spectacles, and dentures.
- Skin condition and antimicrobials used for skin preparation, and by whom.
- Intravenous (IV) site, time started, type of needle or cannula, solutions administered IV (including blood products), and by whom.
- Medication types and amounts (including local anesthetic agents), irrigating solutions used and amounts, and given by whom.
- Tourniquet cuff location, pressure, inflation duration, identification of unit, and applied by whom.
- Estimated blood loss and urinary output, as appropriate.
- Sponge, sharps, and instrument counts as correct or incorrect. If inconclusive, state steps taken in remedy of the situation and notification steps taken.
- Surgical procedure performed, location of the incision.
- Specific equipment used (e.g., laser), electrosurgical unit, dispersive and monitoring electrode(s), and prosthetic devices implanted, if applicable, including the manufacturer and lot/serial number.
- Specimens and cultures sent to the laboratory.
- Site and types of drains, catheters, and packing as applicable.
- Wound classification is documented at the end of the procedure when all risks for infection have been identified.
- Type of dressing applied.
- Any unusual event or complication, and action performed.
- All personnel in the room and their roles, including physicians, visitors, sales personnel, students, and others as applicable.

PROS/CONS

Patient Hand-over

Pros

- A hand-over is defined as a linear transmission of information and responsibility from one qualified caregiver to another.
- TJC recommends a standardized hand-over in their National Patient Safety Goals. It is called the Targeted Solutions Tool for Hand-off Communications.
- AORN also has recommendations for transferring patient care information.
- Standardized protocols are recommended because the hand-over of patients to another health care provider is reported as a high-risk time associated with sentinel events.
- Every facility should establish a format for standardized hand-off/hand-over protocols and policies. Standardized protocols provide critical patient information necessary for safe patient transfer and reduction in communication breakdown.
- Many standardized communication and documentation models exist. Examples of standardized documentation formats include the following:
  1. SBAR (Situation, Background, Assessment, and Recommendation).
  2. I PASS THE BATON (Introduction, Patient, Assessment, Situation, Safety)
  3. Concerns, Background, Actions, Timing, Ownership, Next

4. SHARED (Situation, History, Assessment, Request, Evaluate, and Document)
5. SURPASS (SURgical Patient Safety System)

- Hand-over reporting improved when health care facilities established a format of standardized tools, checklists, and protocols. These protocols can be written, verbal, and or electronic methods of accurate documentation and communication.
- Hand-over communication improved when personnel were educated about the standardized protocols and policies. Positive education methods include role playing, competency training, case studies, anticipated patient needs, and simulation.
- Professional attributes that improve receiving hand-over reports include completing all necessary physiologic tasks before report begins (attaching monitors, securing the patient), reducing noise and distractions, improving listening skills, using standard vocabulary, asking questions, taking notes, and reading back information to verify. The person taking report signs the document and records the names of the personnel giving the report.

Cons

- Communication breakdown has been documented as the root cause of many sentinel events.
- Problems and errors related to poor hand-over include room noise, rushing, errors on record, distractions, multitasking, change of staff, lack of information, personnel physiologic problems, relationship barriers, lack of experience, and number of personnel involved in the hand-over process.
- More research is needed to identify an error-free transfer of information to improve patient outcomes. The current standardization protocols still have breakdowns in communication putting patients at risk for injury.

Incident Report

When an accident or unusual incident occurs involving a patient, employee, or property in the facility, the factual details should be reported to the nurse manager and documented according to institutional policy. Details should be objective, complete, and accurate. They should be written as statements of facts without interpretation or opinion. For example, it should be stated that the area of the patient's skin under the inactive dispersive electrode of the electrosurgical unit was mottled and red when the electrode was removed, rather than that the patient's skin appeared burned by the dispersive electrode. The details of equipment used, including the serial number or asset tag identification of the generator and the lot number of the electrode, should be included.

The action performed as a result of any adverse event should be described in detail. Any equipment in question should be removed from service and tagged as "out of order" for repair by the biomedical personnel of the facility. Any suspect device should be inspected and reapproved for use according to institutional policy before it is returned to service. All devices and their identifying wrappers suspected of being defective should be secured for inspection by the facility's risk management personnel.

Incident reports are completed per policy and retained by the risk management department. They should be reviewed as part of the overall institution and departmental quality improvement and risk management programs. Incident reports are considered work products and constitute privileged information. They may serve to refresh an individual's memory of events, however, for preparation of defense in a lawsuit. The fact that an incident report was completed should not be documented in the patient's permanent record. Examples of situations that require incident reporting are included in Box 3.3.

• BOX 3.3 Unusual Situations That Require an Incident Report

- Falls or unexpectedly finding a patient, visitor, or other personnel lying on the floor
- Injury to patient, visitor, or other personnel
- Needlesticks
- Any fire or smoke event
- Possible theft or loss of an item
- Malfunctioning equipment
- Intruder or unauthorized personnel
- Medication error
- Medication reaction
- Lost sponge or instrument during a procedure (incorrect and unresolved count)
- Object retained within patient

Legal Aspects of Drugs and Medical Devices

In 1906 the U.S. government enacted the Pure Food and Drug Act, with the U.S. Department of Agriculture as the enforcing agency, to ensure the introduction of safe and sanitary foods and drugs to the public. The Food, Drug, and Cosmetic Act of 1938 extended the regulation to include cosmetics, drugs, and medical devices. The FDA, within the Department of Agriculture, became the enforcing agency with authority to implement a preclearance mechanism requiring drug manufacturers to provide evidence of safety before a new drug could be sold. Sutures were classified as drugs.

The Kefauver-Harris Drug Amendments of 1962 added strength to the new drug clearance procedures. Drug manufacturers must prove to the FDA the effectiveness, as well as the safety, of drugs before making them commercially available. These amendments established a mechanism for clinical investigation to evaluate the efficacy of drugs. Depending on the nature of a drug, clinical studies often require several years before the FDA approves commercial sale of a product.

The Medical Device Amendments of 1976 gave the FDA regulatory control over medical devices. A medical device is defined as any instrument, apparatus, or other similar or related article, including any component, part, or accessory, promoted for a medical purpose that does not rely on chemical action to achieve its intended purpose. Under this definition, sutures were reclassified as devices. All of the wound closure materials discussed in this chapter are classified as devices.

In 1988 the FDA reclassified the regulation of many devices (single use and reuseable), including surgical attire, masks, gloves, and drapes. Medical devices are classified and receive FDA

approval before they are marketed. The medical devices are categorized into one of three classifications:

- Class I devices are subject to general regulatory controls that ensure they are as safe and effective as similar devices already being sold.
- Class II devices must establish safety and effectiveness performance standards for a new type of product.
- Class III devices are usually life-sustaining or life-supporting implants or external devices. The manufacturer must file for premarket approval before the device is tested clinically to substantiate effectiveness.

A mandatory device-reporting regulation was put into effect in 1984. This regulation requires manufacturers and importers to report to the FDA any death or serious injury to a patient as a result of the malfunction of a medical device. Through the Safe Medical Devices Act of 1990, health care facilities are required to report directly to the FDA and to the manufacturer the probability that a device caused or contributed to a patient's death, serious injury, or serious illness. Additional requirements for tracking certain permanently implantable devices became effective in 1993. Manufacturers are responsible for tracking devices from the manufacturing facility through the chain of distribution (purchasers) to the end users (patients). Health care facilities that implant and explant (remove) these devices must submit reports to manufacturers promptly after devices are received, implanted, and/or explanted. The manufacturer must be able to provide to the FDA the following specific information:

1. Device
   a. Lot, batch, model, and serial numbers or other identification used by the manufacturer
   b. Date(s) of receipt or acquisition within the chain of distribution
   c. Name(s) of person(s) or supplier from whom the device was received
2. Patient
   a. Date of implantation
   b. Name, address, and telephone number of the recipient patient
   c. Social Security number, if the patient's permission is obtained to release his or her Social Security number to the manufacturer
3. Physician(s) who prescribed, implanted, and/or explanted the device
4. End-of-life information about the device, as applicable
   a. Date of explantation
   b. Date of patient's death
   c. Date the device was returned to the distributor or manufacturer
   d. Date the device was permanently retired from use or disposed of

The FDA monitors the voluntary MedWatch program to encourage physicians, nurses, pharmacists, and other health care professionals to report adverse events and defects or problems with regulated drugs and devices. The purpose of MedWatch is to provide a nationwide standardized system for reporting to the FDA any medical device or drug suspected of causing a patient's death, life-threatening injury or illness, disability, prolonged hospitalization, congenital anomaly, and/or experience that required intervention to prevent permanent health impairment. Adverse events can be reported online at www.fda.gov/Safety/MedWatch/. Examples of reportable problems include latex sensitivity, malfunction of drug infusion pumps, and failure of an alarm during malfunction of a ventilator.

Surgeons who implant or use medical devices, and nurses, surgical technologists, and others who handle them, must be adequately instructed in the proper care and handling of all devices to ensure patient safety. Most adverse events occur when devices are misused, are defective, or malfunction. However, an adverse patient reaction can occur when the device functions properly and is used appropriately. The FDA is responsible for investigating a report of an adverse event or product problem and for taking corrective action.

Ethical Issues

Professions have codes of conduct and documents that include value statements derived from moral concepts. The Code of Ethics of the Association of Surgical Technologists (AST) provides guidance for surgical technologists. Nurses may refer to the International Code of Nursing Ethics and to a code established by their own professional association, such as the ANA Code for Nurses or the Code of Ethics for Nursing of the Canadian Nurses Association. In the statement of the nature and scope of nursing practice titled Nursing, a Social Policy Statement, developed by the ANA Congress of Practice in 1980, nurses committed to respect for human beings "unaltered by social, educational, economic, cultural, racial, religious or other specific attributes of human beings receiving care, including nature and duration of disease and illness." The ethics of a profession establish the role and scope of professional behavior and the nature of relationships with patients and colleagues.

Universal moral principles guide ethical decision making and activities in clinical practice (Box 3.4). These include the following:

- Values are operational beliefs an individual chooses as the basis for behavior. They may change over time. They may create conflicts when value systems are not compatible with the expectations of others. Values reflect ethics. Ethics refers to standards or principles of moral judgment and action. Ethics as a philosophy defines a systematic method of differentiating right from wrong within a specific belief system.
- Professional and societal codes and standards offer guidelines in this determination. Ethics and law are closely related. Legal doctrines often interpret ethical concepts.
- The Bill of Rights of the Constitution of the United States establishes individual rights based on moral principles that respect human worth and dignity. The courts have upheld the right to individual autonomy in making health care decisions, as evidenced by rulings about such issues as abortion, the right to die with dignity, and living wills.

• BOX 3.4 Moral Principles in Decision Making

Autonomy: Self-determination implies freedom of choice and ability to make decisions to determine one's own course of action. Decisions may be made in collaboration with others, based on reasonable and prudent information. Decisions should be acknowledged and respected by others.

Beneficence: Duty to help others seek balance between what is good to do and what might produce harm to another or self.

Nonmaleficence: Duty to do no harm.

Justice: Allocation of human, material, and technologic resources a person has a right to receive or claim (i.e., equality of care).

Veracity: Devotion to truthfulness (i.e., to give accurate information).

Fidelity: Quality of faithfulness, based on trust and honesty, which protects rights of individuals (e.g., dignity, privacy).

Confidentiality: Respect for privileged information received from another person with disclosure only to appropriate others.

Bioethical Situations

An ethical dilemma arises in the work situation when the choice between two or more alternatives creates a conflict between an individual's value system and moral obligation to the patient, to the family or significant others, to the physician, or to the employer and coworkers. Conflicts can be between rights, duties, and responsibilities.

Students and other caregivers should take the time to review the remaining pages in this chapter and make a personal determination about facing some of these situational ethics in practice. Personal moral–ethical conflicts can be avoided by having a predetermined sense of action when faced with situations involving procedures such as abortion, reproductive sterilization, experimentation, organ procurement, and end-of-life decisions. Actions may be governed by religious or philosophic beliefs. Each caregiver should have the opportunity to abstain or participate according to personal choice.

Both legal and ethical considerations can cause conflicts. Legally, a patient has the right to choose among treatment alternatives or the right to refuse treatment. Philosophically, the patient's preference may be different from that of the health care provider. The primary responsibility to the patient is to ensure delivery of safe care. This includes use of appropriate and available technology, but only if this is the patient's choice, with informed consent freely given, or is known to be the patient's wish. Conversely, the patient and the caregiver may be forced to face court-ordered procedures or treatments. This may impose the need to assist in a surgical intervention such as a cesarean section on a woman who has moral or religious objections to this form of treatment but who has been ordered by the court to have the procedure performed for the benefit of the unborn fetus.

This example is extreme, but the courts are constantly working to define the rights of the unborn. In the issue of viability versus possible death, the court usually supports measures necessary to sustain life. The caregiver who participates in a court-ordered procedure is protected by law, provided that the performance of his or her duties meets the standards of care.

Caregivers should decide for themselves the appropriate course of action when dealing with an ethical dilemma. By developing a personal philosophy and by understanding both professional and institutional philosophies, the caregiver may better answer many personal ethical questions such as the following:

- When does life begin?
- When does it end?
- What is my perception of quality of life between conception and death?
- What is my role in health care?
- What is my role as patient advocate?
- What are my moral rights in relation to my personal beliefs and values and those of others?
- Where are the dividing lines between a patient's personal rights to privacy and confidentiality and a legal or ethical duty of disclosure?

A few of the ethical dilemmas facing physicians and perioperative personnel are mentioned for personal consideration. It also should be noted that some of these issues are regulated by state statutes or federal court decisions. All caregivers should be familiar with statutes in the state in which they practice, particularly those regarding participation and the right to refrain on the basis of personal beliefs. The right to refuse to participate may be covered by a law but not at the expense of a patient's safety and welfare. The patient cannot be harmed by acts of commission or omission.

Reproductive Sterilization

Voluntary reproductive sterilization as a contraceptive method may be contrary to the moral, ethical, or religious beliefs of a caregiver. Consent is required to perform reproductive sterilization. Some facilities require consent from a patient's spouse.

Abortion

Legalized abortion allows for induced termination of pregnancy. In the 1973 decision of *Roe v. Wade*, the U.S. Supreme Court ruled that any licensed physician can terminate pregnancy during the first trimester with the woman's consent. During the second trimester, the Court requires a state statute that regulates abortion on the basis of preservation and protection of maternal health. During the third trimester, legal abortion should consider meaningful life for the fetus outside the womb and endangerment to the mother's life and health. By selective abortion, one or more fertilized ova may be aborted so that others may mature properly in a multiple pregnancy, which is perhaps a result of fertility drugs.

In facilities where abortions and other reproductive procedures are performed, employees have the right to refrain from participation because of their moral, ethical, or religious beliefs except in an emergency that threatens the life of the mother. These beliefs should be made known to the employer in writing. Some states have a protective statute for employees and employers regulating good-faith efforts to accommodate employees' beliefs. In other states, laws protect an employee from being forced by an employer to assist in abortions.

Human Experimentation

Procedures still in developmental stages are performed in clinical research–oriented facilities with the patient's informed consent. Human experimentation currently includes cases such as face transplants, uterine transplants, and genetic alteration of fetuses. Those willing to be pioneers in human experimentation have given or will give hope to many patients with poor prognoses. A caregiver should decide if he or she wants to participate in experimental surgery.

Fetal Tissue and Stem Cell Research

Experimentation with human tissues may be of moral concern to some individuals. The acquisition of the tissues may take place in the OR in the form of embryonic tissue, and the implantation may take place in the OR. Fetal tissue lacks lymphocytes that can cause graft-versus-host response. Advantages of fetal tissue include rapid proliferation of cells, quick reversal of the host's condition, and differentiation in response to cues of the host tissue. Studies have shown promise in the treatment of diabetes mellitus, Parkinson's disease, and certain blood disorders and that the fetal tissue used in the treatment of Parkinson's disease continues to proliferate and function for many years after transplant. Tissue from spontaneous abortion and ectopic pregnancy has generally undergone pathologic degradation and is not suitable for this use. The use of fetal tissue and organs is subject to state law.

HIV and Other Infections

The prevalence of human immunodeficiency virus (HIV) infection, with or without acquired immunodeficiency syndrome (AIDS), has created a catastrophic health problem with many inherent emotional issues. Unlike other communicable diseases, HIV infection is an illness with no known cure at this time, although some drug therapies may slow its progression. Its mode of transmission and methods of prevention are known. Therefore

personal biases and prejudices should not discriminate against the infected patient. However, underlying attitudes about homosexuality and IV drug abuse may subconsciously influence the care of such patients. Are HIV-positive patients any different from patients with hemophilia or those who became infected through a contaminated blood transfusion? Should the infant with HIV be treated any differently from an infant with a congenital anomaly? Does the diagnosis make a difference to the health care provider and to the quality of care that the patient receives? Should it?

Knowing that HIV infection is transmitted by blood and body secretions, conscientious application of standard precautions for infection control should provide protection against occupational exposure to HIV, hepatitis, tuberculosis, and other communicable or resistant infections. The ANA Code for Nurses emphasizes that care is given regardless of the nature of health problems.

Other ethical questions concern screening and the reporting of test results versus confidentiality. Do the same considerations apply to team members as to patients? What constitutes valid reasons for restricting or terminating employment on the basis of health status? This question has broader implications than just the issue of being seropositive for HIV. No state mandates by law that a health care worker can refuse to provide care for a patient with HIV infection. Risks versus benefits to self, patients, and team members, plus potential litigation as a result of actions, should be evaluated in making ethical decisions. Confidentiality, privacy, and informed consent are human rights that should be protected, but the right to health care should be protected also.

Both AORN and AST have published statements encouraging health care facilities to provide policies and procedures to ensure the safety of patients and personnel. These organizations believe that providers have a right to know the HIV or other infectious status of patients but that caregivers do not have the right to discriminate against HIV-positive patients. They should follow the Centers for Disease Control and Prevention guidelines in caring for all patients to prevent transmission of infection.

Quality of Life

Surgeons often must make critical decisions before or during surgical interventions regarding the quality of patients' lives after surgical procedures. Palliative procedures may relieve pain.[4] Therapeutic procedures may be disfiguring. Life-support systems may sustain vital functions. Life-sustaining therapy may prolong the dying process. Many questions arise regarding care of terminally ill, severely debilitated or injured, and comatose patients. What will be the outcome in terms of mental or physical competence? When should cardiopulmonary resuscitation be initiated or discontinued? Physicians decide, but all team members are affected by the decisions.

Patients with advance directives have made many of these difficult decisions while in a lucid mental state. This saves the family or legal guardians the anguish of making the decision during times of duress. This helps provide some closure and a small sense of satisfaction that the loved one's wishes were known and followed.

Euthanasia

How is euthanasia defined? Is mercy killing ethical, legal, or justified? Does the patient, family or guardian, physicians, or courts have the right to decide to abandon heroic measures to sustain life? The patient who is aware of the options and whose decision-making capacity is intact has the right of self-determination. OR personnel develop the plan of care guided by an advance directive.

Euthanasia is derived from the Greek words meaning "good or merciful death." Both active euthanasia and passive euthanasia are intentional acts that cause death, but the methods are different. An act of direct intervention that causes death is active euthanasia. Withholding or withdrawing life-prolonging or life-sustaining measures is passive euthanasia. Death is caused by the underlying disease process, trauma, or physiologic dysfunction. This concept differs from physician-assisted suicide. Suicide involves the person causing his or her own demise.

The idea of euthanasia seems to violate traditional principles of medicine to preserve life, but our modern technologies can prolong life without preserving quality. Quality of life can be interpreted as life that has a meaningful value. Most human beings value having cognitive abilities, physical capabilities, or both, and living free of undue pain and suffering. This raises the ethical question of whether physicians should do what they technologically can do.

Right to Die

Courts have determined that patients have a constitutional right to privacy in choosing to die with dignity or a common law right to withhold consent and refuse treatment. A mentally competent adult older than the age of 18 years can execute a living will, an advance directive, directing physicians and other health care providers not to use extraordinary measures to prolong life. Most physicians designate "extraordinary" measures as those that are optional, such as mechanical respiration, hydration, nutrition, medication, or a combination of these and that sustain life. If it is the expressed wish of the patient, the physician writes do-not-resuscitate (DNR) or allow-natural-death (AND) orders.[5]

A living will relieves family members of decision making when the patient becomes terminally ill, incompetent, or comatose. No laws or court precedents deal specifically with the issue of DNR orders in the perioperative environment. Institutional policy should address this matter. Theoretically, a patient can attempt to sue for compensation for expenses under a negligence or battery charge. In general, courts are reluctant to hold health care workers liable for acts performed to maintain life. In *Anderson v. St. Francis,* defibrillation was performed despite a DNR order. The court found that sustaining life was not considered an injury and rejected the compensatory claim.

A patient who has a standing DNR or AND order may require a procedure to decrease pain or palliate uncomfortable symptoms. Before going to the OR, the DNR or AND order should be reaffirmed with the patient, guardian, or person who has durable power of attorney. The status of the DNR or AND order must be clarified before the patient goes to the OR. In an emergency, if there is doubt about the validity of the DNR order or a question concerning reconsideration of the order, the caregiver should participate in resuscitation.[5] If there is any question about the patient changing his or her mind, a second chance may not be an option during an emergency situation. If the patient or legal guardian is specifically clear about upholding the DNR order in the OR, the team has the responsibility to follow the patient's wishes. A caregiver who has a moral objection to upholding a DNR order may request reassignment through the nurse manager of the department.

The issue of discontinuation of life-sustaining measures becomes more difficult in a comatose, mentally incompetent patient who has not executed an advance directive. Family members, in consultation with physicians, may request DNR orders. Caregivers are obligated to follow DNR orders.[5]

Organ Donation and Transplantation

As a result of the Uniform Anatomical Gift Act of 1968, many adults carry cards stating that at death they wish to donate their body organs or parts for transplantation, therapy, medical research, or education. Most states include this information on a driver's license. If this legal authority is not available, some states have a required request law. In the event of legally defined brain death, the caregivers are required by this law to ask the family if they wish to allow organ retrieval for transplantation.

Transplant surgeons rely on the perioperative patient care teams who procure donor organs, eyes, bone, and skin. Organ transplantation has complicated the issue of time of death. Perfusion of oxygenated blood through tissues must be sustained by artificial means during procurement of vital organs with functional viability. Brain death must be clearly established before procurement can proceed.

Legally, death has occurred when an individual has sustained either irreversible cessation of circulation and respiratory functions or irreversible cessation of all functions of the entire brain, including the brainstem. Therefore the accepted definition of irreversible coma for potential donors includes unresponsiveness, no spontaneous movements of respiration, no reflexes, and a flat electroencephalogram.

When brain death is determined by two physicians who are not part of the transplant team, the donor will be taken to the OR with artificial support systems functioning to perfuse organs. Some caregivers have moral questions about assisting with removal of viable organs from seemingly living bodies. When the heart is removed, cardiopulmonary support is discontinued and the anesthesia personnel leave the room. This is a difficult time for the remaining team who may still have the assignment of procuring nonperfused tissues, such as skin, bone, or eyes.

Perioperative caregivers who believe that donation of organs and body parts is a gift of love find it easier and ethically acceptable to participate in procurement procedures. Family members of donors have been encouraged by surgical team members not to focus on their grief, but rather to focus on the gifts of life they are giving unselfishly to the recipients. This does not mean that the donor's family will not go through the grieving process. They will need support. Caregivers learn to cope with feelings associated with the procurement of donor organs in a manner similar to dealing with the sudden death of any patient in the perioperative environment.

Death and Dying

Intellectually, we know that death is inevitable. Death can be a difficult burden for caregivers to bear because our education, experience, and philosophy are dedicated to survival. Regardless of religious or cultural beliefs, death is a mystery, a passage from the known to the unknown. Perhaps partially for this reason, the death of a patient in the OR is an unsettling experience, especially if it is unexpected.

One of the most difficult aspects of a death in the OR for the team members is the period after the actual event. The surgeon goes to inform the family. The assistants and anesthesia provider leave the room. Often the perioperative team is left alone with the patient's body. The patient should be prepared so that the family can view the body in an area adjoining the perioperative environment, where they can have privacy in expressing their feelings. The perioperative nurse may be expected to accompany the family and to lend support during the viewing. A chaplain or other clergy should be called if desired by the family. Specific departmental policies should be developed to assist the caregiver with this difficult aspect of patient care. Coping strategies that can help team members may include the following:

- Realize that everyone involved is part of a team effort.
- Believe in a power greater than the skills of the team.
- Share feelings with others. It is helpful for perioperative patient care team members to talk with each other about what happened. Encourage each other to share feelings associated with the loss. Crying is acceptable behavior.
- Deal with the patient's death by identifying personally with the loss. Empathy is a positive emotion. Working through the grieving process brings a sense of closure to the relationship.
- Some facilities provide support groups to help staff members and bereaved families deal with death.
- Arrange a visit with the hospital chaplain, clergy, or rabbi.

The Perioperative Patient Care Team and Professional Credentialing

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Define the concept of the sterile team.
- Define the concept of the nonsterile team.
- Describe the role of the circulating nurse.
- Describe the role of the scrub person.
- Describe the credentialing process for perioperative nurses.
- Describe the credentialing process for surgical technologists.

KEY TERMS AND DEFINITIONS

Anesthesia provider Member of the nonsterile team who administers anesthetics during the surgical procedure; may be a physician (MD, DO), anesthesia assistant (AA), or a specially trained and certified registered nurse anesthetist (CRNA).

Certification A method of professional evaluation and recognition of an individual for meeting educational, practice, and national standard parameters that extend above minimal competency.

Circulating nurse Perioperative registered nurse (RN) member of the nonsterile team who directs and coordinates the activities of the intraoperative environment during the surgical procedure. Role involves patient assessment, planning, and critical thinking skills.

Credentials Validation of professional recognition, such as licensure or certification.

Delegation A registered nurse or physician can assign and supervise tasks performed by a licensed practical nurse/licensed vocational nurse (LPN/LVN), ST, or other UAP (unlicensed assistive personnel), provided the tasks are not intended for a licensed individual's scope of practice and are within the capabilities of the person being assigned the tasks.

Licensure Governmental regulation of approval to practice in a specific profession to provide specific services. Practicing without a license is illegal and punishable by law. Some license renewals include attainment of continued education in the profession. Licensure is designed to ensure minimal competency of the licensee for the benefit of protecting the safety and welfare of the public. The laws that define the scope of practice governing a registered professional are called practice acts.

Nonsterile team Intraoperative caregivers who provide direct care from the periphery of the sterile field and environment; do not wear sterile attire (i.e., radiology technician, anesthesia technologist).

Perianesthesia nurse Registered nurse (RN) who renders care in the preoperative and postoperative environment. Member of the nonsterile team.

Registration Establishing a record of name, address, and qualifications of a professional with a state authority. This does not establish standards of practice, does not require a certain entry level, and does not provide for continued competency verification or continued education.

Scrub person Member of the sterile team who passes instruments and facilitates the surgical procedure. Is a surgical technologist (ST), registered nurse (RN), or licensed practical or vocational nurse (LPN/LVN).

Sterile team Intraoperative caregivers who provide direct care within the sterile field; wear sterile attire (i.e., surgeon, first assistant, scrub person).

Surgeon Physician (e.g., MD, DO, DDS, DPM) who performs the surgical procedure.

Surgical assistant Member of the sterile team who provides exposure and hemostasis during a surgical procedure. Is a physician, registered nurse first assistant (RNFA), surgical assistant (SA), physician assistant (PA), or certified surgical technologist specially trained and certified as a first assistant (CST/CFA).

Dependence of the Patient on the Qualified Team

The perioperative team works to promote the best interests of the patient at all times. For the welfare and safety of the patient, the entire team must work efficiently as a functioning single unit. The members should be thoroughly familiar with procedures, setups, equipment, and policies and should be able to cope with the unpredictable. Their qualifications must be beyond reproach. They should have a high morale, mutual understanding, trust, cooperation, and consideration. Anyone who cannot function wholeheartedly as a qualified team member has no place in the operating room (OR).

All OR personnel should have the proven knowledge, skill, competency, and ability to perform at an optimal level at all times. The validation of clinical competence is an important aspect of providing safe patient care. Once each member of the team has passed the novice stage, other criteria demonstrate and document the knowledge and skills gained through experience and continuing education. Aligning professionally with local, state, and nationally recognized organizations that establish the standards of practice provides an opportunity for growth. Credentialing and certification may include completing a course of instruction or meeting certain criteria and passing an examination. Other measurements of competence include performance evaluations in a clinical setting.

Credentialing of Qualified Caregivers

Credentialing refers to the processes of accreditation, licensure, and certification of institutions, agencies, and individuals. These processes establish quality, identity, protection, and control for the competency-based education and performance of professional and allied technical health care personnel. Credentialing also protects the public from fraudulent practitioners.

Accreditation of Schools and Facilities

An accrediting body of a voluntary organization evaluates and sanctions an educational program or an institution as meeting predetermined standards and/or essential criteria. The National League for Nursing (NLN) and the Commission for Nursing Education Accreditation (CNEA) accredits schools of nursing. Surgical technology programs are accredited by the Commission on Accreditation of Allied Health Education Programs (CAAHEP) after a satisfactory review and recommendation by the Accreditation Review Council on Education in Surgical Technology and Surgical Assisting (ARC-STSA).

The National Board of Surgical Technology and Surgical Assisting (NBSTSA) offers certification eligibility to individuals graduating from an accredited surgical technology program. The Accrediting Bureau of Health Education Schools (ABHES) accredits many colleges and vocational settings in the United States. Certifying and licensing bodies require graduation from an accredited program before eligibility criteria are met to take professional certification or licensing examinations.

The Joint Commission (TJC) accredits hospitals and ambulatory care centers. Other professional organizations offer accreditation for special-interest groups.

Licensure and Registration

A license to practice is granted to professionals by a governmental agency, such as the state board of nursing or medicine. **Licensure** implies a certain amount of appropriate independence in actions. On completion of a formal academic education, nurses and physicians who successfully pass a state examination receive a license to practice in that state. To maintain this license, they must register with the state as required by law; hence the term *registered nurse*. Licensed practical nurses/licensed vocational nurses (LPN/LVNs) also are licensed.

Most states grant a license by reciprocity or endorsement to applicants who wish to practice in their state but who took the examination in another state. Some states require licensure for some categories of allied health occupations, such as physical therapists.

Licensure is not offered on an indefinite basis. Applicants apply for renewal at specific time intervals determined by each state. Many states require proof of continuing education for nurses and physicians as a prerequisite for eligibility of relicensure.

Registration is a method of state regulation of practice parameters and designation for disciplinary action. Perioperative nurses are *registered* as well as *licensed.*

Certification

A nongovernmental private organization can award a **credential** that attests to level of knowledge above minimal competency of an individual who meets predetermined qualifications. **Certification** may be defined as documented validation of an individual's professional achievement of knowledge and skill in identified standards. To be certified is to demonstrate the attainment of more than minimal competency; it is a statement of certification-level knowledge. Certification is an additional or specialized form of a credential.[1]

Certification is granted for a limited time. To retain this credential, an individual must complete the recertification process established by the certifying body. For recertification, some certifying organizations require a specified number of clinical hours, continuing education contact hours, a written examination, or a combination of these in a portfolio format. Maintaining certification by going through this process demonstrates a high level of motivation and commitment.

Physicians, nurses, and allied health care personnel may be certified by their professional specialty association as competent in knowledge and skills to practice. Applicants take an examination that tests knowledge in the area of specialization.

Perioperative Patient Care Team

The perioperative patient care team is like a symphony orchestra, with each person an integral entity in unison and harmony with professional colleagues to accomplish the expected outcomes. Communication using a comprehensive surgical checklist and briefing can provide a seamless interface between patient care areas and minimize the risk for error (see Fig. 2.1). Preoperatively, the **perianesthesia nurse** initiates the use of the comprehensive surgical checklist and performs the preoperative assessment. The surgeon should mark the surgical site with an indelible ink marker. The patient is transferred to the care of the surgical team, and information concerning the patient's condition is communicated verbally and in writing.

In the OR, the patient is surrounded by the surgeon, the **surgical assistant**, the scrub person, the anesthesia provider, and the circulating nurse. Before the procedure begins, the OR team stops all activities for the "timeout" and reaffirms the correct patient is having the correct surgery on the correct body part. The

patient may participate if awake. The circulating nurse documents this collaboration.

Postoperatively, the perianesthesia nurse receives information from the circulating nurse and the anesthesia provider concerning the surgical procedure and the patient's condition in the form of a hand-over report. The patient remains in the postanesthesia care unit (PACU) until his or her physiologic status is deemed stable by the anesthesia provider.

These individuals, each with specific functions to perform, form the perioperative patient care team. The role of the perianesthesia nurse is described in more detail in Chapter 30. More information about perianesthesia nursing is available at www.aspan.org.

U.S. Medicare and Medicaid regulations Title 42, Public Health, describe conditions for participation of individuals in surgical services departments. In Chapter IV, Part 482, Section 482.51, the regulation states that the OR must be supervised by an experienced registered nurse (RN) and that the circulator must be an RN. It further states that an LPN/LVN and surgical technologists (STs) may serve as scrub persons or assist with circulating duties under the supervision of the qualified RN. A copy of the Center for Medicare & Medicaid Services [CMS] regulation is available at www.aorn.org.

Nonsterile and Sterile Team Members

The perioperative team is subdivided according to the functions of its members:

1. The nonsterile team
   a. Anesthesia provider
   b. Circulating nurse
   c. Perianesthesia nurse
   d. Others (e.g., students, sales representatives, laboratory or radiography personnel)
2. The sterile team
   a. Surgeon
   b. First assistant (second assistant if needed)
   c. Scrub person

The perioperative team also may include biomedical technicians, specialty technicians, and others who may be needed to set up and operate specialized equipment or monitoring devices during the surgical procedure. Specialty technicians are usually considered separately from the main sterile and nonsterile team members. They may not enter the sterile field.

Sterile team members perform a surgical scrub on their hands and arms, don a sterile gown and gloves, and enter the sterile field. The sterile field is the area of the OR that immediately surrounds and is specially prepared for each individual patient. To establish and maintain a sterile field, all items needed for the surgical procedure are sterile and handled in a sterile manner. Only sterile items and personnel dressed in sterile attire may enter the sterile field.

Nonsterile team members do not enter the sterile field; they function outside and around it. They assume responsibility for maintaining sterile and aseptic techniques during the surgical procedure. They handle supplies and equipment that are not considered sterile. Following the principles of aseptic technique, they keep the sterile team supplied, provide direct patient care, and handle situations that may arise during the perioperative care period.

Nonsterile Team Members

Perianesthesia Team

The perianesthesia team consists of RNs and specially trained patient care assistants who care for the patient in the presurgical and postsurgical areas. In some facilities this incorporates an ambulatory or interventional surgery suite.

Preoperatively, the perianesthesia nurse assesses the patient and documents the findings on the comprehensive surgical checklist that will accompany the patient throughout the surgical experience. Some perianesthesia RNs specialize in the care of the patient before the surgical procedure, and others specialize in the care of the patient postoperatively.

Anesthesia Provider

Anesthesia and surgery are two distinct but inseparable disciplines; they are two parts of one medical entity. Adequate communication between the surgeon and the anesthesia provider is the patient's greatest safeguard. The **anesthesia provider** is an indispensable member of the perioperative team. Functioning as a guardian of the patient's physiology throughout the entire care period, the anesthesia provider manages the patient's medication, vital signs, and generalized well-being. Throughout this text the term *anesthesia provider* is used to refer to the person responsible for inducing and maintaining anesthesia at the required levels and managing untoward physiologic reactions throughout the surgical procedure. Functions of medical **delegation** in the area of anesthesia are performed under the overall supervision of a responsible physician or in accordance with state regulations and individual written guidelines approved within the health care facility.

An anesthesiologist is an MD or DO, preferably certified by the American Board of Anesthesiology, who specializes in administering anesthetics to produce various states of anesthesia. To become eligible for certification, physicians complete a 2-year anesthesia residency program after successful completion of medical school. The term *anesthetist* refers to a qualified RN, anesthesiologist assistant (AA), dentist, or physician who administers anesthetics.

An RN is required to have a minimum of a bachelor's degree in nursing or science for entrance into a school of nurse anesthesia. To become a certified registered nurse anesthetist (CRNA), a graduate of an accredited nurse anesthesia program (a minimum of 2 years) is required to have a master's degree in nursing and pass the certification examination of the Council on Certification of Nurse Anesthetists. Nurse anesthetists are recertified every 2 years.

An AA is a master's prepared nonphysician, non-nurse anesthetist who administers anesthesia under the direction of an anesthesiologist. The AA's education consists of a baccalaureate in biologic science and 2 additional years of specialty training in biophysical science. More information on the AA degree is available online at www.anesthetist.org.

Some anesthesia providers prefer to specialize in one area, such as cardiothoracic or obstetric anesthesia. The latter involves the simultaneous care of two patients—the mother and the neonate. In some settings, anesthesia providers participate in teaching and research as well as in clinical practice.

Anesthesia providers are not confined to the perioperative environment, but this is their primary arena. In addition to providing anesthesia during surgical procedures, anesthesia providers oversee the PACU until each patient has regained control of his or her vital reflexes. They also participate in the hospital's program of cardiopulmonary resuscitation as teachers and team members. They are consultants or managers for problems of acute and chronic respiratory insufficiency that require respiratory therapy, as well as for a variety of other fluid, electrolyte, and metabolic disturbances that require intravenous therapy through a central venous catheter. In the intensive care unit (ICU) or emergency

department, their advice may be sought regarding the total care of unconscious, critically ill, or injured patients with acute circulatory disorders or neurologic deficits. Anesthesia providers also are integral staff members of pain therapy clinics.

Circulating Nurse

The **circulating nurse** is a qualified RN. The circulating nurse is vital to the smooth flow of events before, during, and after the surgical procedure. Physical and psychological demands of the circulating nurse's role are described in Box 4.1.

The patient's medical record is required to identify who provided circulating duties. The circulating nurse's role as the patient's advocate and protector is critical and extends throughout the entire perioperative environment. A qualified ST or LPN/LVN may assist with circulating duties under the supervision of the RN.[a] The surgeon is in charge at the operating bed, but relies on the circulating nurse to monitor and coordinate all activities within the room and to manage the care required for each patient. The RN should be continuously knowledgeable about the status of the patient. To some extent, the circulating nurse controls the physical and emotional atmosphere in the room, which allows other team members to concentrate on tasks without distraction.

As of 2014 the laws in 39 states specify that one RN circulates in each room (hospital and ambulatory centers combined). A qualified perioperative nurse should be available at all times to respond to emergencies in the perioperative environment according to the CMS regulations. "Immediately available" has been interpreted to imply that one RN can supervise an unspecified number of contiguous rooms and be immediately available to assist in each of these rooms at any given moment. The RN who is called to a room to manage a crisis is not immediately available to any other patient who may be in need. The circulating nurse would be abandoning one patient to tend to another. This is highly unsafe and places the nurse and the facility at risk for liability.

The circulating nurse is vital to the provision of care that includes, but is not limited to, the following:

1. Applying the nursing process to directing and coordinating all activities related to the care and support of the patient in the OR. Nursing diagnosis and decision-making skills are essential in assessing, planning, implementing, and evaluating the plan of care before, during, and after a surgical intervention. This is the professional perioperative role of the RN circulating nurse.
2. Creating and maintaining a safe and comfortable environment for the patient by implementing the principles of asepsis. The circulating nurse demonstrates a strong sense of surgical conscience. Any break in technique by anyone in the room should be recognized and corrected instantly. Although sterile technique is the responsibility of everyone in the room, the circulating nurse is on the alert to catch any breaks that others may not have seen. By standing farther away from the sterile field than others, the circulating nurse is better able to observe the entire field and the sterile team members.
3. Providing assistance to any member of the OR team in any manner for which the circulating nurse is qualified. This role requires current knowledge of the legal implications of surgical intervention. The circulating nurse knows the organization of the work and the relative importance of the factors involved in accomplishing it. An effective circulating nurse ensures that the sterile team is supplied with every item necessary to perform the surgical procedure efficiently. The circulating nurse must know all supplies, instruments, and equipment; be able to obtain them quickly; and guard against inadvertent hazards in their use and care. He or she must be competent to direct the scrub person.
4. Identifying any potential environmental danger or stressful situation involving the patient, other team members, or both. This role requires constant flexibility to meet the unexpected and to act in an efficient, rational manner at all times.
5. Maintaining the communication link between events and team members in the sterile field and people who are not in the OR but are concerned with the outcome of the surgical procedure. The latter includes the patient's family or significant others plus other personnel in the perioperative environment and in other

• BOX 4.1 Physical and Psychological Attributes of the Circulating Nurse's Role

1. Visual acuity with or without correction is critical to precise observation of the environment, patient, and team and for reading small print. Protective eyewear is required at all times when in proximity to the surgical field or when at risk for a splash/aerosol exposure. Bright lights or dim lights are commonly used throughout the surgical procedure, and people with photosensitivity or susceptibility to light-mediated eye irritation will find the OR environment problematic. Visual accuracy is imperative.
2. Manual dexterity and accuracy of motion are required for fast action during emergencies. Inability to coordinate body motions could cause injury to the patient, team, or self. Physical ability to maneuver around the periphery of the sterile field without causing contamination or disruption of the surgical procedure is critical.
3. Eye-hand coordination is essential for safe and efficient delivery of sterile items to the field. Eye-hand coordination is imperative for the safety and preservation of the sterile field.
4. Ability to concentrate and remain alert during long procedures. Thinking on one's feet is a hallmark of the circulating nurse. Multitasking is essential because the coordination of the room, patient care, team, documentation, and anticipation demands clear thinking.
5. Ability to lift instrument trays of at least 20 lb and assist with moving large equipment or incapacitated patients using proper body mechanics.
6. Auditory acuity in both ears with or without amplification is critical for hearing and understanding commands while machinery is running. Voices are kept low during surgery, especially when the patient is awake. Hearing correctly is imperative.
7. Ability to quickly anticipate and discern commands and needs of the team. Must be able to differentiate and prioritize the needs of the surgical team and the anesthesia provider efficiently and to be able to offer appropriate alternatives in extraordinary circumstances.
8. The ability to speak, understand, and document clearly using the English language is critical to safe patient care. Appropriate terminology and use of approved standard accepted abbreviations are essential to communication in the OR.
9. Communication is essential between the team, anesthesia provider, control desk, family waiting room, laboratories, and perianesthesia care areas. The circulating nurse coordinates pertinent information among all areas concerning the care of the perioperative patient.
10. The ability to remain calm and function quickly, safely, and precisely during an emergency. Must be able to make decisions and problem solve effectively without loss of emotional control.
11. Mental clarity. Use of medications or substances that alter alertness and attentiveness are not acceptable in the OR. Lack of sleep can affect thought processes.
12. Accountability. Takes responsibility for independent actions. Admits error and remedies the situation when breaches in technique or contamination occurs.

[a]42 CFR § 428.51: Federal position on the RN circulator according to the CMS.

departments of the hospital. The ability to recognize and effectively communicate situations involving the patient and/or other team members is a vital link in the continuity of patient care.

6. Directing the activities of all learners. The circulating nurse must have the supervisory capability and teaching skills necessary to ensure maintenance of a safe and therapeutic environment for the patient. Kindly given assistance builds up the learner's confidence. In this capacity the circulating nurse acts as a supervisor, adviser, and teacher.

CNOR: The Certified Perioperative Nurse

A perioperative nurse who has been in clinical perioperative practice for 24 months and who has successfully passed a national examination is certified by the Competency & Credentialing Institute (CCI; www.cc-institute.org) as a certified perioperative nurse, which is credentialed as CNOR. Box 4.2 describes the required eligibility for CNOR certification, and Table 4.1 describes the criteria for recurrent CNOR recertification up to 2025. A transition from the current methods of recertification will be in process over the next 5 years toward a more comprehensive performance-based format. CNORs seeking recertification between the years 2021 and 2025 will be required to recertify using points or re-examination. After 2525, CNOR recertification must be attained by points or re-examination. CE will no longer be used as a recertification measure.

Nurses, who attained CNOR certification after December 31, 2018 as their initial credential do not have the option for use of CE to recertify. They will be required to use the point method or retake the CNOR examination.

The accrediting bodies (National Commission of Certifying Agencies [NCCA] and Accreditation Board for Specialty Nursing Certification [ABSNC]) questioned the validation of contact hours or continuing education (CE) as proof of competency for CNOR recertification. Evidence-based studies by these two certifying bodies demonstrated that minimal competency or entry level knowledge is exhibited by licensure. The studies showed that certification-level knowledge is best exemplified by professional performance in the practice setting. Participation in CE activity is not equivalent to competency or certification-level knowledge. NCCA and ABSNC require a higher standard for nurses certified in a specialty.

Retired CNOR nurses can accept an emeritus status to retain the credential. They are signified by (E) after the main credential of CNOR (e.g., CNOR(E)).

Several nursing specialty organizations, such as the National Association of Orthopaedic Nurses (www.orthonurse.org) and the International Society of Plastic and Aesthetic Nurses (www.ispan.org) offers certification examinations through their certifying bodies as an additional credentialing tool. CNOR certification is valued for its representation of advanced knowledge and upholding high standards of patient care.

Sterile Team Members

Surgeon

The **surgeon** must have the knowledge, skill, and judgment required to successfully perform the intended surgical procedure and any deviations necessitated by unforeseen difficulties. The American College of Surgeons has stated the principles of patient

• BOX 4.2 CNOR Eligibility Criteria

- Licensed RN in state of practice and currently employed full or part time in administrative, teaching, research, or general staff capacity in perioperative nursing.
- Bachelor of science in nursing (BSN) or related degree (BA or BS) is not required for CNOR.
- Two years of perioperative nursing experience (2400 hours).

Roles Eligible for CNOR Certification

- OR staff nurse
- Surgical services administrative nurse manager
- Surgical services nursing coordinator
- Assistant surgical services supervisor
- Surgical services director
- Surgical services information technology specialist
- Surgical services budget and finance manager
- Surgical services central processing manager
- Surgical services materials manager
- Surgical services quality assurance coordinator/auditor
- Surgical services head nurse
- Surgical services assistant head nurse
- Surgical services team leader
- Surgical services charge nurse
- Perioperative educator or staff development director (whether teaching RNs, student nurses, or surgical technologists)
- Private RN scrub nurse
- RN first assistant
- Perioperative administrative supervisor
- Medical-surgical instructor in perioperative nursing
- Perioperative clinical nurse specialist or nurse clinician
- Full-time student who meets applicant status requirements
- Perioperative nurse consultant
- Individual who handles the perioperative role in a noninvasive/invasive procedure setting, such as a radiology suite, a cardiac catheter laboratory, an office surgery setting, or an endoscopy suite
- Clinical education consultant (who provides in-service programs to OR staff)
- Case manager

Roles Ineligible for CNOR Certification

- Nurse anesthetist (eligible only if functioning as a perioperative nurse)
- PACU nurse or manager (eligible only if relieving in the OR as needed or has responsibility for OR/surgical services)
- Emergency department nurse
- OR labor and delivery nurse (eligible only if surgical procedures such as cesarean sections are done in delivery room)
- RN sales representative (eligible only if performing the role of perioperative nurse part time or the role of perioperative educator, i.e., providing in-service programs)
- Director or assistant director of nursing service (eligible only if directly responsible for the OR)
- RN hospital administrator/assistant administrator (eligible only if directly responsible for OR/surgical services)
- Nurse in surgical care or surgical rehabilitation units
- ICU or coronary care unit nurse
- Infection control nurse/nurse epidemiologist (eligible only if directly responsible for OR/surgical services)
- Veterinary OR nurse
- Cardiopulmonary perfusionist (eligible only if performing the role of perioperative nurse)
- Nurse with inactive licensure and/or graduate nurse status

TABLE 4.1 CNOR Recertification

Examination for Recertification	Contact Hour Method[a]	PortfolioPoint System: Totaling 300 Points *(Include Reflection Form and Documentation of Events)*
Previously certified during previous 5-year period	125 approved contact hours in 5 years. One year is January 1 to December 31 of same year. 75 contact hours continuing education; must be specific to perioperative nursing 65.5 contact hours may be earned via continuing medical education (CME) (1 CME = 1 contact hour) 62.5 contact hours Must be part of academic credit toward a baccalaureate degree or higher. Grade of C or better. (1 semester hour = 15 contact hours) (1 quarter hour = 10 contact hours)	Documentation of applied learning to professional activities within the previous 5-year certification period Professional resumé for previous 5 years *Select 4 of the following activities from the previous 5 years:* Educational presentations Academic courses completed or taught Continued education (35 contact hours)[a] Professional writing Standards application Patient-centered care Precepting-mentoring-coaching Risk mitigation/management Evidence-based practice/research Contributions to: • Professional organization • Institution (committees)

A discount applies for AORN members. Consult www.cc-institute.org for more information and recertification applications.
[a]Contact hour recertification method will be eliminated by 2525 for CNORs who initially certified before December 31, 2018. Nurses who attained initial certification after December 31, 2018, must use the point method or retake the examination to recertify.

care that dictate ethical surgical practice. Protection of the patient and quality care are preeminent in these principles. The surgeon's responsibilities include preoperative diagnosis and care, selection and performance of the surgical procedure, and postoperative management of care.

The care of many surgical patients is so complex that considerably more than technical skill is required of a surgeon. The surgeon cannot predict that a surgical procedure will be simple and uncomplicated. The surgeon must be prepared for the unexpected by having knowledge of the fundamentals of the basic sciences and by having the ability to apply this knowledge to the diagnosis and management of the patient before, during, and after surgical intervention. The surgeon assumes full responsibility for all medical acts of judgment and for the management of the surgical patient.

A surgeon is a licensed MD, DO, oral surgeon (doctor of dental surgery [DDS] or doctor of dental medicine [DMD]), or doctor of podiatric medicine (a podiatrist [DPM]) who is specially trained and qualified by knowledge and experience to perform surgical procedures. After earning a bachelor's degree, all physicians complete the equivalent of 4 years of medical school. To become a surgeon, a physician completes at least 2 years of general surgical residency training before completing additional years of postgraduate education in a surgical specialty. The surgical residency provides the physician with education and experience in the preoperative evaluation, intraoperative treatment, and postoperative care of patients. Consultation and supervision are available from faculty and attending surgeons.

By virtue of their postgraduate surgical education, most surgeons practice within a specific surgical specialty. Highly trained and qualified surgeons limit themselves to their specialty, except perhaps in emergency situations.

Qualification for surgical practice involves certification by a surgical specialty board approved by the American Board of Medical Specialists. American specialty boards grant certification for surgical practice. All boards governing the surgical specialties require at least 3 years of approved formal residency training, and most set the minimum at 4 or 5 years. Any physician who aspires to become a board-certified surgeon must meet these requirements. The complete 2019 list of specialty boards can be found at www.abms.org.

Surgical procedures may be performed by physicians who do not meet the previously discussed criteria. These physicians include those who received an MD degree before 1968 and who have had surgical privileges for more than 5 years in a hospital approved by TJC, where most of their surgical practice is conducted; those who render surgical care in an emergency or in an area of limited population where a surgical specialist is not available; and those who by reason of education, training, and experience are eligible for but have not yet obtained certification.

A surgeon must become a member of the medical staff and be granted surgical privileges in each facility in which he or she wishes to practice. Standards for admission to staff membership and the retention of that membership are clearly delineated in the bylaws formulated by the medical staff and are approved by the governing body of the hospital. The credentials committee has the primary responsibility for thoroughly investigating not only the training of an applicant but also his or her integrity, technical competence, and professional judgment. In making its recommendations, this committee can limit a surgeon's privileges as appropriate, which ensures that each surgeon performs only those services for which he or she has been deemed competent.

Patients are entitled to protection and the assurance that a surgeon's surgical privileges are limited to those for which he or she has been trained and competence has been demonstrated. The patient's choice of and confidence in a surgeon, as well as adherence to instructions and advice, are factors in the outcome of surgical intervention. A discerning patient will check the surgeon's qualifications before surgery.

A competent surgeon is a physician who realistically appreciates his or her own cognitive skills and personal characteristics and can intervene effectively in a patient's illness or injury.

Appropriate clinical skills (e.g., data gathering, decision making, problem solving) and appropriate personal characteristics (e.g., humanistic concern, accountability, compassionate interpersonal behavior) are important attributes of a surgeon.

First Assistant

Under the direction of the surgeon, a qualified first assistant helps maintain visibility of the surgical site, controls bleeding, closes wounds, and applies dressings. The first assistant handles and manipulates tissues and uses instruments to provide hemostasis. The role of and need for a first assistant will vary with the type of procedure or surgical specialty, the condition of the patient, and the type of surgical facility. In determining this need, the characteristics of the surgical procedure should be evaluated for anticipated blood loss, anesthesia time for the patient, fatigue factors affecting the OR team, and the potential for complications. This role is critical to the well-being of the patient. All first assistants must be granted privileges to practice by the medical staff department in the facility of employment or practice. Detailed information about the role and duties of the first assistant can be found in Chapter 5.

For many simple procedures, it is unreasonable to insist that a second surgeon assist a competent surgeon. Reimbursement is generally not provided for simple cases. The surgeon should evaluate all factors to determine his or her need for assistance during the surgical procedure and consider that some insurance providers do not reimburse for a physician first assistant. However, the assistance of another qualified surgeon is usually necessary for procedures requiring considerable judgment or technical skill and those requiring more than one sterile team. The hazards of a surgical procedure may depend more on the condition of the patient than on the complexity of the procedure itself. The surgeon should be able to provide rationale for his or her decision if challenged or if not in compliance with medical staff bylaws. More information can be found at the American College of Surgeons website, www.facs.org. Lists of specific surgeries requiring MD/DO or other assistants are located on this website.

Scrub Person

The **scrub person** is a patient care staff member of the sterile team. The scrub role may be filled by an RN, LPN/LVN, or ST. The term *scrub person* is used throughout this text to designate this role and to elaborate on the specific technical and behavioral functions of the individual performing on the sterile team in this capacity.

The scrub person should not simultaneously function in the role of first or second assistant. Performing additional tasks takes the scrub person's attention away from the primary responsibilities of maintaining the sterile field and facilitating the surgical procedure. Holding retractors, for example, can cause permanent injury to a patient if inappropriately positioned, maintained in alignment exerting pressure, or placed in contact with electrocautery inadvertently.

The scrub person is responsible for establishing and maintaining the integrity, safety, and efficiency of the sterile field throughout the surgical procedure. Knowledge of and experience with aseptic and sterile techniques qualify the scrub person to prepare and arrange instruments and supplies and to facilitate the surgical procedure by providing the required sterile instruments and supplies. The scrub person must anticipate, plan for, and respond to the needs of the surgeon and other team members by constantly watching the sterile field. Manual dexterity and physical stamina are required. Other important assets include a stable temperament, an ability to work under pressure, a keen sense of responsibility, and a concern for accuracy in performing all duties. Box 4.3 describes the physical and psychological attributes required of the scrub person in the sterile scrub role.

Two scrub persons may join the team in teaching situations or during extremely complicated or hazardous surgical procedures. One scrub person may pass instruments and supplies to the surgeon while the other prepares the supplies. Two scrub persons should be assigned if two complete teams are working simultaneously.

An experienced preceptor may join the team to teach, guide, and assist the learner function as a scrub person. When unexpected, unusual, or emergency situations arise, specific instructions and guidance are received from the surgeon or RN. The ST provides services and assists with patient care under the supervision of an RN at all times.

Some facilities permit RNs or STs privately employed by surgeons to come into the OR to perform the scrub role for their employers. These private scrub persons should adhere to all hospital policies and procedures and to approved, written guidelines for the functions they may fulfill. They are not covered under the facility's liability insurance and should carry their own policy as

• BOX 4.3 Physical and Psychological Attributes of the Scrub Person's Role

1. Visual acuity with or without correction is critical to threading small needles and reading small print. Protective eyewear is required at all times when at the surgical field. Bright lights or dim lights are commonly used throughout the surgical procedure, and people with photosensitivity or susceptibility to light-mediated eye irritation will find the OR environment problematic. Visual accuracy is imperative.
2. Manual dexterity and accuracy of motion is required for fast action during emergencies. Inability to coordinate body motions could cause injury to the patient, team, or self. Manual dexterity is imperative.
3. Eye-hand coordination and alertness are essential for safe handling of instruments during surgery. Eye-hand coordination is imperative for the efficiency of the procedure.
4. Ability to delay nutritional intake or bathroom breaks for prolonged periods during long procedures.
5. Ability to stand in a confined space for prolonged periods.
6. Ability to lift instrument trays of at least 20 lbs and assist with moving large equipment or incapacitated patients using proper body mechanics.
7. Auditory acuity in both ears with or without amplification is critical for hearing and understanding commands while machinery is running. Voices are kept low during surgery, especially when the patient is awake. Hearing correctly is imperative.
8. Ability to quickly anticipate and discern commands and needs of the team. Must be able to differentiate between instruments and supplies efficiently and to offer appropriate alternatives in extraordinary circumstances.
9. The ability to speak, understand, and document clearly using the English language is critical to safe patient care. Appropriate terminology and use of approved standard accepted abbreviations are essential to communication in the OR.
10. The ability to remain calm and function quickly, safely, and precisely during an emergency. Must be able to make decisions and problem solve effectively without loss of emotional control.
11. Mental clarity. Use of medications or substances that alter alertness and attentiveness are not acceptable in the OR. Lack of sleep can affect thought processes.
12. Accountability. Takes responsibility for independent actions. Admits error and remedies the situation when breaches in technique or contamination occurs.

independent contractors. There is no such thing as working under someone else's license such as a physician or an RN. Each person is responsible for personal liability. Further discussion of independent practitioners can be found in Chapter 3.

Private scrub persons can create liability for the facility because the facility will be held liable by virtue of permitting them to work within the facility. They should not perform first-assisting or be considered first assistants unless they are appropriately educated and credentialed in the role. Several states have addressed who may and may not first assist in surgery.

CST: The Certified Surgical Technologist

STs who have completed an accredited surgical technology program and successfully passed an examination attesting to their theoretic knowledge are certified by the NBSTSA, the main certifying body for STs. These individuals are entitled to use the designator CST after their names as a credential. Box 4.4 describes eligibility for taking the CST examination.

As of 2010, graduates of accredited surgical technology programs are required to take the NBSTSA certification examination as a graduation requirement. Application for the certification examination may be made as soon as 30 days before graduation for the graduating class to apply as a group. Certification fees are discounted for Association of Surgical Technologists (AST) members. Special packages are available from AST that include membership and registration for the examination. The results of the examination provide data for measuring an accredited program's effectiveness.

As of 2018, nine states require the CST credential for employment. These states are New York, New Jersey, South Carolina, Tennessee, Indiana, Massachusetts, Texas, Nevada, and Oregon. Other states are in the process of working to get legislation passed to require certification. The map of current required certification states can be found at www.ast.org. STs who were employed before the date of the CST requirement are permitted to remain in the role of scrub person. Military and federal government employees are exempt. The CSTs are permitted to function under the direction of the RN circulator and may not suture, administer medication, or apply wound dressings according to the laws governing CST role activities. Refer to the laws governing CST practice in the individual state of employment.

As of 2020, certification for the CST is valid for 2 years. The CST must be renewed to remain active. It can be renewed by retaking the CST examination or attainment of 30 approved continuing education (CE) credits. Recertification fees are discounted for AST members. Calculations for accruing CE credits can be found in Box 4.5. Providers of CE credits must apply to AST for approval of the offering. Continuing education forms are available for download from www.ast.org.

• BOX 4.4 Eligibility for Certification by Examination for Surgical Technologists

- STs may recertify by examination every 2 years or 30 CE credits
- Graduate of a CAAHEP-accredited surgical technology program
- Graduate of an ABHES from the U.S. Department of Health and Human Services. For additional information, visit www.abhes.org
- Graduate of an accredited Alternative Accelerated Delivery program attached to an accredited school of surgical technology
- No minimum practice hour requirement (accredited programs have minimum case number ratings for new graduates)

Consult www.nbstsa.org for additional information.

The Surgical First Assistant

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify key components of the first assistant's knowledge and skill levels.
- List pertinent perioperative activities of the first assistant.
- Describe the patient care disciplines that with appropriate education function in the role of the first assistant.
- Discuss the legal implications of the first assistant role.

KEY TERMS AND DEFINITIONS

Anastomosis Creating a patent connection between two tubular structures by use of suture or specialized staples.

Approximation Bringing the edges of an incision or wound together with closure medium.

Buzzing a forceps A method of applying the active electrode of a monopolar cautery against an instrument clamped to the patient's tissue for the purpose of spot hemostasis. The flat side of a metal cautery blade is placed in contact with a clamped instrument below the level of the operator's hand before activation of the current. The edge of a Teflon-coated cautery blade is placed against an instrument clamped to patient's tissue below the level of the operator's hand before activation of the current.

Cleavage lines Tissue planes where the natural line of tissue growth permits dissection between areas that maintain anatomic structure.

Debridement Trimming the wound edges of devitalized tissue before packing or closure.

Dissection Separation of tissue planes by sharp or blunt means.

Dynamic tension The stress on skin caused by underlying musculature, joints, and body motion.

"Golden period" An estimated time in which the wound can be closed by primary intention with minimal risk to wound integrity and healing. Influences include anatomic location, mechanism of injury, and amount of contamination in the wound. The golden period is approximately 6 to 8 hours after initial injury for optimal healing.

Hemostasis Preventing the loss of blood. Stopping the flow of blood. The best method is direct pressure. Random clamping of vessels can lead to damage of underlying structures such as nerves, tendons, or other structures.

Incise cut Scalpel is used in a perpendicular position to slice tissue in a linear direction.

Langer's lines Natural lines along skin caused by tension inherent in the structure of the dermal-epidermal layers. Healing in the natural lines produces a smaller scar. **Transection** across the Langer's lines does not follow the natural musculofascial tension and will produce a wider scar.

Ligation The act of tying or occluding an anatomic structure.

Palmed Method of holding an instrument in which the working end is nested in the palm of the hand of the assistant and the fingers remain free to grasp other items in the field. The working end can be presented and made functional by a rotation of the wrist. This method can be used for countertraction with some manual retractors.

Perpendicular The intersection of surfaces at right angles. The scalpel is held perpendicular to the tissue during incision. The belly of the blade is used to incise tissue for best control over the depth of the cut.

Press cut Scalpel is pushed into the tissue rather than slid to incise. Press cutting can be a form of intentional puncture. A precise cut results when the scalpel is held like a pen.

Raising a flap Perpendicular countertraction is placed on superficial tissues as large areas are undermined by dissection. Care is taken not to disrupt vascularization of the elevated tissue.

Retraction Displacement of structures by use of the hand or an instrument to expose the surgical site.

Scrape-cut Scalpel is dragged laterally across tissues to separate cell layers rather than full tissue layers.

Skin tension The turgor of the skin that is either static or dynamic. Tension factors largely in the final healing of the incision and the appearance of the scar.

Splitting Separation of muscle tissue along the fascial layers. A form of blunt dissection.

Sponging A method of providing exposure by removal of blood and fluid from the surgical site. The preferred way to sponge is to blot or pat the area so as not to remove biologic clots.

Static tension The constant state of skin position over the framework of the body. Also known as **Langer's lines**.

Suction Negative pressure used to clear the visual field of blood and body substances. Various styles of tips and tip protectors are used. On occasion, a rigid suction tip can be used to remove fluids and retract tissues simultaneously.

Surgical assistant Member of the sterile team who provides exposure and hemostasis during a surgical procedure. A physician, registered nurse first assistant (RNFA), surgical assistant (SA), physician assistant (PA), or certified surgical technologist (CST) specially trained and certified as a certified first assistant (CFA).

Suture (verb) The act of sewing tissues with the goal of **approximation**, not strangulation. (noun) A thread used for sewing tissue in surgery. Suture knowledge is critical. Types include barbed, absorbable or nonabsorbable, multifilament or monofilament, and natural or synthetic.

Thenar grip Method of holding an instrument in which the ring handle is secured in the palm at the base of the thumb instead of placing the thumb through the ring. A small portion of the ring finger may be situated within the opposing ring of the handle.

Traction–countertraction Displacement of a structure by pulling the tissue in an opposite direction to facilitate sharp or blunt dissection of tissue planes.

Transection Cutting across natural anatomic lines. Can be done by sharp dissection or electrocoagulation.

Triangulation Suturing three opposing points of a tubular structure so that the distance between two points can be approximated in a straight line.

Tripod grip Holding an instrument or scissors in a steady position with the index finger on the box lock hinge and the thumb and ring finger partly in the ring handles for ease of release.

Undermining Dissection of subsurface tissue planes. Care is taken not to devascularize upper layers of tissue or cut nerves. Undermining decreases tension of the overlying tissues. Areas of higher **skin tension** benefit from this technique.

First Assistant's Knowledge and Skill Level

Surgical Anatomy and Physiology

The patient's body is a complex biosystem. Every surgical procedure interrupts multiple facets of a patient's anatomic structure and physiologic function. Lack of knowledge about each structure and its function could cause untoward disruption and injury. A single injury will affect many aspects of the patient's outcome and could progress to permanent disability or death. Anatomy and physiology are closely intertwined and should be considered as inseparable components of the whole person.

Knowledge of anatomic structures is critical to the first assistant. Tissue manipulation with instruments requires expert working knowledge of what is grossly seen and what is occluded from view. Improper **retraction** of tissue that has nervous and vascular structures contained within could cause complications, such as neurologic dysfunction or vascular obstruction, resulting in thrombosis or embolization. Lack of this knowledge led to permanent damage to a child's sciatic nerve as documented by *Healthtrust v. Cantrell* in Alabama.[a] In this lawsuit, the surgical technologist (ST), who was performing in the role of surgical first assistant, was unable to identify the location of the sciatic nerve and caused serious injury with a retractor. The ST stated that he knew how to use retractors and held them where the surgeon placed them. This is an unacceptable and unsafe practice.

The surgical first assistant must absolutely know all the ramifications of every action performed in the role and its effect on the patient's outcome. The actions of the surgical first assistant should reflect the ability to identify all of the normal and abnormal structures in the surgical site and make intelligent, informed decisions about patient safety. *Each first assistant is responsible for personal liability.* There is no such thing as "working under someone else's license" as commonly misinterpreted by some surgical staff members.

[a] *Healthtrust v. Cantrell* (689 S0 2d 822 [Ala] 1997).

Pharmacology

Medications taken by the patient can cause complications in the perioperative environment. The first assistant should have a clear understanding of each drug the patient takes and its effect on the surgical procedure. Anticoagulants, for example, could cause intraoperative bleeding or postoperative hematoma. Other drugs such as birth control pills can predispose the patient to deep vein thrombosis, which in turn could lead to pulmonary embolism. Vasoconstrictors in the local anesthetic can delay the normal inflammatory process necessary for incisional healing. Patients who take hypoglycemic medication may be predisposed to metabolic problems during the procedure and poor healing or infections postoperatively. Knowledge of each drug's pharmacologic use and action can help prevent complications throughout the perioperative care period. The first assistant and the circulating nurse should collaborate concerning patient sensitivities and allergies.

Psychomotor Dexterity

Precise, purposeful movement at the sterile field is important for the maintenance of the sterile field and the protection of the patient and team. Many instruments used could cause puncture injury if mishandled, and the resultant contamination could cause transmission of a serious illness such as human immunodeficiency virus (HIV) or hepatitis B or C. Clumsiness can cause instruments to fall from the field to the floor, resulting in damaged equipment. Use of an item for a purpose other than its intended function can create liability for the facility if someone is harmed.

Efficiency is important to facilitate the procedure. The surgeon relies on the first assistant to help manipulate tissues with instrumentation in both open and endoscopic procedures. For open procedures, the surgical site is visually larger and requires the first assistant to be a "second set of eyes." The surgeon's attention may be focused on a particular organ system, and the first assistant helps by providing exposure and observing for problems in the periphery.

For endoscopic procedures, the visual field is limited to the image on the video monitor. The first assistant needs a steady hand when using endoscopic instruments, because even the slightest motion can cause the entire surgical field to shift, placing the patient at risk for injury and causing nausea in team members who are viewing the video monitor. Extreme caution is exercised to prevent injury to tissue not in the direct visual field.

Procedure Knowledge and Techniques

The first assistant needs to know each step that will be encountered during the surgical procedure. It is important to anticipate and think in advance about each step to help the procedure move smoothly. The first assistant should have clear knowledge about not only the functional steps but also the indications for the procedure. Refer to Table 1.1 for the most common indications for a surgical procedure.

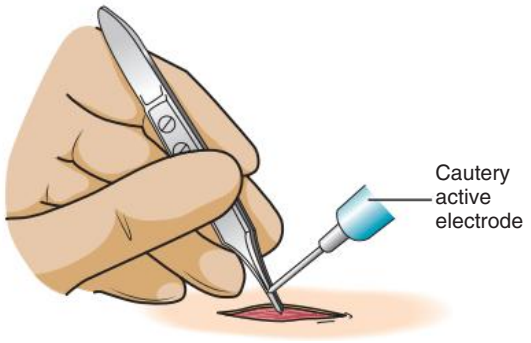
When the surgeon incises tissue, the first assistant usually provides a clear field by retraction (traction or countertraction), **sponging**, or **suction**. Some circumstances require the use of hemostatic actions, such as clamping, suturing, cauterizing, or application of some other pharmacologic preparation to stop bleeding.

The surgeon may request the first assistant to "**buzz the forceps**," which means placing the active electrode against a forceps that is holding patient tissue and delivering electrical current after the tip is in complete contact with the instrument (Fig. 5.1). The gloved hand holding the forceps should have as much contact with the instrument as possible before the current is delivered. This decreases the amount of current passing over the holder's hand and prevents concentration of electricity at a focal point on the hand. The current is delivered below the holder's hand and as close to the actual patient tissue as possible to minimize the risk for an alternative current pathway. The forceps is not permitted to touch any other part of the patient's tissue or other instrumentation during this process or the patient will suffer burns to nontarget tissue.

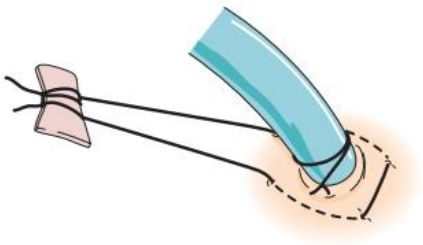
Knowing how and when to perform each action is part of the knowledge base of the first assistant. Random clamping or cautery application can cause serious tissue damage.

Surgical Site Management

Management of the surgical site is a crucial part of the successful outcome of the procedure for both physiologic and aesthetic reasons. Physiologically, a surgical site infection could be devastating to the health of the patient and be an incredible cost factor during the recovery period. Aesthetically, the closure is what the patient sees at the end of the procedure and how he or she judges the quality of care.



• **Fig. 5.1** Buzzing the forceps. The active electrode tip is placed against the forceps to deliver current to a specific spot of bleeding.



• **Fig. 5.2** The surgical drain should be secured with a suture.

The first assistant commonly assists in closing the skin and applying dressings or supportive materials, such as casts. Improper technique of closure can lead to poor wound healing and unsightly scarring. Securing drains appropriately facilitates surgical site healing and minimizes the risk for dead space where a hematoma or seroma can form (Fig. 5.2).

What Does the First Assistant Do?

Position, Prep, and Drape the Patient

The first assistant is frequently responsible for positioning the patient on the table after the anesthesia provider indicates it is safe to do so. In the absence of the first assistant, other members of the team may perform this function. Provision for safe exposure of the surgical site without compromising the physiology of the patient is the key to a successful procedure.

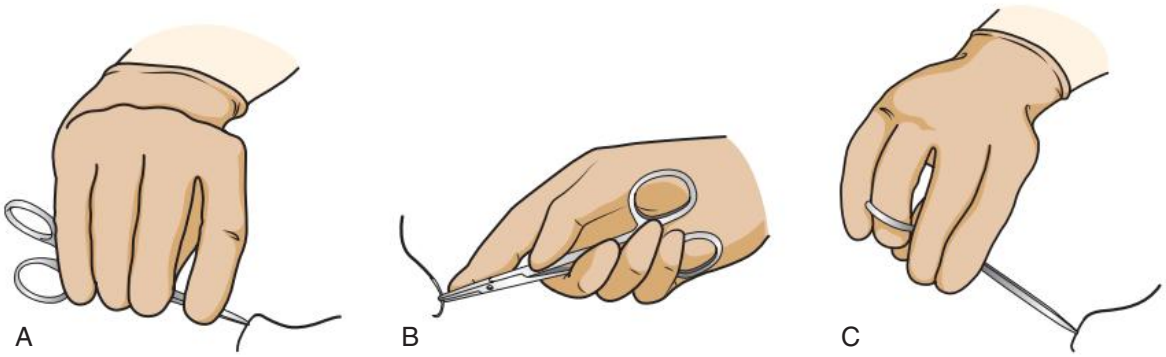
The dispersive electrode (i.e., patient return electrode; Bovie pad) is placed after the patient is in the final resting position for the procedure. Positioning the patient after the pad (Bovie pad) is in place can cause the pad to slip or gape, preventing full contact with the skin. It should not be removed and reapplied for any reason. The Bovie pad should never be cut to size. The prep solution should not be permitted to pool or drip under the pad. Alcohol-based preps are flammable, so care is taken that the prep is completely dry before drapes are applied. Be sure that the safety straps are correctly positioned. The straps should be over the patient's blanket where they are visible before the drapes are applied.

Keep in mind that the height of the OR bed should be adjusted to suit the reach of the tallest person at the sterile field. Shorter individuals should stand on steps or platforms for ergonomic comfort and adequate visualization of the surgical site. Sitting is only appropriate when the entire team is seated so as not to change the level of the sterile field. Chapter 26 describes the processes for positioning, prepping, and draping the patient.

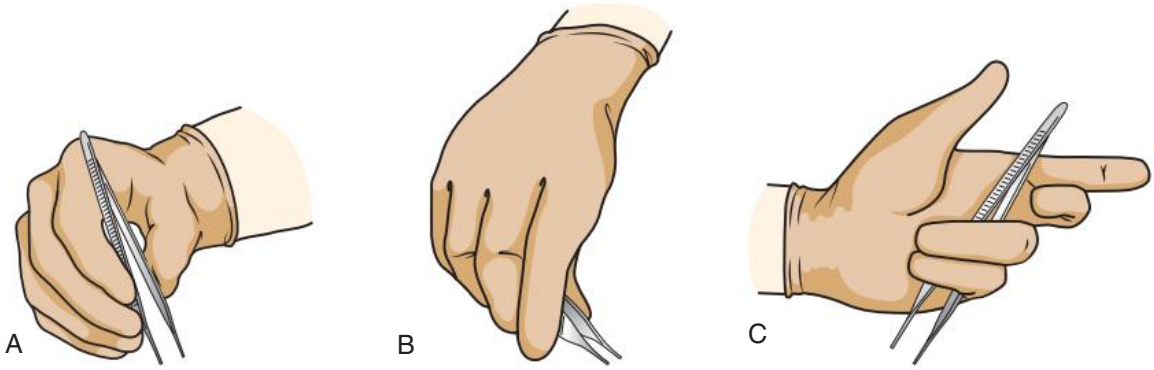
Handle Instrumentation

The role of the first assistant involves knowledge, skill, and dexterity in handling and using surgical instrumentation. A skilled first assistant can make the role look easy, but in fact his or her skill is reflected by precise action. Fumbling or struggling indicates lack of knowledge and skill in the role. The standard of care for the use of equipment or instrumentation in the role of first assistant includes the following:

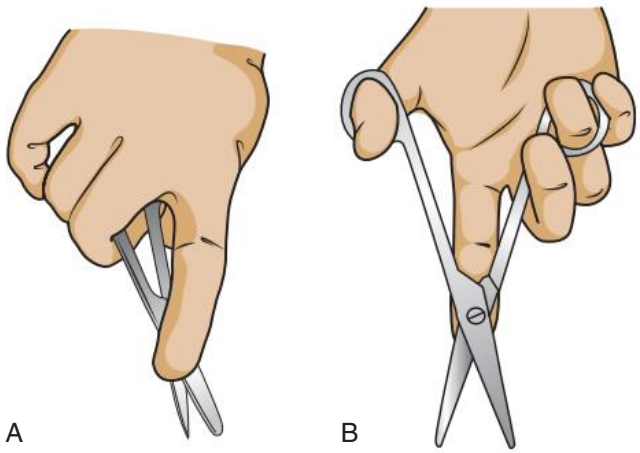
- Knowledge of the equipment and instrumentation
- Knowledge of how and when to use the equipment and instrumentation
- Dexterity of holding and using basic instrumentation (Figs. 5.3 to 5.6)



• **Fig. 5.3** **A,** Holding a needle holder correctly in dorsal view. **B,** Holding a needle holder correctly in palmar view. **C,** Incorrect way to hold a needle holder, with finger in.



• **Fig. 5.4** **A,** Correct way to hold forceps. **B,** Incorrect way to hold forceps. **C,** Palming a forceps.

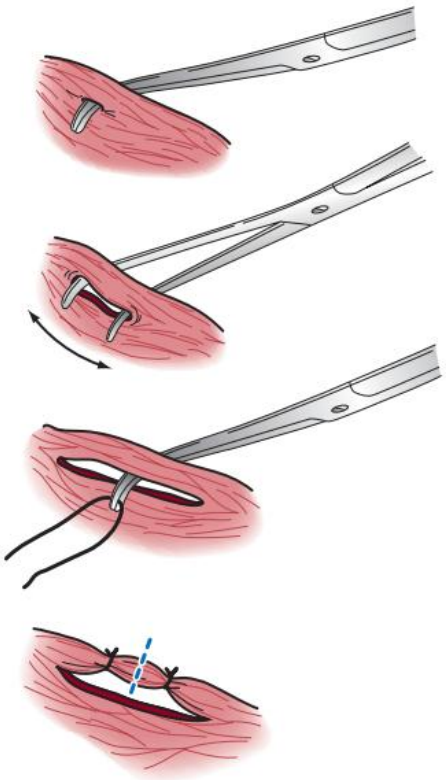


• **Fig. 5.5** **A,** Correct way to hold scissors, using the tripod grip showing dorsal hand view. **B,** Correct way to hold scissors with tripod grip showing the palmar hand view.

- Skill in the use or operation of the equipment and machinery
- Knowledge of potential for injury to underlying and surrounding tissues

Provide Exposure

Methods of providing exposure include use of rigid and flexible retractors, grasping instruments (e.g., clamps, forceps), Silastic bands (e.g., vessel loops), rubber drains (e.g., Penrose), umbilical



• **Fig. 5.6** Using a free tie to occlude a blood vessel.

tapes, Raytec sponges, laparotomy tapes, suture traction, plastic isolation bags (bowel bags), and suction, as well as by direct hand positioning. More recent technology includes the use of saline and a carbon dioxide mister/blower to keep the field clear of blood during "off pump" cardiac bypass grafting. Care is taken not to introduce an air bolus into an open vessel.

The method used to provide exposure is carefully selected. Physical attributes of the patient are considered, such as body size, tissue type, adjacent structures, depth, and type of exposure needed. The presence of blood or body fluid can require the use of suction as part of the exposure process. Prolonged need for surgical exposure may require the use of a self-retaining retractor as possible. Whenever tissues are exposed to air for extended periods, the first assistant should be sure to irrigate the site lightly with an appropriate irrigant.

Use of manual retractors can be physically demanding, and prolonged use can contribute to repetitive stress injuries of the assistant's wrist and arm causing carpal tunnel syndrome. Most retractors are designed to be held in an ergonomic fashion and do not require the forces associated with a tense, struggling grasp (Fig. 5.7). If the retractor in use causes the assistant to struggle, another style may be indicated for use.

Suction should be used with caution. Evacuation of fluids to clear the field of vision should be done in a manner that is not injurious to adjacent structures. The direct force of the vacuum against tissues can cause suction lesions that can become inflamed and necrose. Blind suctioning should be avoided because organs such as the spleen could be perforated and cause hemorrhage.

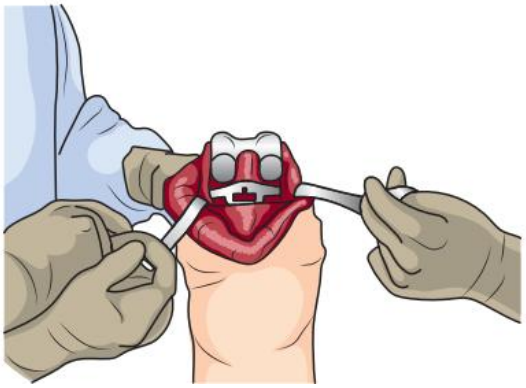
Provide Hemostasis

Prevention of active bleeding and blood loss is a major part of every surgical procedure. The surgeon takes great care to avoid vessels and organs during dissection because blood and body fluids obscure vision in the surgical field and the loss of blood is a detriment to the patient. Unfortunately, some maneuvers during the procedure cause bleeding, and this bleeding must be cleared and controlled. The clearing of the field is part of the exposure process, but the control of bleeding and blood loss is referred to as **hemostasis**. Prevention of retained pools of blood or serum that could create a nidus for infection in tissues is accomplished by the elimination of dead space when tissues are closely approximated.

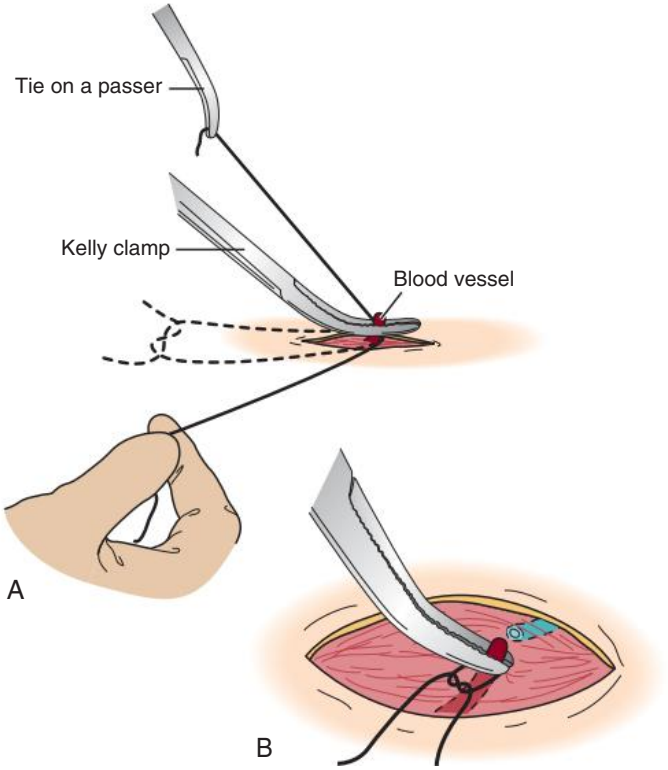
Methods and mechanisms of hemostasis are described in detail in Chapter 29, but a brief description is provided here for first assistant role description.

Hemostasis is provided by mechanical, chemical, or thermal means. The decision of which method to use at a given point in a procedure requires significant knowledge and skill. Examples of each method include but are not limited to the following:

1. *Manual hemostasis.* Direct pressure over a part; indirect pressure adjacent to a part.
   a. Clip (metallic, plastic, temporary, permanent, absorbable)
   b. Suture (suture ligature, free tie; see Fig. 5.6)
   c. Clamp and tie (hemostat: crushing or noncrushing; Fig. 5.8)
   d. Tourniquet (Rummel vascular sliding occlusion, vessel loop, umbilical tape, Penrose drain, pneumatic tourniquet). Occlusion of the circulation should be held to the least amount of time possible to prevent tissue damage.
   e. Hand and/or fingers over area to create pressure. Directly hold or blot sponge over site. Do not wipe off the newly formed clot; doing so will cause bleeding to resume.
2. *Chemical hemostasis.* Agent is placed over a localized bleeding surface to control active bleeding. Care is taken not to allow the material to be introduced into the systemic circulation. Hemostatic materials should not be permitted to contaminate blood salvage systems. The returned blood could potentially cause an embolus. Chemical hemostatic agents are topical (liquid, gelatin sponge, collagen fibers or sponge, cellulose, fibrin glue, or albumin). EPINEPHrine is commonly added to local anesthetics for its vasoconstrictive properties. (This is contraindicated in small distal vessels of the digits, penis, ears, and nose.)
3. *Thermal hemostasis.* Electrosurgical units (ESU) or lasers are the most common means of thermal hemostasis. Safety is a critical factor in the use of such equipment. Do not use thermal methods in the presence of oxygen exposure (i.e., airway or thoracotomy) to minimize the risk for fire. Personnel using



• **Fig. 5.7** Retractors are ergonomically designed to provide exposure with minimal assistant fatigue.



• **Fig. 5.8** **A,** Using a clamp to occlude a vessel. **B,** Using a free tie around a clamped vessel.

thermal hemostatic devices should have appropriate training and credentials. Chapter 20 describes the most commonly used devices for hemostasis in more detail.

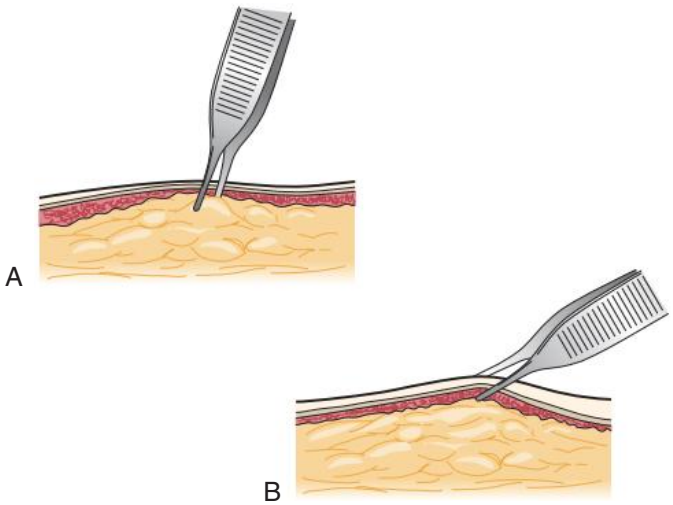
a. *Electrosurgery unit (ESU).* Monopolar ESU requires the use of a return electrode on the patient. An active electrode can be touched directly to tissue or to a forceps holding a segment of tissue. Enhanced monopolar units may have argon beam (argon gas) coagulation properties that are useful for large bleeding surfaces. The tip of the argon beam coagulator is not touched directly to the bleeding surface because it can clog. The argon gas is nonflammable and is used to clear blood away as the current flows across the bleeding surface. Bipolar ESU requires no return electrode. The active and inactive electrodes in the tips of the instrument prevent the current from passing through the patient's body.
b. *Laser.* Extreme caution is exercised at all times during laser use. Eyewear of the appropriate optical density is worn by everyone, including the patient. The environment should not support inadvertent injury by any stray laser light.

Handle Tissue with Instrumentation

The first assistant should always be aware of each tissue type and the appropriate way to handle it. All tissue should be handled with care, using the fewest instruments possible. Knowledge of the instrumentation and its intended use is critical. Some instruments are considered crushing and should not be used to handle delicate lumens. Skin edges can be crushed by inappropriate grasping with forceps (Fig. 5.9).

Forceps should be used on tissue with care. Tight grasping can cause perforations, also known as "button holes," in tissue that will scar or leave tissue defects that may not heal correctly. Clamps should never be placed randomly because of the potential for structural destruction. The fingers are placed lightly into the ring handles, and the clamp is steadied by an extended index finger used to "tripod" the shanks of the instrument.

The first assistant should always be able to apply a clamp and quickly retract the fingers without entanglement in the rings. A delicate grasp should remain on the instrument as it holds the tissue securely. Traction on the attached instrument is appropriate when the structure is to be removed or excised. No traction should be placed on soft tissue in process of repair.



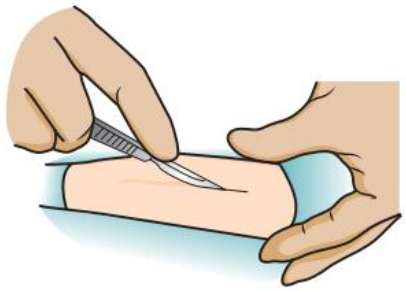
• **Fig. 5.9 A,** Correct way to grasp subcutaneous tissue with forceps. **B,** Incorrect way to grasp tissue by crushing the dermis and epidermis in the jaws of the forceps.

Dissection

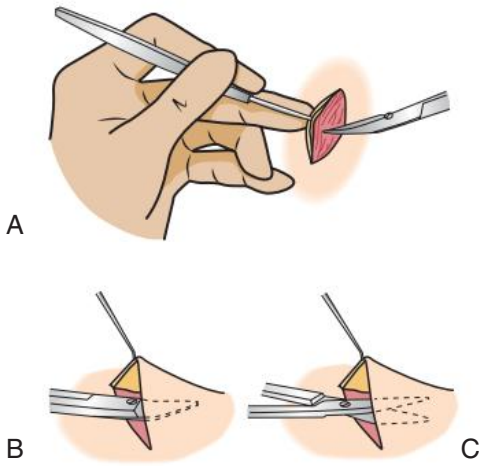
The first assistant should be familiar with and skilled in methods of tissue **dissection**. Procurement of vascular conduit or preparing kidneys for transplant requires the first assistant to know sharp and blunt methods of separating tissue. ESU can be used for dissection.

Sharp methods require the use of a scalpel or scissors. Some tissue is slippery or highly mobile. Use of **traction–countertraction** maintains enough tightness to prevent excess jagged edges as the primary incision is made using a scalpel. A dry sponge can be used in countertraction to stabilize the skin for a straight incision (Figs. 5.10 and 5.11).

Scalpels are used to sharply open the skin, separate tissues, and create precise incisions. The scalpel blade is held **perpendicular** to the surface as it cuts. Allowing the blade to lie at an angle causes the incision to bevel the surface, which in turn can undermine the skin, harming the circulation. The grip of the individual fingers provides varying degrees of pivot, balance, and pressure. The size of the blade is determined by the area to be incised. The scalpel is



• **Fig. 5.10** Using a scalpel to create incision with right hand and exerting traction with the left.



• **Fig. 5.11** Techniques for **undermining** the skin with scissors. **A,** Skin is peeled back over the left middle finger. Edge is held by delicate skin hook retractor. Scissors are used to nip at subcutaneous tissue. **B,** Closed scissors are placed under the skin at the incision line. **C,** Scissors are opened and spread to first bluntly dissect and separate tissues with the outer edge of blades. Sharp dissection can be used secondarily from within the pocket of dissection.

held differently according to the type of tissue and the incision being created. The scalpel can be held like a

1. Pencil with the index finger alongside the superior edge (the dull ridge) of the blade for fine shallow lines made in a "slide" motion; the wrist rests on the surface of the area to be incised and the cutting edge does not have full contact with the skin's surface.
2. Pencil with the index finger over the superior ridge of the blade for a **press cut**; the finger acts as a stop as the blade enters the tissue.
3. Violin bow for a deeper straight cut with maximum contact with the cutting edge; the hand is positioned over the scalpel, but the wrist is not in contact with the patient's body. When a sawing motion is used the risk for fat necrosis from devitalized tissue in the incision increases.
4. Pencil with the point of the scalpel directed at the tissue and the entire handle at a right angle to the body for a puncture cut.
5. Straight razor to use in a sideways scraping motion to debulk or debride tissue.

Scissors use a cross action to transect tissue. The same physical instrument handling is used in **debridement**. Care is taken not to completely insert the fingers into the ring handles of the scissors. A delicate balance between the finger tips and the first phalangeal joint of the thumb, index, middle, and ring fingers prevents the fingers from being ensnared in the handles during dissection. The index finger should extend along the back of the blades like a tripod for stability.

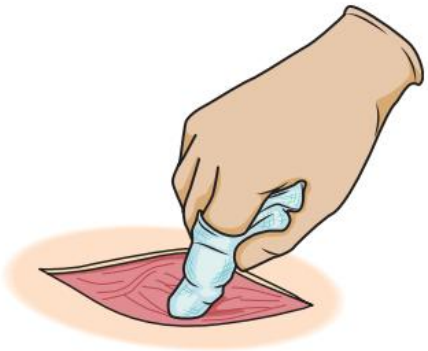
The dexterity of opening and closing the scissors permits the user to insert the closed tips between layers and slowly spread the blades to separate tissue planes bluntly followed by precise sharp cutting of the individual layers. The curve of the scissors usually matches the curve of the hand with the tips pointing upward for most cuts. A few backward cuts require the scissors to be held with the curve opposite the curve of the hand. The straight scissors are not often used for cutting tissue.

Blunt methods commonly use dull edges of instruments or a sponge-covered finger (Fig. 5.12). Instruments designed as planar dissectors are used to peel away tissue in blunt dissection fashion. For small areas, the blunt end of the scalpel can be used to peel back tissue bluntly.

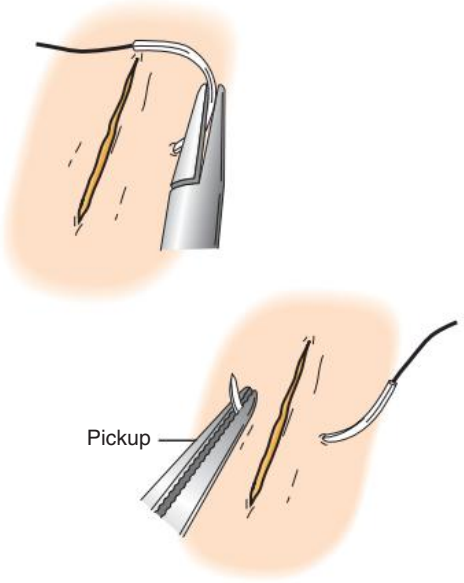
Chapters 19 and 20 describe instruments and equipment used by the first assistant in surgery.

Suture

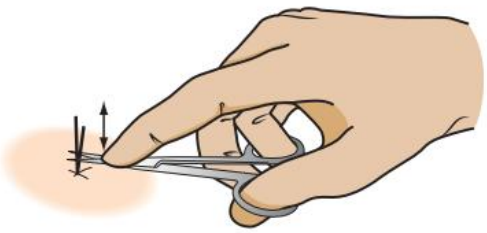
The first assistant may be required to **suture** (Fig. 5.13) and cut suture (Fig. 5.14) during and at the end of the procedure. Suturing is considered a form of closure and can entail the use of conventional suture material and needles, metallic or absorbable clips, staplers, wound tape strips, wound glue, wire, and other materials for joining tissue. Intraoperative suturing is performed for hemostasis, stabilization of a part, traction, or other tissue manipulation. At the end of the procedure the incision is closed by a closure method using one of the aforementioned devices.



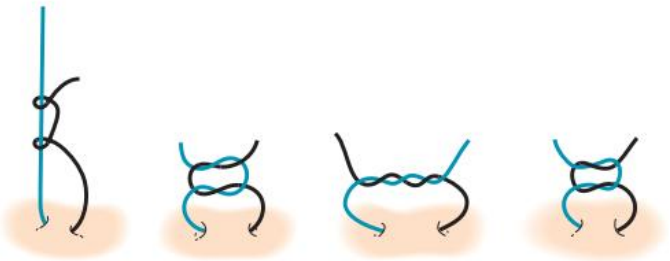
• **Fig. 5.12** Blunt dissection using a gauze sponge over the first finger.



• **Fig. 5.13** Correct way to introduce the suture needle into the skin.



• **Fig. 5.14** Correct way to cut suture.

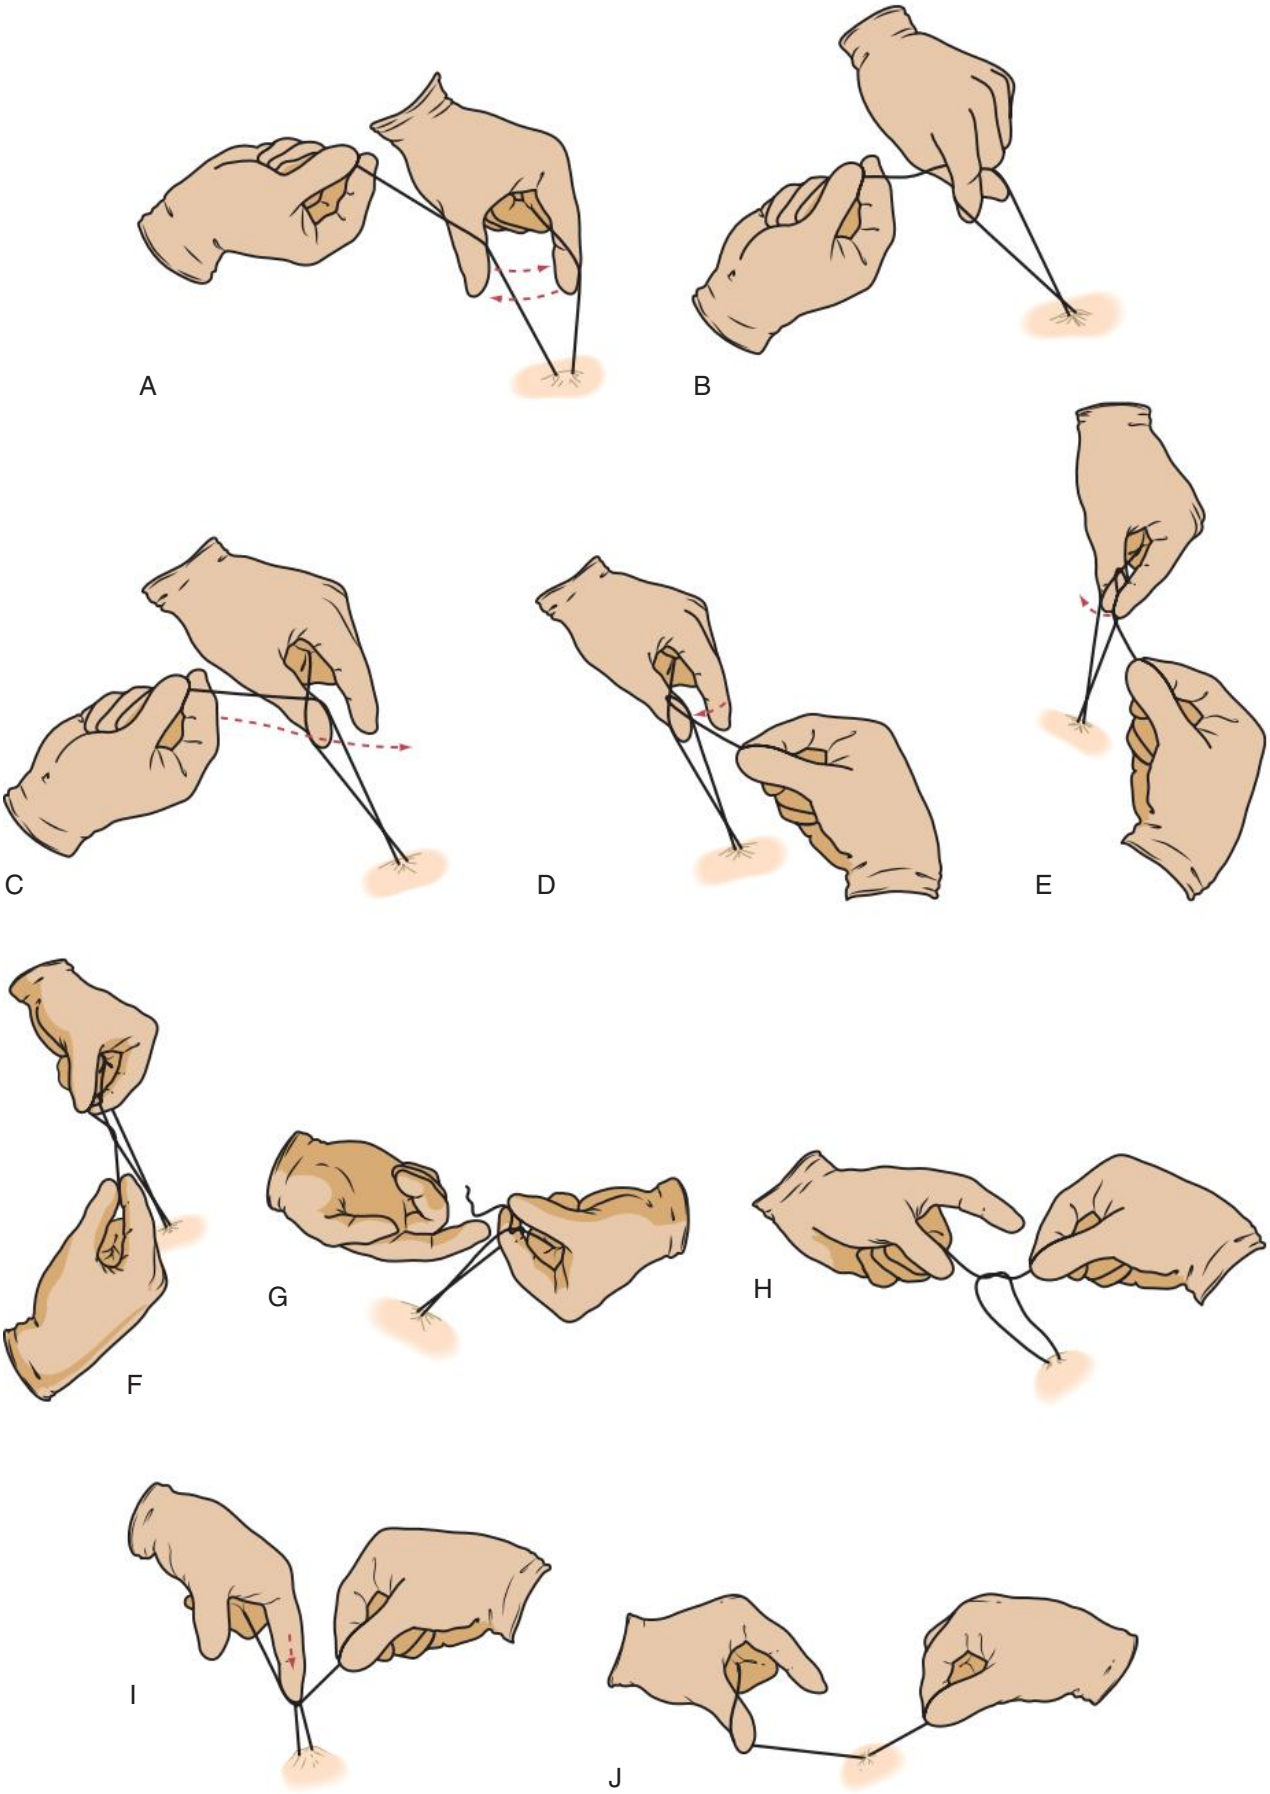


• **Fig. 5.15** Types of knots used in surgical procedures.

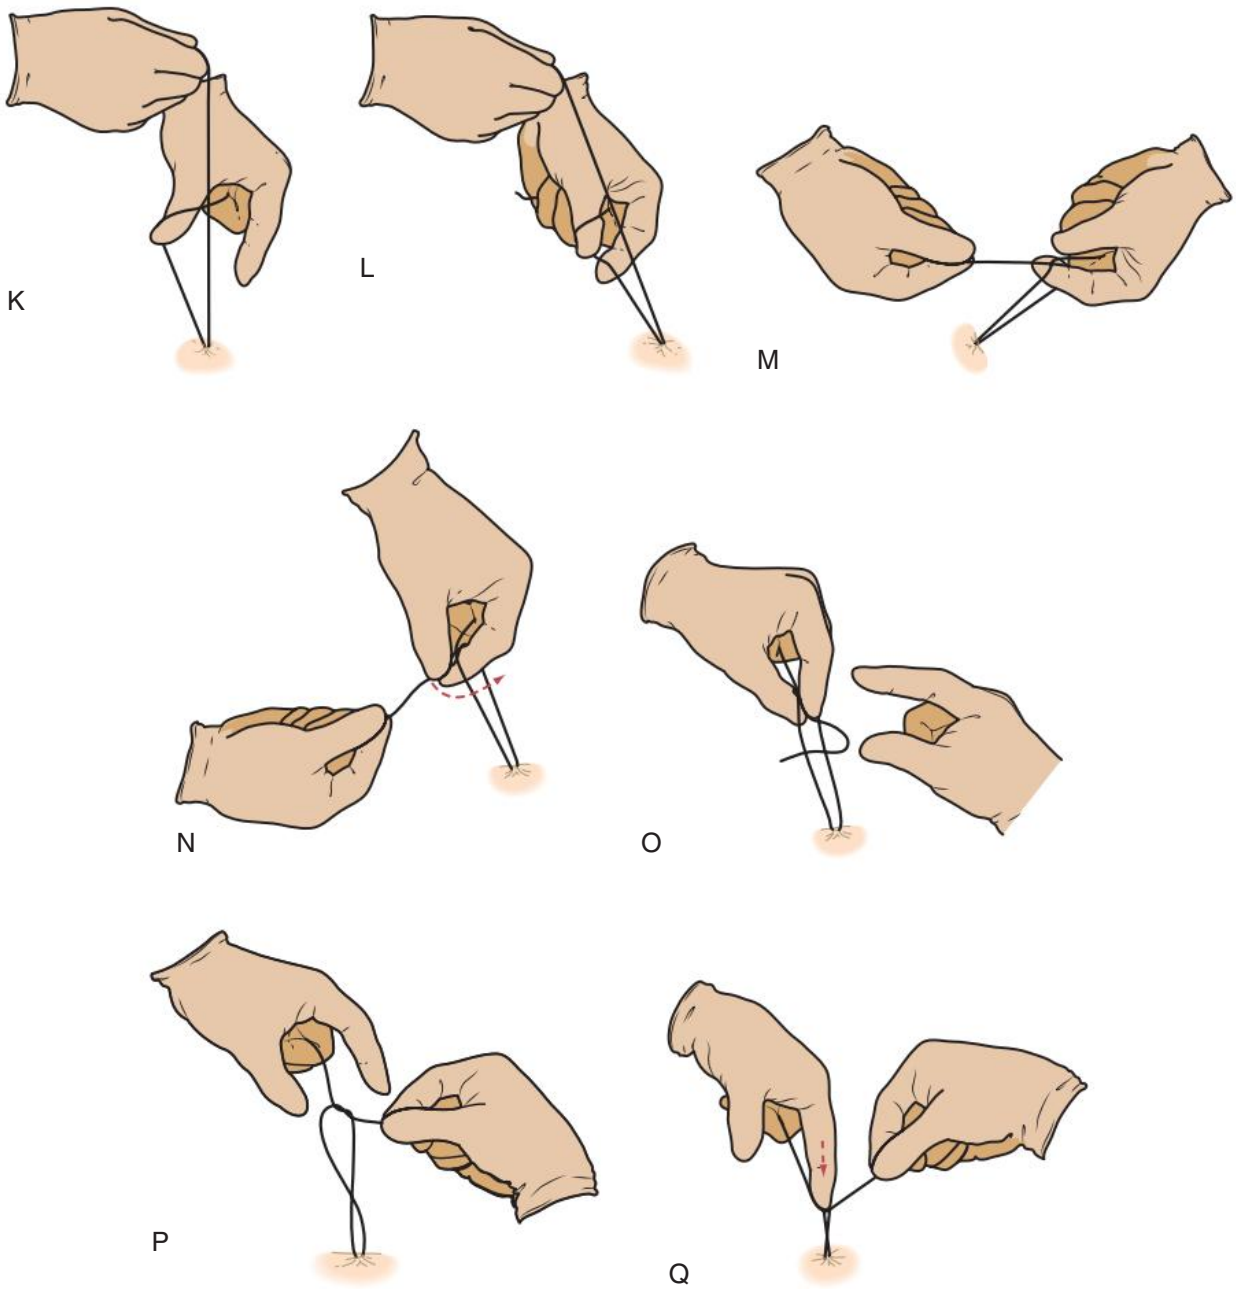
Traumatic wounds have a specific set of criteria for closure. The decision for closure timing and mechanism is determined by degree of contamination, location on the patient's body, the mechanism of injury, and in some patients, the duration of time between injury and closure, referred to as the "**golden period**." This period is based on the previously mentioned factors. Additional discussion of suture and techniques is found in Chapter 28.

Knot tying requires extensive practice and skill (Fig. 5.15). An insecure knot can lead to an obstructed view during the procedure if bleeding is not controlled and to postoperative hemorrhage leading to hematoma. Knot tying for conventional surgery is performed by one of the following methods:

- Two-handed tie (Fig. 5.16)
- Instrument tie (Fig. 5.17)
- One-handed tie (Fig. 5.18)



• **Fig. 5.16** Two-handed tie.



• **Fig. 5.16, cont'd**

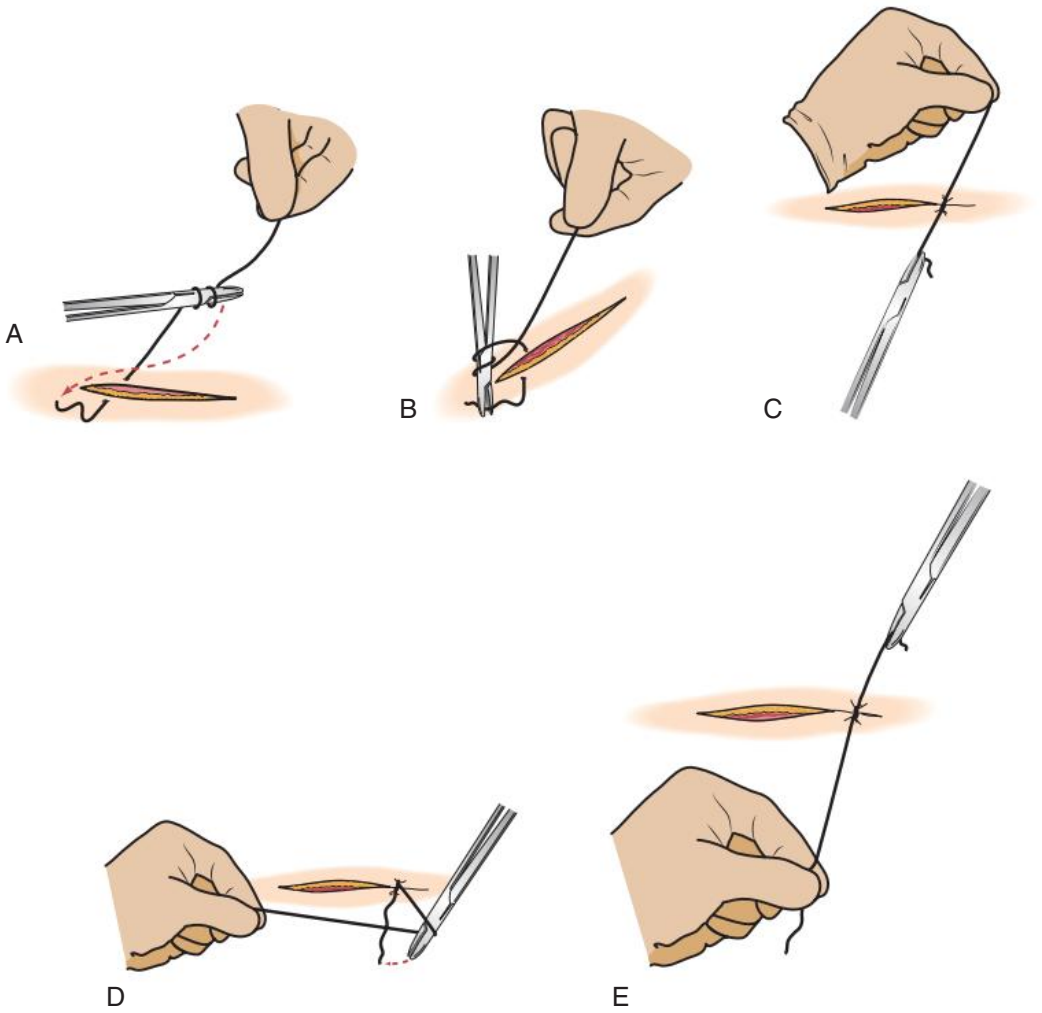
Recognize Surgical Hazards

Surgical hazards are described in Chapter 13. The first assistant works with the surgeon and the rest of the team to provide a safe environment. Every step of the procedure requires diligence and care. The first assistant should be able to identify potential hazards and prevent them. Should an untoward event occur, the first assistant should know the steps to take to resume a safe environment. Primary hazards are biologic, physical, and chemical. Each hazard has a multitude of manifestations. Examples of hazards include, but are not limited to, the following:

- *Biologic hazards.* Exposure to contamination by both the patient and the team. This can be blood, plume, excreta, transudate, exudate, tissue, semen, or any other physiologic substance.
- *Physical hazards.* Risk for sharps puncture, fire, tissue damage, pressure injury, burns, physical mechanical stress, electrocution, or other physiologic damage to the patient or team.
- *Chemical hazards.* Medications, prep solution, sterilants, anesthetics, cement, cytotoxic material, or any substance not derived from biologic sources.

Respond Appropriately to Emergency Situations

The first assistant should be credentialed in cardiopulmonary resuscitation (CPR), preferably at the advanced cardiac life support (ACLS) level. The first assistant is a key member of the team during lifesaving procedures. Emergencies can be environmental fires or other events that place human life at risk.



• **Fig. 5.17** Instrument tie.

Patient Assessment

The assessment of the patient is an ongoing activity practiced by all the professionals rendering direct care. The advanced practice first assistant is master's degree prepared and has extensive education in physiology. Some states have granted prescriptive privileges to particular disciplines that participate in perioperative patient care. Orders written by first assistant personnel are cosigned by the surgeon or anesthesiologist; an exception is the nurse practitioner writing a prescription permitted under the authority of his or her own state. Nurse practitioners are advanced practice nurses who have a number assigned by the U.S. Drug Enforcement Agency that is included with the written prescription.

Disciplines Associated with First-Assisting in Surgery

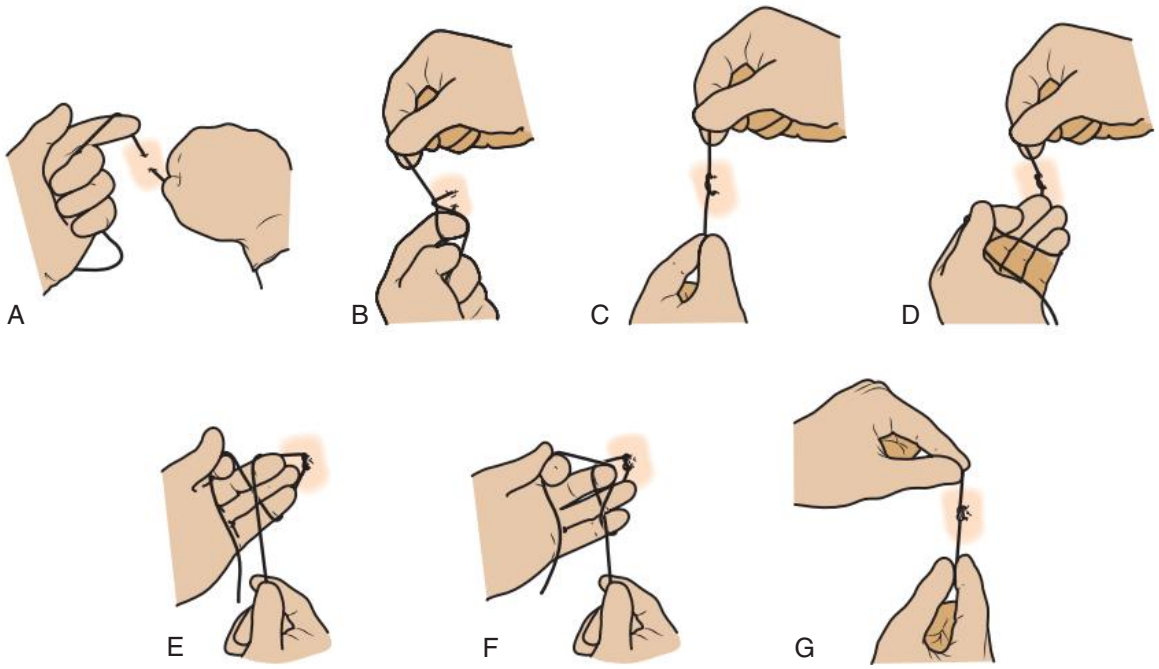
Registered Nurse First Assistant

A certified perioperative nurse (CNOR) who successfully completed an accepted program based on the Standards for the Education the Registered Nurse First Assistant (RNFA) by AORN (the Association of periOperative Registered Nurses) may seek a position as a registered nurse first assistant (RNFA) with a private surgeon, hospital, or clinic. An Advanced Practice Registered Nurse (APRN) is not required to be a CNOR since certification is part of advanced practice.

A baccalaureate degree (BA or BS) or higher is required to enter an accepted RNFA program as of January, 2020. RNFA is a recognized job description that can be credentialed by certification after completing 2000 hours in RNFA practice and taking an examination. A baccalaureate degree is required to sit for the examination. The credential is certified registered nurse first assistant (CRNFA).

Nurses who completed an accepted RNFA program that includes 120 hours of internship are eligible to take a separate examination sponsored by the National Assistant at Surgery Certification (NASC) organization. This examination is a form of certification that provides a credential for 3 years while completing the 2000 practice hour requirement for the CRNFA. It can be renewed and does not require a baccalaureate degree. The credential is registered nurse assistant at surgery (RNAS-C). The 3 year certification interval is useful for nurses working towards a bachelors degree in compliance with the CRNFA requirement.

The RNFA functions under the direct supervision of a surgeon and is permitted to first-assist by the medical service department at the facilities of practice. The RNFA functions solely as the first assistant and should not simultaneously perform the functions of a scrub nurse or circulator. Performing both roles diverts attention away from the primary focus of the sterile field and subsequently away from the patient. A sample performance description is



• **Fig. 5.18** One-handed tie.

shown in Figure 5.19. The qualifications to function as a first assistant should include, but are not limited to, the following:

- Demonstrated competency in both scrub and circulating nurse roles for a minimum of 2 years
- Knowledge and skill in applying the principles of aseptic and sterile techniques to ensure infection control
- Knowledge of surgical anatomy, physiology, fluid and electrolyte balance, acid-base regulation, clinical pathology, and wound healing because these factors relate to surgical procedures
- Comprehension of risk factors and potential intraoperative complications and knowledge of actions to minimize them
- Technical skill and manual dexterity in handling tissue, providing exposure, using instruments and devices, providing hemostasis, tying sutures and knots, and applying dressings
- Ability to recognize safety hazards and initiate appropriate preventive and corrective actions
- Ability to perform cooperatively and effectively with other team members
- Ability to perform effectively in stressful and emergency situations
- CNOR is maintained. Advanced practice nurses are exempt from the CNOR requirement because they have advanced certification. Canadian perioperative nursing certification is recognized by the Competency & Credentialing Institute (CCI).
- Certification in CPR (basic cardiac life support [BCLS] or ACLS preferred)
- Completion of formal RNFA program based on the AORN RNFA Core Curriculum and the AORN standards for RNFA education

Curriculum for the RN First Assistant

Since 1995 the role of the RNFA is recognized in all 50 states as within the scope of nursing practice as an expanded role of the perioperative nurse. Recognition as an RNFA is controlled by individual state boards of nursing.

Voluntary certification is attained by successfully passing the national CRNFA examination. CCI has developed a national certification examination for the eligible RNFA that includes the following requirements:

- Licensed as an RN in the state (country or province) of practice
- Baccalaureate degree or higher (copy of diploma must be included in application packet)
- CNOR or certification in advanced practice nursing (APRN). Canadian perioperative certification is recognized by CCI
- Completion of an RNFA program based on the AORN RNFA Core Curriculum and the AORN standards for RNFA education
- 2000 hours of first-assisting experience during a period of 5 years; 500 hours must be within 2 years of taking the certification examination. Documentation of 2000 hours must be included with the application
- 1400 hours must be in the intraoperative role; 600 hours may be in preoperative or postoperative settings
- Documentation of clinical competency

After meeting all requirements and successfully passing the certification examination, a certified RNFA may use the title certified registered nurse first assistant (CRNFA) as an official credential. The CRNFA may recertify every 5 years by contact hours or by examination. Eligibility for recertification includes maintenance of CNOR status and documentation of active clinical practice as an RNFA with continued clinical competency for the 2-year period preceding the recertification date. A combination of clinical practice hours or points can be used for recertification. Box 5.1 describes recertification through combined methods.

For ease of processing, the certifications for CNOR and CRNFA were merged in January 1998 to allow recertification at the same intervals.

Certified Nurse Midwife

Certified nurse midwives (CNMs) are credentialed as advanced practice nurses to provide perinatal care. The CNM is a master's

Registered Nurse First Assistant Sample Performance Description

Job Title: Registered Nurse First Assistant (RNFA)

Purpose of Position:
Assist under the direction of the primary operating surgeon in the perioperative care of the patient undergoing a surgical experience. The RNFA uses the nursing process in the formulation of the plan of care. The RNFA functions within the policies and guidelines established by the facility and reports directly to the Surgical Unit Manager. The RNFA is an expanded role of the registered nurse and is accountable for exemplifying leadership and professionalism in the implementation of the role.

Qualifications:
1. Graduate of accredited school of nursing
2. Licensed to practice in the state of Ohio
3. Minimum of 24 months perioperative experience, both scrubbing and circulating
4. Satisfactory completion of CCI approved RNFA program
5. Certification in perioperative nursing (CNOR)
6. Certified in cardiopulmonary resuscitation, basic life-saver BCLS (CPR-ACLS preferred)
7. Accumulation of 125 contact hours of continuing education every 5 years to maintain CNOR status.
8. BSN and 2000 practice hours in role of RNFA if planning certification (CRNFA) credential with CCI.

Functions:	Satisfactory Performance:
1. Preoperative assessment and teaching of the patient and family (significant other)	1. RNFA reviews objective and subjective data. Is aware of lab results and pending tests. The assessment includes the patient as a member of a family unit and a member of society. RNFA is aware of cultural and personal influences in the interpretation of assessment data. RNFA communicates findings to the primary surgeon.
2. Formulation of nursing diagnoses	2. RNFA interprets the assessment data and plans care appropriate to the pending surgical procedure. RNFA collaborates with the primary surgeon and others to facilitate the pending surgical procedure and the attainment of favorable patient outcomes.
3. Recognizes potential hazards and initiates corrective action	3. RNFA is aware of the environment observing for potential sources of injury to self, team, and the patient. RNFA practices universal precautions at all times and is in observance of OSHA regulations.
4. Practices within the guidelines established by the state of licensure	4. RNFA:
	a. Handles tissue
	b. Provides exposure
	c. Uses instrumentation
	d. Sutures
	e. Provides hemostasis
	f. Closes tissue and skin
	Prohibitions:
	a. May not perform the intended procedure
	b. May not perform the task of the surgeon
	c. Does not simultaneously function as scrub nurse

• **Fig. 5.19** Sample performance description for registered nurse first assistant.

prepared RN who has been licensed and credentialed by the state board of nursing in his or her practice locale. The scope of practice includes antenatal care, gynecologic care, parturition care, and postnatal care. The CNM works with female patients in wellness centers, preventive settings, and childbirth. Occasionally a pregnant patient will present with complications requiring cesarean delivery. Usually the CNM has been with the patient throughout labor and is present when the determination is made by the physician to perform a surgical delivery. The surgically trained CNM can shorten the interval wait for additional surgical staff to arrive by first-assisting in the cesarean birth.

5. Demonstrates intraoperative competency as an RNFA	5. Knowledge:
	a. Principles of asepsis and infection control
	b. Surgical anatomy and physiology
	c. Surgical procedures
	d. Recognizes hazards and effects safety measures
	Skill:
	a. Manual dexterity
	b. Suturing and ligating
	c. Providing hemostasis
	d. Exposing the surgical site
	e. Positioning, prepping, and draping
6. Continuous assessment of the patient during the intraoperative phase of the surgical experience	6. RNFA observes condition of patient and initiates emergency measures as needed.
7. Postoperative assessment, evaluation and teaching	7. RNFA accompanies the patient to the postoperative unit as needed and communicates with the patient and family (significant other) as designated by the primary surgeon. RNFA, in collaboration with the primary surgeon and others, evaluates the attainment of expected outcomes.
8. Communicates postoperative information as directed by primary surgeon	8. Writes orders as per policy for verbal orders with the co-signature of the primary surgeon.
9. Adheres to institutional policies and procedures reflecting attendance, registered nurse professional responsibility, standards of care, and communication through chain of command	9. Observes institutional policy and practices the art and science of registered nursing in the expanded role of the RNFA

• **Fig. 5.19, cont'd**

• BOX 5.1 CRNFA Recertification Requires That the CNOR Credential Is Maintained

Clinical Practice Hours and Points

- 1000 clinical practice hours (at least 700 hours must be intraoperative care) and 400 points
- 500 clinical practice hours (at least 350 hours must be intraoperative care) and 500 points

Recertification by Examination

- 1000 clinical practice hours to recertify by examination; 700 hours must be intraoperative care.

The CNM works collaboratively with an obstetrician who performs the surgical procedure. Most states permit the CNM who has had appropriate additional training to function in the role of first assistant in the cesarean procedure. Training includes surgical anatomy, procedure steps, suturing, and the safe use of surgical instruments. This does not necessarily qualify the CNM as a fully credentialed RNFA for all procedures, but rather only those procedures associated with the female reproductive system during childbirth. Some CNMs first-assist during gynecologic procedures on nonpregnant patients with additional training and medical staff credentialing. The CNM does not meet the requirements for certification as an RNFA unless a formal RNFA course has been completed. The CNM in the first assistant role in the cesarean section provides continuity of care with his or her patient population.

This role is supported by the American College of Nurse-Midwives, the American College of Obstetricians and Gynecologists, and the American College of Surgeons. Some state boards of nursing prohibit the CNM from first-assisting. They state that the CNM must also meet the same educational requirements as an RNFA to be permitted to first-assist. (More information is available at www.midwife.org/.)

Physician Assistant

The medical staff may approve privileges for an allied health care professional referred to as a physician assistant (PA) who is qualified by academic and clinical training to first-assist in the operating room (OR) and function in other areas of perioperative patient care. The extent of a PA's practice is defined by state law, facility policy, and preference of the employing physician. Prescription authority has been granted at various levels in 48 states.

Most students entering PA school have at least 4 years of health care experience and a minimum of a bachelor's degree. Many PA programs are housed within medical schools, and their graduates are referred to as physician extenders. The first 2 years of the program are accomplished in the same classes with the medical students. The clinical component of their education includes 2000 clinical hours, and practice requirements include registration or licensure by the state in which they practice. The role of the PA evolved in the late 1960s and now incorporates 134 accredited programs throughout the United States that incorporate 26 months of PA education.

Physician assistant is a generic term with two subcategories: the assistant to the primary care physician in the clinical area and the first assistant to the surgeon. The PA who functions as a first assistant in surgery is required to have surgical training in addition to the baseline PA education. The surgical education process usually encompasses six semesters of clinical surgical experience. Eligibility for acceptance by the medical staff either as a PA or a **surgical assistant** (SA) is determined by the following criteria:

- Exercising critical thinking within areas of competence, with the physician member of the medical staff having the ultimate responsibility for patient care
- Participating directly in the management of patients under the supervision or direction of a member of the medical staff
- Documenting progress notes on patients' medical records and writing orders to the extent established by the medical staff
- Writing limited prescriptions in 47 states, Guam, and the District of Columbia; the educational requirement is a minimum of 78 credit hours in pharmacology
- Performing direct patient care in conformity with applicable provisions of medical staff bylaws, which may include obtaining medical histories and performing physical examinations

The SA performs duties under the direct supervision of a surgeon, who maintains the direct responsibility for the patient. The assistant may perform tasks delegated by the surgeon for the care of patients in any setting for which the surgeon assumes responsibility. The SA education program has an intense intraoperative focus.

After completion of a formal Commission on Accreditation of Allied Health Education Programs/Accreditation Review Committee on Education for the Physician Assistant (CAAHEP/ARC-PA)–accredited academic program, the PA or SA should attain national certification by taking the Physician Assistant National Certifying Exam (PA-C). The recertification period is 6 years and includes a 100-hour continuing education (CE) requirement every 2 years. The medical staff bylaws delineate the practice privileges of the assistant within the hospital.

Reimbursement for services is made to the PA's employer. Medicare reimburses at 85% of the physician's fee schedule for clinical care and 13.6% of the surgeon's fee for first-assisting in surgery. The PA's reimbursement is paid directly to the employer whether it is a private physician practice or a hospital surgical department. More information is available at www.aapa.org. (Specific questions can be addressed by e-mail at aapa@aapa.org.)

Surgical Technologist

A certified surgical technologist (CST) may also be trained to first-assist in a program of study approved by the Association of Surgical Technologists (AST) and the National Board of Surgical Technology and Surgical Assisting (NBSAST). An associate's degree should be the minimal entry-level requirement for CSTs who enter a postgraduate first-assisting program as described by NBSTSA and Accreditation Review Commission for Surgical Technology and Surgical Assisting (ARC/STSA), the certifying and accrediting bodies for surgical technology. For CSTs with at least 2 years of first-assisting experience during the previous 4 years, a national first-assisting certification examination is available from the NBSTSA. After successfully passing this examination, the CST first assistant may use the initials CST/CFA.

At the time of original certification as a CFA, the CST time period of the certification is adjusted to be of the same duration as the CFA portion of the certification. Both aspects of the certification will be adjusted for the same period of 2 years. Recertification as a CST/CFA is accomplished by providing documentation of practicing as a CST/CFA for 2 years during the certification period and by obtaining 37.5 CE credits approved by the NBSTSA. Another option is to document 2 years of practice as a first assistant and take the certification examination again.

Several states have indicated that first-assisting is not within the role of the ST. The ST should not first-assist unless he or she has attended a formal first assistant training program accepted by the ARC/STSA or NBSTSA. Basic ST programs following the core curriculum for surgical technology do not prepare an ST for first-assisting duties. Random clamping, mishandling of tissue, or holding retractors inappropriately can cause serious injury and should not be taken lightly. (More information is available at www.ast.org.)

Administration of Perioperative Patient Care Services

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Define the role of the perioperative management team.
- Describe the relationship between the perioperative environment and other patient care departments.
- Define the role of intradepartmental surgical services committees.
- Facilitate mediation in conflict resolution.

KEY TERMS AND DEFINITIONS

Administrator Person who directs or manages departmental affairs; may be a nurse or physician.
Capital budget Monies for larger purchases that have lasting-use implications for a time-defined period. Some items depreciate over time and need replacement as technologies change.
Committee Group within the organization that is assembled to perform a specific task.
Evidence-based practice Procedure or activity that is validated with scientific proof in a clinical setting.
Inservice education Departmental programs designed to introduce or demonstrate equipment, techniques, or procedures used in perioperative patient care.
Learning organization Functional group that includes all personnel involved with the facility. The organization needs to learn from experience and the environment if it is to survive and grow. Stagnation and inflexibility are costly and a main cause of failure and financial loss.
Manager Person who plans and executes directives passed down from administration.
Materials Supplies, such as reusable or disposable goods, ordered and maintained in stock for departmental use in patient care.
Operational budget Monies appropriated for the costs of day-to-day business.
"Sacred cow" Practice that continues despite lack of scientific evidence or validation with evidence-based practice.
Systems thinking Process by which the learning organization collectively examines practices and processes during analysis of root causes. This mechanism examines long-term activity, not just one single change. It is a circular process of business and people skills.

Establishing Administrative Roles

The perioperative patient care team surrounds the patient throughout the perioperative experience. This direct team functions within the physical confines of the operating room (OR), which is one part of the physical facilities that comprise the total perioperative environment. Other areas in the perioperative environment include preadmission testing (PAT), the ambulatory services unit (ASU), and the postanesthesia care unit (PACU). Likewise, the perioperative patient care team makes up only one part of the human activity directed toward the care of the surgical patient.

Many other people function in an indirect relationship with the patient and contribute vital supporting services toward the common goal of ensuring a safe, comfortable, and effective

perioperative environment. The relationship and duties of perioperative staff members vary according to the size and extent of the physical facilities and the number of personnel employed. No person's job is insignificant. Each staff member has important functions to perform, and each is responsible for assuming a part of the total workload.

The purpose of this chapter is to acquaint the perioperative staff with the role of the management team and the nature of the job they have to perform. This is not a "how-to" chapter on management but, rather, a descriptive collection of structural and elemental components of the underpinnings of a surgical services department.

Current online leadership-based information keeps managers informed of new developments in the perioperative arena.

Magnet Recognition

Leading the Way to Magnet Status

The Magnet Recognition Program was founded in the early 1990s by the American Nurses Credentialing Center (ANCC) as a way to improve health care management, staffing, and outcomes. Magnet recognition is the highest acknowledgment on a national level of ongoing nursing care excellence through education and development.[1] Detailed information and a visual diagram are available at www.nursingworld.org.

Activities in a Magnet hospital are highly visible to the public and point to 14 forces that form the core values of this distinguished title (Box 6.1). The five primary hallmarks of Magnet status are as follows, and individual manuals are available:

1. *Transformational leadership:* Demonstrated vision, influence, clinical knowledge, and expertise in professional nursing practice.
2. *Structural empowerment:* Mission, values, and vision are manifest in outcomes through professional partnerships and collaborations with the staff.
3. *Exemplary professional practice:* Application of the nursing process and the emergence of new knowledge are reflected with the response from patients, families, the team, and the community at large. This is a circular process.
4. *New knowledge, innovation, and improvements:* Continual implementation of improved methods and new information helps refine the system through **evidence-based practice**. Individualized care uses a blend of new and old techniques.
5. *Empirical quality results:* The end result of care is compared with benchmarks established along the way. Making a difference is emphasized through innovation and creativity. Standards remain, but flexibility is the strategy to gain new learning directed at improved outcomes.

• BOX 6.1 Fourteen Dimensions of Magnet Recognition Status (Known as "Forces of Magnetism")

1. Quality nursing leadership
2. Organizational structure
3. Management style
4. Personnel policies and programs
5. Professional models of care
6. Quality of care
7. Quality improvement
8. Consultation and resources
9. Autonomy
10. Community and the hospital
11. Nurses as teachers
12. Image of nursing
13. Interdisciplinary relationships
14. Professional development

Eligibility for Magnet Status

A formal application is preceded by an analysis of current workplace status. The nursing division must be part of a larger health care organization. A manual is available from the ANCC website www.nursingworld.org to assist in determination of eligibility. The process includes a documentation phase and a site visit by the Magnet recognition appraisal committee. The site visit is funded totally by the applicant organization. The Commission on Magnet Recognition renders a decision concerning status within 3 to 4 months of the site visit and a review of all application documentation. Magnet recognition is effective for 4 years, during which time spot inspections may be made to assess for variances.

Some prerequisites to application include, but are not limited to, the following requirements:

1. Data collection concerning quality and outcomes must become part of a national database for benchmarking nurse-sensitive quality indicators at the patient care division level.
2. Commitment to educational preparation of nursing administration:
   a. The Chief Nursing Officer (CNO) is required to be master's degree prepared when the application is submitted. The baccalaureate or master's degree may be in nursing. The CNO must participate in the highest structural governance and be ultimately responsible for all nursing divisions.
   b. Since January 2013 a baccalaureate degree in nursing is required for 100% of nurse managers or nurses in an educational role at the time of application.
3. ANCC's *Nursing Administration: Scope and Standards of Practice* must be in effect for adequate measuring and surveying by Magnet site visitors.
4. The organization must be in full compliance with all local, state, and federal laws and regulations.
5. Compliance with National Safety Patient Goals from The Joint Commission (TJC) is required.
6. Policies and procedures must be in place to permit nurses to voice concerns about the practice environment without retribution.

Maintaining Magnet Status

Ongoing quality improvement and evaluation of performance are documented in writing during the first 2 years of Magnet status. Staff and physician demonstrations of collaborative teamwork are highly valued aspects of the Magnet credential. Changes in management personnel and differences in attainment of expected outcomes may trigger the need for additional reporting or an additional site visit.

During the third year of Magnet recognition a renewed application for the credential is made complete with arrangement for a site visit. All measurable indicators outlined in the Magnet Application Manual must remain at 100% of Magnet criteria to maintain or request redesignation of the credential of Magnet status.

Benefits of Magnet Status

Nursing care is more clearly defined, which offers the opportunity for professional growth and enrichment and thereby supports

recruitment and retention of staff. Nursing turnover is minimized. Nursing **administrators** utilize programs such as the Effective Performance Management Strategies for Nurse Leaders to provide guidance for a stable managerial environment. Magnet status can be highly publicized and prized by the marketing department of the facility. Reimbursement sources recognize the credential and use the facility as a referred recommendation to insured groups. The public views the credential as a reassuring atmosphere of safe, efficient care.

Management of Surgical Services

Perioperative Administrative Personnel

Personnel should know the direction of the entire organizational effort as a prerequisite for successful functioning. Administrative personnel are responsible for interpretation and education of hospital and departmental philosophy, objectives, policies, and procedures to the perioperative staff. These terms are generally found in the orientation manual and can be defined as follows:

1. *Philosophy:* Statement of beliefs regarding patient care and the nature of perioperative nursing that clarifies the overall responsibilities to be fulfilled.
2. *Objectives:* Statements of specific goals and purposes to be accomplished during the course of action and definitions of criteria for acceptable performance.
3. *Policies:* Specific authoritative statements of governing principles or actions, within the context of the philosophy and objectives, that assist in decision making by providing guidelines for action to be taken or, in some situations, for what is not to be done.
   a. *Basic policies:* Statements of the principles of the administration and its approach to functioning. Examples include disallowing smoking by anyone on facility premises.
   b. *General policies:* Guidelines of the principles dealing with everyday situations that affect all personnel within the hospital. Examples include requiring all personnel, regardless of role, to be certified in cardiopulmonary resuscitation (CPR).
   c. *Departmental policies:* Guidelines structured to meet the needs of a specific work unit (e.g., OR policies). Examples include dress codes for specific areas.
4. *Procedures:* Statements of task-oriented and skill-oriented actions to be taken in the implementation of policies.

Perioperative Nurse Manager

In most accredited facilities a registered nurse (RN) is responsible for administration and supervision of all perioperative patient care services. The perioperative environment is a business unit and high-cost center of the hospital. It is usually run by an administer, director, or vice president and managed as a business to control costs and maintain effectiveness. The title and functions of the perioperative nurse manager is reflected by the size of the facility and complexity of the administrative responsibilities.

In larger hospitals the perioperative nurse manager may hold some variation of the title of director of perioperative services or assistant vice president. Because of the magnitude of the administrative duties, actual supervision of personnel may be delegated to a line manager or charge nurse. In smaller hospitals in which administrative responsibilities focus mostly on one department, the perioperative nurse manager directly supervises personnel. In other situations, one nurse may manage more than one clinical service, such as the OR, PACU, ASU, special procedures room, or central processing department. The term **manager** is used throughout this text to designate the perioperative nurse responsible for coordinating patient care and related support services of the department.

The perioperative nurse manager should have strong knowledge of nursing theory and practice, specialized knowledge of OR technique and management, and knowledge of business and financial management. The manager should possess leadership and people management skills to supervise and direct patient care within the perioperative environment according to established principles and professional standards.[2] The main function of the manager is to provide leadership that promotes a cooperative team effort. Leaders need additional business skills and knowledge, which concern functions of management that include planning, organizing, staffing, directing, and controlling, problem solving, decision making, coordinating, and communicating.

People Skills and Communications

The perioperative manager works to build a successful team. Communications are fostered through the philosophy extended by those in leadership. Perioperative personnel use many tools to communicate information. Some of the standardized mechanisms for relaying information and enhancing team performance are expressed in the following list:

1. *TeamSTEPPS* (Team Strategies and Tools to Enhance Performance and Patient Safety) was developed for the Department of Defense Patient Safety Program in collaboration with the Agency for Healthcare Research and Quality. It includes core values of teamwork such as leadership, situation monitoring, mutual support, and communication. The outcomes affect performance, knowledge, and attitudes. I PASS THE BATON I is the mnemonic that describes the communication activities as part of TeamSTEPPS. Detailed information can be found at www.ahrq.gov/TeamSTEPPS.
2. *Leadership* organizes and articulates clear goals. Decisions are made with input from team members, who feel empowered enough to speak when information needs to be imparted to the group. Team relations are supported, and conflicts are resolved. Events are planned, problems are solved, and performance is improved by evaluating processes.
3. *Situation monitoring (STEP: S*tatus of patient, *T*eam members, *E*nvironment, and *P*rogress toward goal) is an ongoing process of constant vigilance for progress or regress of goal attainment. Each team member is responsible for personal safety.
4. *Mutual support* is actively given and received by all team members. Feedback is timely, considerate, and respectful. Information exchanged is specific and directed toward improvement of team performance. Concerns should be voiced and elicit a response to be certain of successful communication. If a situation is an essential safety breach, any team member may "stop the line," meaning that the activity or procedure immediately halts without fear of repercussions. The goal is still met without compromising relationships.
5. *Communication* ranges from basic information to critical dialogue. One structured communication technique uses *SBAR (S*ituation: What is going on with the patient? *B*ackground: What is the clinical context or history related to the patient? *A*ssessment: What is the presumed problem? *R*ecommendation and request: What can we or I do immediately to correct the situation?) Other communication tools such as: HUDDLE (Healthcare Utilizing Deliberate Discussion Linking Events), SWITCH, or SURPASS can be used. The method of communication should be standardized, include all team members,

and may include a checklist. A briefing should take place before each procedure and debriefing before the patient is transferred from the OR to the postanesthesia area.[3]

The "call out" and "check back" feedback methods are used to validate the correctness of the received message (e.g., the surgeon asks for 10 mL of lidocaine plain, and the scrub person repeats "10 mL lidocaine plain" as the syringe is passed to the surgeon's hand). The surgeon should acknowledge the correctness of the exchange. "Handover," or patient transfer of care, report is included in this activity. Transitions of care include shift change, breaks, addition of team members to the field, and change of surgeons or anesthesia providers.

Barriers to Effective Communication

Human factors can interfere with communication and team effectiveness. Some problems include rapid turnover in team members, lack of knowledge, personnel who are rushed for time, withholding of information, pecking order, defensive behaviors and insecurity, laziness, complacency, poor follow through, fatigue, excess workload, distractions, conflicts between team members, lack of role clarity, and misunderstandings.

Managers must work toward a just culture in the OR to minimize the human factors that affect safe performance of patient care. A continual appraisal of actions and outcomes should focus on accountability for patient and team safety, even if it means losing some productivity.[4]

Managerial Responsibilities

The manager is responsible for the allocation and completion of work but does not do it all or make all of the decisions. Qualified personnel are employed, and they are delegated increasing responsibility as they develop competence in their work. An organizational attitude develops that can function well in the manager's absence.

The manager implements and enforces hospital and departmental policies and procedures. He or she constantly analyzes and evaluates all patient care services rendered and, through participation in research, seeks to improve the quality of patient care given. The manager retains accountability for all related activities in the perioperative environment. The scope of this accountability includes the following tasks:

- Provision of competent staff and supportive services that are adequately prepared to achieve quality patient care objectives.
- Delegation of responsibilities to professional nurses and assignment of duties to other patient care personnel.
- Responsibility for evaluation of the performance of all departmental personnel and for assessment and continuous improvement of the quality of care and services.
- Provision of educational opportunities to increase knowledge and skills of all personnel.
- Coordination of administrative duties to ensure proper functioning of staff.
- Provision and fiscal control of **materials**, supplies, and equipment.
- Coordination of activities between the perioperative environment and other departments.
- Creation of an atmosphere that fosters teamwork and provides job satisfaction for all staff members.
- Identification and resolution of problems in a decisive, timely manner.
- Initiation of data collection and analyses to develop effective systems and to monitor efficiency and productivity.

Clinical Coordinator

An assistant nurse manager aids in administration and supervision of nursing service in the OR and is directly responsible to the perioperative nurse manager. This nurse acts as administrative head in the absence of the manager. The position usually does not exist in small hospitals. In large hospitals one or more clinical coordinators provide leadership to specific services and assist with the management of manpower and material resources.

Head Nurse or Charge Nurse

The head nurse or charge nurse functions in a line management position as a liaison between staff members and administrative personnel. In some hospitals the title of head nurse is given to the person whose position is comparable with that of a coordinator. In other, typically smaller, hospitals the perioperative nurse manager functions more or less in the capacity of a head nurse; for simplicity, the term *head nurse* is used to refer to this role.

In large hospitals with many surgical specialty services a head nurse may be responsible for the administration and direct supervision of patient care in a particular specialty service, such as ophthalmology, neurosurgery, cardiovascular surgery, or urology. With this structure, several head nurses are in the department. These head nurses should have the technical proficiency necessary for the specialty service for which they are responsible and should have sufficient managerial ability to plan for and administer effectively the patient care activities.

The duties of the head nurse include, but are not limited to, the following tasks:

- Planning for and supervising patient care activities within the OR suite or specific room(s) to which he or she is assigned.
- Coordinating patient care activities with the surgeons and anesthesia providers.
- Maintaining adequate supplies and equipment and providing for their economic use.
- Observing the performance of all staff members and providing feedback.
- Interpreting the policies and procedures adopted by the department and hospital administration.
- Informing the perioperative manager of needs and problems that arise in the department and assisting with problem solving.
- Assisting with orientation of new staff members.

Functions vary in different hospitals, but the position of head nurse, with its direct and continuous responsibility for both patients and staff, is an important one.

Perioperative Business Manager

Some hospitals employ a perioperative business manager, who sometimes has the title of unit manager. This person may report to the perioperative manager or directly to the hospital administrator. Lines of authority and responsibility between the business manager and the perioperative nurse manager should be clearly defined regardless of the organizational structure. The business manager directs the management of daily operational and indirect patient care functions in the perioperative environment.

Non-nursing administrative duties should include maintenance of a clean, orderly, safe environment within the department for patients and personnel. This entails more than removing visible dust and dirt.

A safe environment is defined as free of contamination, electrical and fire hazards, and negligence. Formulation of procedures is necessary. Personnel should be trained. However, inspection and follow-up are equally important. The business manager coordinates

these efforts with the supporting service departments: housekeeping, maintenance, laundry, and materials management.

A business manager may prepare and administer the department budget. This duty may include maintaining inventories and evaluating supplies and equipment. If the hospital does not employ a business manager, the nurse manager or coordinator assumes responsibility for these duties.

Advanced Practice Registered Nurse or Clinical Nurse Specialist

Within any organization a formal structure of authority and responsibility exists. However, the evolution of technology and the acute illnesses of patients have changed the focus of functions for many nurses within the hospital organization. With experience the advanced practice registered nurse (APRN) can manage patient care and direct the activities of others. This practitioner may hold the title of perioperative nurse clinician, clinical nurse specialist (CNS), or APRN. Although the term *practitioner* is used to describe any or all of these advanced roles, differentiation is made within the profession on the basis of formal academic education that includes master's degree preparation and specialty certification.

The CNS is comparable to other perioperative APRNs in an advanced role and is a graduate of a master's degree program in nursing (master of science in nursing [MSN]), with a clinical specialty. APRNs and CNSs serve as role models for and consultants to the professional nursing staff and as teachers of patients and other personnel. The CNS conducts research to validate nursing interventions. These skills can be used effectively for advanced practice in the perioperative environment.

Some APRNs are registered nurse first assistants (RNFAs), and those who have attained certification in this role are credentialed as certified registered nurse first assistants (CRNFAs). APRNs in this role are not required to concurrently maintain a certified perioperative nurse (CNOR) status because of other advanced certifications. The AORN position statement concerning APRNs as RNFAs requires completion of an RNFA program that meets the AORN standards set for RNFA education as of January 1, 2016.

The APRN is capable of exercising a high degree of discriminative judgment in planning, executing, and evaluating nursing care based on the assessed needs of patients with one or more common clinical manifestations. A practitioner may develop the plan of care for a group of orthopedic patients, for example. This plan is coordinated for each patient with the surgeon, other professional nurses, and allied health care personnel who assist in the performance of functions related to the plan.

Clinical nursing interventions are not necessarily performed by the practitioner. The APRN decides which nursing interventions can be performed by others and which he or she personally should do. These decisions are based on personal interaction with each patient and knowledge of the clinical condition. The practitioner exercises a degree of autonomy and independence within the clinical setting. Some state boards of nursing have permitted select APRNs to have minimal prescriptive powers.

Because a practitioner has advanced academic preparation in theoretic knowledge and clinical experience in a particular clinical patient care setting and is an expert in nursing situations in that setting, qualified clinical coordinators may function as practitioners. In this role they assist in planning the total care for each surgical patient, in coordinating nursing and supportive services, and in participating in the orientation, development, and evaluation of caregivers assigned to direct patient care functions in the perioperative environment.

The APRNs who assess individual patient needs through personal patient interviews and physical examinations and who plan for individualized care in the perioperative environment truly function as perioperative nurse practitioners. Using specialized judgment and skills, they make decisions relative to direct and indirect patient care in the perioperative environment. Solving problems and making decisions are the heart of professional management and professional leadership.

The practitioner may work solely or primarily with the surgeons in a specific surgical specialty. Some APRNs work as independent contractors with a surgical group as a qualifier for APN certification. This concept of nursing specialization coincides with the specialization of surgeons. With practice and formal or informal study, nurses develop expertise in planning and implementing care for patients with comparable surgical problems. Skills and knowledge become highly specialized. Surgeons in that particular specialty rely on these nurses to supervise the care of their patients and to direct less experienced personnel on the perioperative team.

Perioperative Education Coordinator

Planned educational experiences are provided in the job setting to help staff members perform competently and knowledgeably. Most hospitals have a staff development department committee to plan, coordinate, and conduct educational and training programs.

An orientation program is planned for each new employee. All new personnel should become familiar with the philosophy, objectives, policies, and procedures of the hospital and patient care services. This general orientation program assists the new employee to adjust to the organization and environment. It is coordinated with an orientation to the duties in the unit to which the employee is assigned.

The inservice coordinator may be a member of the staff development department, the administrative staff, or both. This person is responsible for planning, scheduling, and coordinating the orientation of new staff, including a review of policies and procedures, performance description, and standards specific to the perioperative environment. On the basis of an assessment of individual skills the new employee is given guidance and supervision for a period of weeks to months until basic competencies are adequate for independent functioning. Head nurses, preceptors, and other experienced staff members assist with the orientation of new personnel.

Inservice education programs should be planned to keep the perioperative staff up to date on policies, new techniques, equipment, and patient care practices. Programs that focus on fire prevention, electrical hazards, security measures, and resuscitation training are important to ensure personnel and patient safety and are usually required yearly. Professional and technical programs designed to develop specialized job knowledge, skills, and attitudes that affect patient care are planned and presented. The inservice coordinator is responsible for assessing the educational needs of staff members collectively and individually and then for planning, scheduling, coordinating, and evaluating inservice programs. This individual may also conduct some sessions.

Staff development programs conducted on a continual basis enhance employee performance by maintaining job knowledge and clinical competence. Inservice programs may be supplemented by other appropriate continuing education programs held outside the health care facility or presented by qualified people who represent the industry.

Preceptor

The orientation process is facilitated by a one-to-one relationship between the new employee and an experienced staff member. The preceptor teaches, counsels, advises, and encourages the orientee until he or she can function independently. The preceptor is accountable for assessing the orientee's abilities, assigning activities accordingly, and assisting in carrying out duties safely. Learning needs can be assessed through interviews, observation, and a skills checklist.

To ensure consistency in teaching, the preceptor coordinates development of appropriate and measurable behavioral objectives for the orientee with the inservice coordinator, the management staff, or both. The preceptor should evaluate performance and offer constructive feedback to build the orientee's self-confidence. To be effective, the preceptor should have an interest in teaching and should have acquired the necessary skills and experience with adult learners. Some facilities offer a preceptor class that outlines topics such as communication and setting performance goals to become a successful preceptor. A facility may offer a monetary increase for performing in the preceptor role.

Interdepartmental Relationships

The perioperative environment is one of many departments within the total hospital organization. For continuity in patient care, many departments coordinate their efforts through the administration of the formal organizational structure of the hospital.[5]

Every hospital has a governing body that appoints a chief executive officer (CEO), usually with the title of hospital administrator, to provide appropriate physical resources and personnel to meet the needs of patients. Administrative lines of authority, responsibility, and accountability are defined to establish the working relationships among departments and personnel (Fig. 6.1).

A nurse executive, sometimes referred to as vice president of patient care services or director of nursing services, reports to the hospital administrator. The perioperative nurse manager reports to the nurse executive if perioperative services are a division under management of the nursing service. In some facilities, perioperative services are an independent unit not managed by the nursing service. The perioperative nurse manager then reports directly to the CEO, an assistant administrator, or the chief of one of the medical services. Through either channel of administration, many activities in the perioperative environment are coordinated with other patient care units and departments within the facility.

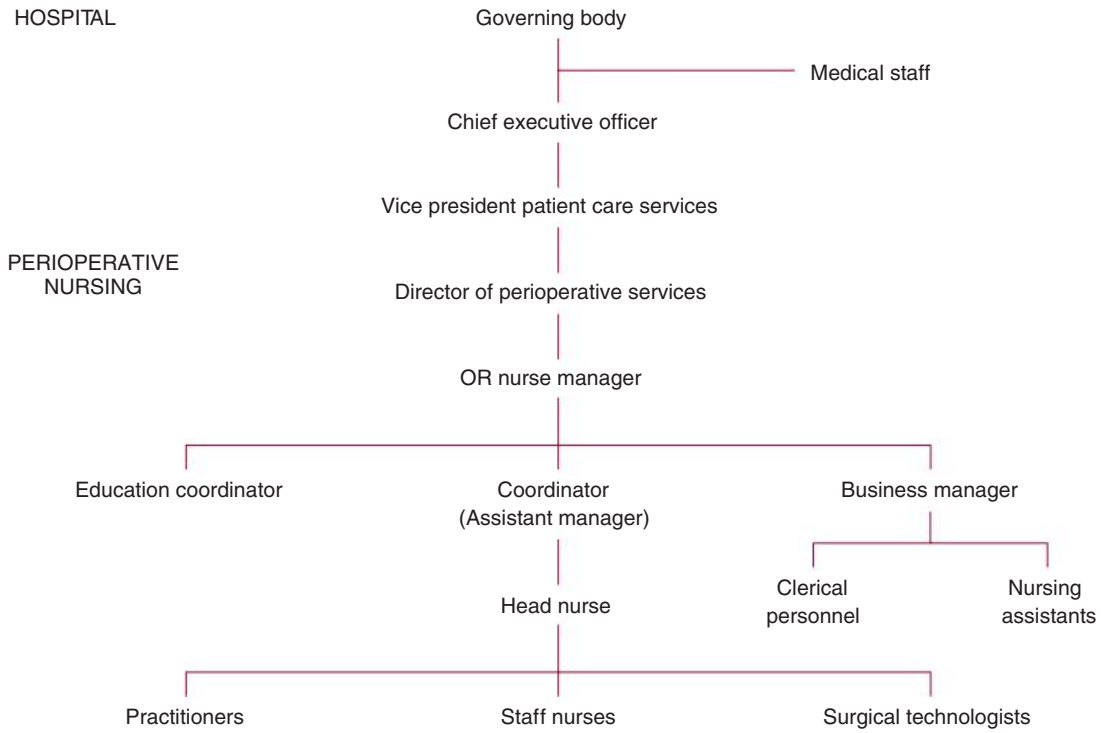
Patient Care Departments

Patient Care Division

Patients come to the OR directly from a short-stay or in-house patient care unit, an outpatient ambulatory care area, or the emergency department (ED). Channels of communication should be kept open among perioperative personnel and patient care personnel in other units. Coordination of preoperative preparation and transportation of patients prevents downtime in the perioperative environment. Many facilities use a comprehensive checklist system to ensure adequate preparation of surgical patients in a timely manner. This document accompanies the patient throughout the intraoperative and postoperative periods for continuity of care. An RN or licensed practical nurse/licensed vocational nurse (LPN/LVN) signs or initials each item accomplished. By the time the patient leaves for the patient care unit, all individual patient preparations have been completed along with a detailed handover report.

Emergency Department/Trauma Center

Often, victims of trauma and acutely ill patients are seen initially in the hospital ED. Cardiopulmonary resuscitative and other equipment is available for initiation of prompt triage and treatment.



• **Fig. 6.1** Management structure. Administrative lines of authority, responsibility, and accountability are defined to establish working relationships among departments and personnel.

Minor injuries usually can be treated in the ED. Some patients must be scheduled for an emergency surgical procedure, however. These patients may arrive in the OR before the results of all diagnostic tests are confirmed; therefore communication among the OR, ED, laboratory, and radiology personnel is vital to the success of surgical intervention. OR personnel should be advised as to the nature of the injury or illness to prepare all needed equipment and obtain supplies for the emergency surgical procedure.

Designated regional trauma centers should have teams of surgeons, anesthesia providers, and perioperative personnel who are immediately available in the hospital 24 hours a day. A trauma nurse coordinator is administratively responsible for all personnel and activities to ensure comprehensive trauma care.

Intensive Care Unit

Because surgery has become more specialized and complex, specialized patient care facilities where concentrated treatment can bring the patient to a satisfactory recovery have become a necessity. This care is provided in an intensive care unit (ICU), which is open 24 hours a day, 7 days a week. It is staffed by highly trained and specialized RNs. Critically ill patients who need constant care for several days are admitted directly from the OR, PACU, ED, or other patient care unit. Each bedside is equipped with therapeutic and monitoring equipment.

Depending on the size of the facility and its specialty services, more than one specially designed and equipped surgical intensive care unit (SICU) may be provided. One ICU may admit only cardiovascular surgical patients (coronary care unit [CCU]), another may admit only pediatric patients (pediatric intensive care unit [PICU]). In addition to SICUs, most hospitals also have a unit for nonsurgical (medical) patients (medical intensive care unit [MICU] or the neonatal intensive care unit [NICU]). The increased efficiency afforded by these units serves the best interests of both the facility and the patient. They create the most effective use of personnel and equipment and result in lower morbidity and mortality rates.

Movements of patients to and from the SICUs should be closely coordinated with the anesthesia provider, the perioperative nurse, and the PACU personnel. If the surgeon or anesthesia provider anticipates that a patient will need intensive care postoperatively, a SICU bed is reserved at the same time the patient is scheduled for the surgical procedure. The appropriate SICU should be notified promptly when the surgeon determines an unanticipated need for a bed. Sometimes the patient must wait in the OR or PACU for an available bed; occasionally, elective surgical procedures are postponed because sufficient SICU beds or staff are not available.

Obstetric Services

The obstetric unit is divided into three separate areas: labor and delivery (L&D), postpartum care, and newborn nursery. Most L&D units are equipped and staffed for delivery by cesarean section (C-section). However, in other hospitals, patients scheduled for either elective or emergency C-section are brought to the OR. In addition to supplies needed for the surgical procedure, adequate resuscitative equipment must be available for the newborn. Some facilities require the OR personnel to be on call for all C-sections in both the OR and the L&D unit.

The L&D units that staff for C-sections provide their own circulating and scrub nurses. These nurses are eligible for CNOR status. Many departments are staffed with their own RNFAs specific to the role of assisting on C-sections. Certified nurse midwives (CNMs) serve in the first assistant capacity after appropriate training but are not considered RNFAs unless they have completed an RNFA program in accordance with AORN Standards for RNFA Education.

Patient Services Departments

Radiology and Nuclear Medicine Departments

Frequently, personnel from the radiology (x-ray) and nuclear medicine (radiation oncology) departments assist with diagnostic or therapeutic interventional procedures in the OR. For some procedures, perioperative personnel may need to go to the radiology department to assist the surgeon during an interventional procedure that necessitates sterile technique. Many surgical services departments have an onsite radiologic interventional room for endovascular procedures, such as angioplasty or vascular stenting. Specialized interventional procedure rooms may be located near the main OR in the event an open procedure is necessary. An emergency plan should be in place for this type of situation to have available staffing, OR, and necessary equipment.

Whenever a diagnostic or surgical procedure is scheduled that will require use of radiology equipment or a radioactive implant, all departments should be notified at least the day before. This facilitates the scheduling of personnel and workload in all departments. Provisions for handling hazardous materials can be made.

Pharmacy

Many drugs are routinely stocked in the OR suite for the anesthesia providers' use, and some are kept for use by the surgeons during surgical procedures. These are obtained via requisition from the pharmacy. Narcotics are always kept under lock, and each dose is recorded as it is dispensed. A satellite pharmacy may be established in the surgical services department to dispense unit doses of medication on a per-case basis.

Pharmacists are resource people who convey drug information to physicians and nurses. They should be responsible for preparing all admixtures, but often the mixing of medications is done by RNs in the preoperative holding area, OR, PACU, and SICU to expedite administration. The pharmacist is responsible for quality control of drug product services throughout the hospital.

Blood Bank

All hospitals have a blood transfusion service or blood bank. This is a highly technical service for collecting, testing, processing, and distributing blood products. If the hospital does not have its own blood bank, blood may be supplied from a regional blood center. Written policies and procedures for blood transfusion services must conform to the standards of the American Association of Blood Banks. These standards include criteria for accepting blood donors, laboratory testing of donor and recipient blood, and preparing and administering blood products for therapeutic purposes. Blood banks dispense whole blood, plasma, packed cells, or platelets only as they are needed.

If in advance of an elective surgical procedure the surgeon anticipates that blood loss replacement may be necessary, the patient may have his or her own blood (autologous) drawn and stored in the blood bank for autotransfusion—a blood replacement

procedure. Blood bank technicians also may participate on autotransfusion teams for collection of patient blood intraoperatively and postoperatively.

If autologous blood is not available or additional units of donor blood (homologous) are needed, a sample of the patient's blood is sent to the blood bank for type and cross-match. In emergency situations this blood sample may be sent from the ED or the OR. The units of blood products ordered by the surgeon or anesthesia provider are prepared and labeled with the patient's name and blood data. Suspected or recognized adverse reactions to blood transfusion must be documented on the patient's chart and reported to the blood bank.

Pathology Department

The pathologist, a physician who specializes in the cause and effect of disease, may be on call at a moment's notice to examine tissue while the patient is anesthetized. This enables the surgeon to proceed immediately with a definitive surgical procedure if malignant tumor cells are found, without subjecting the patient to a second surgical procedure at a later time.

A small laboratory may be located within the perioperative environment with equipment for microscopic tissue examination. This laboratory may be used for other tests and for taking photographs of tissue specimens removed from patients. Routinely, all tissue removed during a surgical procedure is sent to the pathology department for a minimum of gross examination.

Clinical Laboratory

Samples of blood, urine, and body fluids are taken to the clinical laboratory for analysis. Some analyses are routinely performed preoperatively. Others are done during a surgical procedure, such as blood gas analysis. Samples are obtained and immediately sent to the laboratory, or they may be obtained during a surgical procedure for analysis later, such as a culture for determination of the cause of an infection.

Biologic testing of sterile supplies is done routinely. The perioperative environment may undergo biologic testing when a contamination problem is suspected. The bacteriologist, who specializes in the study of microorganisms, may come into the OR suite to collect samples for testing, or OR personnel may collect samples and send them to the laboratory. The results provide a method for evaluating the effectiveness of procedures and the degree of adherence to environmental standards.

Departmental Service Divisions

Medical Records Department

Clinical records include the admitting diagnosis, the patient's chief complaint, complete history and physical examination findings, the results of laboratory examinations, and the physician and nurse care plans. Most hospitals are moving toward electronic medical records accessible to all authorized caregivers via computer and the Internet. Records should state the therapy used, including surgical procedures, and include progress notes, consultation remarks, the patient's condition on discharge, and observations in case of death. A summary of the hospitalization experience should be complete. These records are signed in writing or electronically by the physicians and nurses attending the patient.

The anesthesia record completed during the surgical procedure by the anesthesia provider also becomes part of the patient's record. The circulator should document pertinent remarks regarding the care rendered in the OR and the patient's response on the nurses' note sheets or the progress notes. Documentation is a responsibility of all professional team members who implement direct patient care.

Notes about the surgical procedure should be explicit, dictated promptly after completion of the procedure, and incorporated into the record of each surgical patient. For the surgeons' convenience, many hospitals have dictating machines or a phone hookup with the medical records department installed within the OR suite, usually located in the dressing room or lounge. Voice recognition software can be used to dictate procedural notations in the patient's electronic records. Many surgeons have handheld dictation/transcription devices for immediate use and convenience.

Details of the preoperative and postoperative diagnosis and the surgical procedure itself may have medical and legal significance. Transcription of the surgeon's dictation and maintenance of the patient's chart after discharge from the hospital are responsibilities of the medical records department. The patient's printed chart may be put on microfilm or captured electronically for storage.

Environmental Services

Housekeeping functions are recognized as important preventive measures to eliminate microorganisms from the hospital environment. Each hospital establishes an environmental routine for its particular needs. Usually the environmental services personnel and the perioperative personnel share housekeeping duties in the perioperative environment.

The amount of cleaning done by the perioperative personnel varies from one hospital to another. In many hospitals the members of the environmental services department terminally clean all furniture, flat surfaces, lights, and floors once a day at the end of the surgical schedule. In other facilities, they also clean the furniture and floors before the schedule starts and between each surgical procedure throughout the day. Specific details concerning the care of the perioperative environment can be found in Chapter 12.

Regardless of which plan is followed, environmental services personnel should have a storage area within the OR suite where they keep their equipment and supplies. Equipment used for cleaning in the OR is not taken outside the suite.

The director of environmental services and the perioperative nurse manager plan the division of work. Personnel in each department should understand their responsibilities. The perioperative nurse manager checks the work of the environmental personnel and keeps in touch with their director concerning their performance.

The director evaluates and chooses the proper solutions for effective cleaning, sets up a program and standard of performance for personnel, and sees that personnel are properly oriented and taught the appropriate procedures, including procedures for removal and disposal of trash and soiled laundry.

Use of a checklist helps to cover all areas to be cleaned and inspected on a routine and preventive maintenance basis, whether it is daily, weekly, or monthly. Weekly or monthly cleaning routines include walls and ceilings, in addition to the daily cleaning schedule within the perioperative environment.

The director impresses on the personnel the importance of the work and the part they play in enabling the perioperative personnel to carry out aseptic technique. The environmental personnel

function as members of the team when working with the scrub persons and circulators between surgical procedures.

Facilities Engineering

The facilities engineering department works closely with the OR department by providing a preventive maintenance program. This program includes routine monitoring of ventilation and heating, electrical and lighting systems, emergency warning systems, and water supply. Humidity is recorded every hour in the engineering department. Engineering department personnel should perform a monthly check of all electrical equipment. In addition, the department regularly tests the autonomous emergency power source and maintains a written record of inspection and performance.

The hospital water supply system should not be connected with other piping systems or with fixtures that could allow contamination of the water supply. The hot water supply and steam lines have temperature-control devices and filters regulated by the engineering department personnel. They are cleaned, and filters are changed on a routine schedule, usually weekly, to prevent accumulation of mineral deposits, especially in areas where hard water is used.

Clinical Biomedical Engineering

Competent technical personnel should be available to every area of the hospital to ensure the safe operation of equipment. Nearly every surgical procedure uses some form of powered instrumentation. Because of the variety and complexity of new instrumentation currently in use, most hospitals have a clinical engineer or biomedical equipment technician on staff or at least available. Large facilities may employ multiple engineers and technicians who specialize in medical equipment. This technical support group assists perioperative personnel in evaluating and selecting new equipment as well as installing, operating, and maintaining current equipment.

The clinical engineer is systems and applications oriented. This individual can compare different models and manufacturer specifications and provide recommendations for purchase. The biomedical equipment technician is knowledgeable about the theory of operation, the underlying physiologic principles, and the practical safe clinical applications of biomedical instrumentation. This individual can test, install, calibrate, inspect, service, and repair equipment. Every preventive service or repair is recorded in an instrument history file.

Materials Management

In an effort to control escalating health care costs, many hospitals belong to contract buying groups. This concept has changed the nature of the purchasing function and the management of supplies. The organizational administrative structure varies, but the basic functions of materials management are purchasing, processing, inventorying, maintaining proper function, and distributing supplies and equipment. Several departments are responsible for supplies.

Purchasing Department

The purchasing director coordinates the hospital's acquisition of supplies and equipment. Standardization of products used throughout the hospital fosters quantity purchases, which provides leverage in negotiating prices with vendors. Items that are too expensive to stock in large quantities or that are used infrequently are ordered through the purchasing department as needed. In some hospitals this department is referred to as materials management.

Central Storeroom

The purchasing director or materials manager determines the supplies to be stocked for the hospital. Bulk inventories are received and warehoused in the central storeroom. Each department then requisitions supplies as needed.

Central Processing Department

One area of the hospital is designed specifically for processing, storing, and distributing supplies and equipment used in patient care. This department may be referred to as central service or central supply; central processing; supply, processing, and distribution; or materials management. The functional design and workflow patterns provide for separation of soiled and contaminated supplies from clean and sterile items. Supplies are replenished on the patient care units on a predetermined schedule to maintain standard inventory levels. This may be done by central service with an exchange cart system (i.e., a cart of fresh supplies is exchanged for the one in use).

Control of patient charges for supplies also may be coordinated by central service. Inventory control is computerized in most hospitals. Bar code technology on individual packages may facilitate patient charges and inventory management.

Laundry Services

Many disposable nonwoven fabrics are used. However, some woven fabrics are processed daily for use in the hospital, such as patient gowns, bedding, and towels. Hospitals that do not have laundry facilities as part of their physical plant use a commercial laundry service. An adequate inventory should be maintained for daily use. The manager of laundry services assists in determining appropriate inventories and supervises the laundry processes. Reusable fabrics that must be sterilized before use are packaged and sterilized either in the central service or the sterile processing department.

Human Resources Department

Careful selection of capable, highly motivated people contributes to efficiency and effectiveness. The human resources department helps screen applicants with appropriate qualifications. Those applicants with potential for available positions are referred to the appropriate department head.

Potential employees are processed through human resources before an interview with the perioperative nurse manager is scheduled. The human resources department assists in hiring and terminating all employees. This department also provides resources for employee assistance and assists with progressive discipline.

Human resource departments sometimes use hiring or staffing (recruitment) agencies to find candidates for specific jobs that fit the needs of the facility, such as nursing, managers, and physicians. Online services have made job hunting easier and can reach many people. The use of agencies can reduce the cost of staffing a large full-service human resources department.

Coordination Through Committees

A **committee** is a group of people delegated to consider, investigate, take specific action on, and report on a matter of mutual concern or interest. Many activities within the facility are coordinated by multidisciplinary committees.

Each committee has a chairperson who conducts the flow of each meeting. A report that includes an attendance roster should be generated to document the activities of the meetings. Each committee member has a special contribution to make in the progress of the work of the group. Each member has a voice in the final outcome charged to the group.

Committee members are usually allotted time during the workday to attend meetings. Other compensation should be made when meetings are scheduled at times when members are not scheduled to work.

Surgical Services Committee

The surgical services committee is composed of the medical staff members who are vital to the management of the perioperative environment. One surgeon is appointed chief or director of the department of surgery. In teaching hospitals a surgeon is appointed chief of each specialty service (e.g., chief of orthopedics). The anesthesia department also designates a director of that department. These individuals are responsible for professional practice and administrative activities within their respective departments. They should maintain continuing evaluation of the professional performance of all members of the medical staff who have been granted privileges in their specialty. They also serve as liaison representatives between the medical staff and the hospital administrators.

The chief of surgery, the chiefs or representatives of the specialty services, the chief of the anesthesia department, the perioperative nurse manager, the coordinator, and the OR business manager meet at regular intervals to review departmental activities. The hospital administrator and vice president of perioperative services also may be members of this committee or may be invited to attend meetings relevant to their concerns.

The surgical services committee formulates policies and procedures that pertain to use of facilities, a schedule of surgical procedures, and maintenance of a safe environment. Evaluation of techniques and selection of new products may require a review of reports from other departmental surgical services committees, in addition to those prepared by perioperative personnel.

Because this committee determines policies and procedures for efficient functioning within the OR suite, persistent problems are brought before the committee, where recommendations for corrective action are made. For example, if temperature and humidity controls are not being effectively monitored or maintained, the committee may recommend to the hospital administrators that procedures be reviewed and revised by the maintenance department or that new equipment be installed.

If surgeons are repeatedly late in arriving, thus delaying the surgical schedule, a stronger policy may be indicated for the control and better use of facilities. If a new product is purchased, a new procedure may need to be written to specify its use and care.

Through data collection and a problem-solving approach to decision making, the surgical services committee seeks to improve the working relationships of all members of the OR team and the supportive services concerned with activities within the perioperative environment. Specific areas of concern for the surgical services committee include, but are not limited to, the following topics:

- Setting goals and objectives for the department.
- Monitoring policies and procedures.
- Planning for growth of services.
- Interrelationships between patient care areas within the department and the facility.
- Sanctions for noncompliance with policies and procedures.
- Review of preparations for the accreditation process.
- Resolution of subjects that interfere with the flow of the surgical services department.

Policies and associated directives formulated and approved by the committee serve as guidelines for governing the actions of surgeons, anesthesia providers, and the patient care staff while they are in the perioperative environment. The perioperative nurse manager shares with the surgical services committee, hospital administrators, and nursing service the responsibility for clarification, implementation, and day-to-day enforcement of approved policies and procedures.

Operating Room Safety Committees

Radiation Safety Committee

The radiation safety committee reviews the use of radiation exposure monitoring badges. This group sets policies and procedures for maintaining a safe environment where ionizing radiation is present. The committee may establish routines for periodic checking of lead aprons for intactness and for investigating reports of noncompliance with safety practices.

Laser Safety Committee

The laser safety committee establishes policies and procedures, standards, documentation systems, and credentialing criteria for the use of lasers in the health care facility. The laser safety committee also may be responsible for the development of training and continuing education programs for physicians, nurses, and surgical technologists. This committee may be a subcommittee of the surgical services committee. Members should include, but are not limited to, the chief of surgery, the chief of anesthesia, physician representatives from each surgical specialty that uses the laser, the perioperative nurse manager, the laser nurse specialists, a biomedical technician, and a representative of administration.

This committee may delegate safety surveillance duties to a laser safety officer (LSO), who is responsible for identifying problems and safety concerns with the use of lasers. The LSO may be a physician, nurse, or specially trained laser technician. The LSO is given the authority to stop any laser procedure if safety is in question.

Infection Control Committee

The infection control committee investigates hospital-acquired (formerly referred to as nosocomial) infections (HAIs) and seeks to prevent or control them. Membership may vary but should include representatives of the medical staff, hospital administration, and nursing service and the epidemiologist or infection control coordinator. Representatives from other departments attend meetings when the agenda is relevant to their particular concerns.

The committee meets at least quarterly. Members form a defense against HAIs by reviewing environmental factors and by determining whether the hospital is providing a safe environment for patient care. They review all infection reports and investigate HAIs. Committee members also review policies and procedures and scrutinize the entire chain of asepsis in an effort to determine and then eliminate possible sources of infection.

This committee has the authority to approve changes necessary to eliminate any hazardous practices. Included in its jurisdiction is the education of personnel so that they can provide a high standard

of patient care. A health care facility has a moral duty to provide a safe environment for its patients. The infection control committee aids the hospital in fulfilling this duty. Surveillance personnel assist in directing infection control policies, procedures, and practices.

Measures are taken to improve postoperative infection prevention by a national quality partnership of hospitals, referred to as the Surgical Care Improvement Project (SCIP). The list of prevention measures can be found at www.jointcommission.org. By adhering to the recommendations of the SCIP project the additional costs and length of stay can be reduced by establishing evidence-based practices for prevention of surgical site infections (SSIs). The Center for Medicare & Medicaid Services (CMS) will not reimburse facilities for treatment of infections acquired during the hospitalization period.[6] Best practices associated with the SCIP project can be found in Box 6.2.

Infection Control Coordinator

An infection surveillance, prevention, and control program uses the services of a strategic person and agent of the infection control committee, the infection control coordinator (ICC). Because this person is often an RN with special training in epidemiology, microbiology, statistics, and research methodology, he or she may be called an infection control nurse (ICN) or nurse epidemiologist.

The ICC monitors the environment for infections and works closely with the infection control committee. The ICC's duties are as follows:

1. Promptly investigates outbreaks of disease or infection that are over expected levels.
2. Promptly identifies the origin and cause of outbreaks with epidemiologic study.
3. Acquires, correlates, analyzes, and evaluates surveillance data and bacterial colony counts, which includes gathering information to compute and classify specific wound infection rates for all invasive procedures. Rates should be entered in the infection control committee record and be available to the department of surgery.
4. Tracks factors that contribute to infection problems.
5. Consults with directors of critical areas, such as the OR. If an outbreak of SSIs occurs, the ICC confers with the OR nurse manager. They review patient intraoperative records to determine whether the infected patients had the same procedure or same surgical team or were operated on in the same room. They review antiseptic agents used for skin preparation, antibiotics used for intravenous (IV) lines, wound irrigation, and other commonalities in the patient care setting. If a patient develops signs and symptoms of SSI within the immediate postoperative period, a causative factor in the OR is suspect.
6. Coordinates educational programs for personnel who influence infection control. The ICC is a consultant to all hospital personnel and a liaison officer in disseminating information on infection prevention and control.
7. Assists in employee health programs in regard to screening, immunizing, and monitoring the personal health of personnel.
8. Assists in development and implementation of improved patient care procedures.
9. Compares monthly statistics. A significant rise in the monthly reported SSI rate is cause for concern. Reports and data can be helpful in evaluation of aseptic practices if they are brought to the attention of personnel.
10. Reports appropriate diseases to public health authorities.
11. Compares products for effectiveness. The infection control committee approves disinfectants and antiseptics, for example, based on recommendations of the coordinator.
12. Obtains information from surgeons about evidence of infection after discharge and conducts retrospective studies for statistical analysis.

In short the ICC identifies problems, collects data to find the causes, investigates solutions, and makes recommendations for appropriate hospital policies and procedures to prevent infections. In evaluating infection problems the ICC attempts to find a common denominator, which often leads to the source of the problem. For example, an outbreak of postoperative respiratory infections would lead to an investigation of the cleaning and sterilizing procedures of anesthesia equipment and ventilators. Success of the control program depends in part on the information provided by a conscientious staff, including physicians.

Infection Control Program

An effective infection control program aims to reduce the incidence of infections and to control sources. Information collected through surveillance serves as a basis for corrective action. This information includes written records and reports of known or potential infections among patients and personnel. In 2017 the Healthcare Infection Control Practices Advisory Committee (HICPAC) published the Guideline for the Prevention of Surgical Site Infection. HICPAC is a federal committee that gives advice to the Centers for Disease Control and Prevention (CDC) and Department of Health and Human Services (DHSS). The guidelines can be found at www.cdc.gov/HICPAC.

Guidelines and standards for infection control and surveillance are also published by TJC in the *Accreditation Manual for Hospitals* and by the CDC.[7] In general, these standards and guidelines include:

- Establishment of an effective hospital-wide program for surveillance, prevention, and control of infection.
- Establishment of a multidisciplinary committee to oversee the program by reviewing surveillance reports and by approving policies, procedures, and actions to prevent and control infection.

• BOX 6.2 Overview of the Surgical Care Improvement Project (SCIP) for the Prevention of Surgical Site Infection (SSI)

Antibiotic Prophylaxis (Only if Necessary)

One hour before incision—fluoroquinolone (ciprofloxacin)
Two hours before incision—vancomycin (Vancocin) (if indicated)
Antibiotic discontinued within 24 hours postoperatively (48 hours for cardiac patients)

Normothermia

Immediate postoperative body temperature 36° C to 38° C within 1 hour of the surgical procedure

Appropriate Hair Removal

Hair is removed only as necessary with clippers away from the OR.

Urinary Catheters

Urinary catheters are removed within 1 to 2 days of the surgical procedure.

Serum Glucose

Maintain serum glucose between 80 and 110 mg/dL for cardiac patients and <200 mg/dL for other patients. Serum A1C should be <7%.

- Assignment of a qualified person to be responsible for management of the infection surveillance, prevention, and control program.
- Provision of written policies and procedures pertinent to infection surveillance, prevention, and control for all patient care departments and supporting services.
- Provision of patient care support services that are adequately prepared to perform all required infection surveillance, prevention, and control functions.

Surveillance

The CDC, an agency of the HSS, is the third largest section of the U.S. Public Health Service. Functioning on both national and international levels, its activities are multifaceted. It carries out a national surveillance of disease incidence and a program, including health education, in prevention of communicable diseases.

Through liaison with state and local health departments, the CDC provides assistance and consultation to health care facilities for specific problem solving, analysis of surveillance data, and onsite investigation of serious outbreaks of infections. As part of its commitment to the prevention of HAIs, the CDC furnishes information on how to structure an infection-control program.

Continuous Performance Improvement Committee

Members of the performance improvement committee include representatives of both clinical and administrative personnel. This committee monitors routine activities, evaluates clinical outcomes, reviews incident reports, and conducts problem-focused studies in an effort to identify practices deemed substandard.

Actual practices may be in violation of policy or not in compliance with accepted standards or governmental regulations. Noncompliance puts a hospital or ambulatory care facility at risk for legal liability. A productive and efficient committee implements actions designed to eliminate real or potential problems, improve patient care, and reduce financial loss. Because of an emphasis on cost containment, use of facilities and risk management also may be concerns of this committee.

Many facilities employ a quality improvement coordinator or a risk manager to ensure implementation of committee decisions. The primary function of the person in this position is to assess actual practices and evaluate outcomes of patient care. The continuous performance improvement (CPI) coordinator may receive and respond to complaints about patient care or environmental hazards.

Each hospital department and patient care area may have its own quality improvement subcommittee. These unit-based committees monitor performance, identify ways to constructively solve competency problems, and seek opportunities for improvements in practices.

Other interdepartmental subcommittees may focus on specific activities or problems that require input from several disciplines. Reports from these subcommittees are reviewed by the CPI coordinator. Mutual problems are shared with the hospital committee.

Ethics Committee

A multidisciplinary ethics committee should represent the hospital and the community it serves. Representatives include physicians, nurses, social workers, patient relations liaisons, clergy, lawyers, bioethicists, and laypersons from the community. Their primary purpose is to educate the staff and the community regarding moral principles and processes of ethical decision making in the face of diverse subjects that arise in the care of critically and terminally ill patients. They provide consultation to professional staff, patients, and families. This committee recommends policies and guidelines on such subjects as informed consent, research protocols, and advance directives.

Perioperative nurses and surgical technologists often are confronted with social, ethical, and legal decisions concerning genetic and reproductive biology, organ transplantation, and death with dignity. The ethics committee can provide a forum for discussion of these subjects. Some hospitals have a nursing bioethics committee in addition to the hospital committee. These committees provide education and consultation and develop policies and procedures. They are not decision-making bodies. They do not get involved in disciplinary matters.

Hospital Safety Committee

Representatives from administration, nursing service, medical staff, infection control, engineering and maintenance departments, environmental/housekeeping services, and the safety director form the nucleus of the hospital safety committee. This group writes policies and procedures designed to enhance safety within the hospital and on hospital grounds. They exchange information with the risk management and quality improvement committees and conduct hazard surveillance programs. They meet at least bimonthly to investigate and evaluate reported incidents. Action is taken when a hazardous condition exists that could result in personal injury or damage to equipment or facilities.

Disaster Planning Committee

Health care facilities should have an organized plan in place to care for mass casualties if a major disaster occurs. External disasters happen outside of the health care facility, such as a terrorist attack, an airplane crash, or an event of nature (e.g., flood, Hurricane Katrina in 2005).

Internal disasters, such as a fire or an explosion, happen inside the health care facility. In cases such as an active shooter, it can be external or internal. A safety plan should be in place to keep personnel safe, but at the same time triage victims quickly.[8] With the large number of documented cases, facilities need to be prepared and make it part of emergency training. Many resources, tool kits, and emergency preparedness guides are available. Planning by the internal disaster committee includes consultation with local civil authorities and representatives of other medical agencies to establish an effective chain of command and to make appropriate jurisdictional provisions. This planning results in disaster-site triage to separate and distribute patients to ensure the most efficient use of available facilities and services.

Disaster drills are held at least twice a year to test the plans developed by the committee, to seek to improve them, and to familiarize personnel with them. Plans for both types of disasters include the following details:

- *Central command center:* An information center within the hospital to facilitate a unified medical command and the movement of patients.
- *Triage center:* A receiving area for the injured. Severely wounded patients are given emergency care according to their needs and are sent at once to the OR, or to other units as indicated, or transferred to another facility. Ambulatory patients may be

treated in the ED for slight injuries and sent home, or admitted to the hospital as indicated.
- *Documentation and communication:* Special disaster medical records or tags that accompany patients at all times to document identification, treatments, medications, destination, and plan of care.
- *A plan of organization of personnel:* As soon as a hospital receives word of a disaster during the evening or night, several strategic people are called. These persons in turn telephone others previously assigned to them, and these call still others, until the full staff has been notified.
- If the disaster occurs during the day, the full staff is usually on duty, although any off-duty personnel may be called. Other departments are alerted and come on duty as needed, including personnel for the blood bank, laboratory, pharmacy, materials management, radiology department, and patient care units, including the OR, PACU, and ICU. Some laundry and processing personnel also may be alerted. Some strategic maintenance personnel should be available, especially electricians.
- *Written departmental instructions for personnel:* For the perioperative staff, these instructions may include sign-in procedures, checklists of duties, and patient scheduling procedures.

Personnel must know where to report, what to do, and where extra supplies are kept in case of an emergency. Extra supplies are stored in reserve in sufficient quantities to fill possible needs for a minimum of 1 week.

Surgical Services Management

Management of the surgical services department is strategic to the success of this high-cost center within the institution. Power and authority go hand-in-hand in the roles of administrators and managers. Authority can be bestowed on a person in the role, but power is the ability to influence the outcome in a particular direction. The skillful and effective manager uses both of these attributes to maintain control over the activities and decision making of the department. Primary managerial activities revolve around safe and efficient patient care, leadership, and budgetary concerns.

Administrative and Management Behaviors

Accreditation

Ongoing policy and procedure updates decrease the need for last-minute compliance documentation necessary for TJC. Most accreditation cycles are 3 years, which is ample time to establish and maintain an accreditation-responsible program. Some managerial considerations for staying in readiness include:
- Set a routine schedule for reviewing and updating policies and procedures. Do not wait until a visit is anticipated to start trying to clean up outdated practices.
- Model each behavior in patient care after the desired outcome. Secure the physicians' support.
- Share information with the staff about the department's progress toward full compliance. Invite some of the surgeons to the meetings. Feature each stride with a report from the achievers during routine staff meetings.
- Keep a copy of the survey questions for the staff to review.
- Establish small groups to tackle small manageable tasks. Collectively this action amounts to a large improvement in participation. Tasks can be delegated to each service.
- Be sure the staff has all the necessary supplies, resources, and support to accomplish the mission.
- With a positive attitude, present each item to be worked. Use the staff's natural talent and creativity. Provide feedback. Coach and encourage.
- Pitch in and help when needed. Make time for the team. Do not micromanage, but take a "hands-on" approach to support the momentum.
- Reward the accomplishments on an ongoing basis, not just for the moment.
- Remain current with evidence-based practices. Dated or unfounded policies and procedures can undermine the authority of the manager in the eyes of the staff and physicians.

Leadership Qualifications and Competency

Leadership is difficult to define, but it is nonexistent without subordinate cooperation. The manager's style, capability, knowledge base, practice reputation, and experience help set the pace for the progress of the department. People skills are very important. Throughout the staff complement, some people show informal leadership abilities that can be positive or negative. Some hallmarks of leadership competency include the following attributes:
- Critical thinking skills
- Objectivity
- Use of credible sources
- Planning ability
- Flexibility
- Creativity
- Self-control
- Negotiation skills

Informal leaders can be harmful if their influence directs the staff away from the main mission of the OR. Winning the support of informal leaders is a significant stride toward better cohesiveness for the staff. Informal leaders can be disruptive when communications break down among the ranks.

The main focus is continual improvement by tempering activities and behaviors of the individual in accordance to the needed productivity of the organization. Each member of the team needs to identify personal strengths and personal relationships with the organization that is working toward becoming a **learning organization.** Peter Senge, in his book *The Fifth Discipline,* identified five constructs that are either group or individual relationships with the organization. The process cannot be paced with an exact timeline; however, it can be measured by improved productivity and personnel in a stable working relationship. The five constructs are simplistically paraphrased as follows:
- *Personal mastery:* Clarify and deepen personal focus.
- *Mental models:* Identify the internal beliefs that cause us to act in a certain way.
- *Shared vision:* Working "on the same page" as the rest of the team. Sometimes this requires more commitment than compliance for growth of the vision, which is where some personnel try to break away and do their own thing.
- *Team learning:* A coordinated group activity in which ideas are receptively expressed in an open dialogue. No judgments are made as would happen in a discussion. Everyone is required to listen and not criticize the ideas of others in the group.
- *Systems thinking:* Discover the root causes of events and fuse the other four constructs together to effect long-range improvement.

Systems thinking is a way to improve the quality of care and help set standards that can be expanded or contracted to meet the needs of the facility and the patient population. When the learning organization has a process of systems thinking in place, the

emphasis is on the system, not the individual staff member. Error reduction in the OR can commonly be traced back to a flaw in a system that permitted something to go wrong, such as a retained sponge or a sharps injury. When a decent system is in place and followed by the group, the risk for error is minimized.

Leading by Example

The surgical services staff needs to have respect for the management team. Encouraging the staff to become professionally active on committees or in shared governance, then joining them in professional activities, can help cement a sense of pride in accomplishment.

Nurse managers who have no clue about evidence-based practices are not only harmful to the organization but also less respected by the staff. Failure to keep up with the times makes the nurse manager appear unintelligent and uncaring, especially when the staff attend outside workshops for updates and are met with disdain by the manager. Incompetent managers are a common cause of losing staff to other more progressive facilities.

Perioperative nurse managers should be professionally involved and should be certified as CNORs and possibly certified as administrators.

Although an advanced academic degree is not always necessary, it does make a statement of respect for education and personal growth. Support for line managers and staff who are pursuing baccalaureate degrees is an admirable trait in the management structure.

Rounding up Those "Sacred Cows"

Policies and procedures should have a firm foundation in scientific research and evidence-based practice. Practices that continue despite lack of scientific evidence are referred to as "**sacred cows**." Managers lose much credibility and look ignorant when they enforce dated practices. The staff respects the manager more when he or she can support the basis for best practice behaviors. Mechanical performance of tasks without knowledge of why is a hazard to the patients and the staff. Excuses given by managers commonly include:

- "This is how we do it here."
- "This is how we have always done it."
- "We don't do it that way here" (in reference to the introduction of a newer, more modern approach).
- "The national standards are only voluntary, not mandatory."
- "This is how I was taught. That's good enough for my staff."
- "I did not know that the staff was doing that activity in that manner."
- "Because this is how I want it done."
- "You need to do it this way to save time."

Demanding that the staff perform procedures according to nonexistent rationale is counterproductive. The manager looks incompetent when the staff is required to follow protocols that are not founded in evidence-based practice. Some areas for investigation concerning "sacred cows" in the OR include the following intraoperative behaviors:

- Requiring shoe covers and masks in all areas of the surgical suite
- Cover gowns and laboratory coats worn when leaving the OR
- Forbidding the use of nail polish, including fresh nail polish
- Skin preparations as sterile procedures
- Surgical site hair removal
- Home-laundered versus facility-laundered scrubs
- Timed scrubs, counted brushstroke scrubs, and hand hygiene antisepsis
- Extent of between-case cleaning
- Excessive draping
- Setting time parameters on the sterility of items
- Flash sterilization

Professional Involvement

Managers should be members of their professional organizations and take part in the care and activities that drive their profession. Managers should also be certified with a professional credential.

The administrative and management staff should be knowledgeable about current standards and trends in perioperative patient care. Offering to host professional meetings at the facility or holding open houses for new potential surgical services staff or other departments shows an interest in the departmental growth and insight into to the activities behind the closed doors.

Meetings

Most management personnel are required to attend and plan a multitude of meetings that pertain to the business of the department and the hospital as a whole. When planning daily activities, they should consider the need to attend these communication sessions. The manager should establish routine meetings within the surgical services department for the dissemination of information as appropriate and adhere to a set time parameter for the proceedings.

Some meetings require the attendance of people from other departments and need to be carefully planned. Offering to hold the meeting in a neutral location can help prevent disruptions by office phones and other distractions.

The chairman or leader of a meeting should realize the importance of the meeting beginning and ending promptly. Complex topics should be interspersed with simpler group communications. Solicitation of agenda items from attendees in advance helps the chairman plan ahead and maintain the order of business with minimal digression.

Setting the Agenda

Establishing a time period and content for each meeting is important. Personnel attending meetings should estimate the amount of time they need to plan for attendance. The manager needs to plan a release time for meeting attendees that does not interfere with the daily operation of the surgery department. A meeting agenda should have the following items in its composition:

- Introductions of new personnel and guests
- Short overview of discussion topics
- Old business
- New business
- Special topics
- Delegation of new tasks
- Exchange of information for the good of the group

Minutes of the Meeting

Records of each meeting should be kept at a central location in the department. Personnel in the process of patient care or other shifts may not be able to attend formal staff meetings and need to keep informed about current events in the hospital and department. Secretarial staff or a designated team member should document pertinent facts for the record and verify the accuracy with members of the committee before the group meets for a session.

A loose-leaf notebook with meeting overviews can be maintained in a common area available to all departmental staff members. Some departments set up Internet blog sites where staff

members can sign in to participate and communicate ideas. Copies of the minutes can be sent to appropriate people within the facility on a need-to-know basis. The minutes also serve to validate the activities transacted and any resolutions or expectations of future business.

Personnel Management

Motivation and Building a Unified Team

Staff meetings are useful forums for group exchange of ideas, reporting, and concerns. The manager should have regularly scheduled meetings with a formal agenda that has provision for staff input. Allowing the staff to have some ownership of the surgical services department encourages pride in group endeavors.

When the department consists of several areas with specific functions separate from the others, smaller group meetings can be beneficial to work through items not of interest to the entire department. The PACU personnel may have different subjects of interest than the OR team. Collective meetings are useful for consolidating matters that are common to all the areas.

Planning for adequate and appropriate staff to safely and efficiently provide patient care during the implementation of the surgical schedule is a complex task. The 2014 AORN Position Statement on Perioperative Safe Staffing and On-Call Practices indicates there should be one RN circulator and one scrub person allotted per case with adequate relief for breaks and meals. The average staffing pattern should be 67% RN to 33% surgical technologists. Orientees are not counted in staffing ratios and are assigned a peer preceptor for the orientation period. The recommendation follows that a staff member should not be assigned to work more than 12 hours in a 24-hour period and no more than 60 hours per work week. Staff should have at least 8 hours of uninterrupted sleep when off-duty. The only situation in which the time elements are prolonged is in the event of a disaster (internal or external). Policies should be formulated to outline staffing in extreme circumstances.

Sometimes managers try to cut corners by stretching the staff numbers to bare-bones teams. Remember that staff efficiency, satisfaction, and retention are not built on working employees to a frazzle. Plans are necessary for break and lunch relief. Consideration should be given to assignments that are emotionally or extremely physically draining. Provision for the relief of an extremely stressed team member is reassuring to the entire staff that they too will not be abandoned by management if the case becomes more complex, lengthy, or emotionally draining than expected. Staff satisfaction is an important part of achieving Magnet status.

Retention of staff is a cost-saving measure. Staffing decisions should not be made based solely on costs. Safety for the patient and the entire team should be foremost in the scheme of planning. The manager should think about the processes associated with hiring, orienting, and maintaining each person on the payroll. Some parameters for staffing newly hired nurses include the following:

- Development or purchase of a perioperative nurse education program
- Recruitment costs
- Duration of orientation
- Preceptor costs
- Materials costs

The cost-effective means for retention is to look for what contributes to staff satisfaction. Giving the staff the opportunity to participate in staffing decisions such as "on-call time" or mandatory overtime can help prevent staff burnout and resignations. Studies show that overworked and exhausted staff frequently cause more human error and increase staff turnover.

Delegation of Duties

When a task is assigned to personnel within the department, the person receiving the instruction should be fully capable and knowledgeable in the action to be taken. The manager should consider the appropriateness of roles and the assignment of duties according to the standards of care and, in some instances, the legality of the role. For example, many states have laws that indicate only an RN may perform the role of circulator. Some states have laws that indicate who may or may not perform in the role of first assistant. Thought should be given to potential consequences of assigning staff to roles that are out of their scope of practice.

Clear instructions should be given, and feedback should be received to indicate understanding. Recognition of a job well done should be freely given. Consequences for poor performance should be moderated appropriately. Competency of each employee should be validated on a regular basis, and incompetent employees should be brought up to speed or put on notice of progressive discipline.

Conflict Management

The OR is a closed environment with a potentially fragile morale. When personnel work closely together for long periods, small disagreements can commonly take place. The manager may need to intervene periodically. Both sides of the disagreement must be heard before any action takes place. Disruptive behavior should not be tolerated; instead it should be managed with firmness and professionalism. Most facilities have developed a "zero-tolerance" policy for unprofessional behavior on the part of surgeons or staff (i.e., humiliation, degradation, harassment, bullying, etc.).

Lateral Violence

Conflicts should not be allowed to fulminate to overstated proportions. Use of the term *violence* indicates the presence of victims. Abuse within the ranks is a form of violence and includes nonverbal innuendos, verbal confrontation, backstabbing, undermining behaviors, sabotage, and gossip.

Personnel have indicated that within their first 6 months they experienced some form of lateral violence. Box 6.3 describes some of the common verbal and nonverbal lateral violence behaviors.

Dissatisfaction among the staff leads to low morale, inadequate performance, and increased personnel turnover.[9] Compromise is a middle-of-the-road approach and should not favor one

• BOX 6.3 Examples of Verbal and Nonverbal Lateral Violence Behaviors Between Staff Members and Surgeons That Should Not Be Tolerated

- Eye rolling, eyebrow raising, and tongue clicking
- Verbal affront: name calling and put-downs
- Backstabbing and undermining to other staff and surgeons
- Sabotage and setting up for failure
- Withholding information or hiding of equipment or supplies
- Invasion of privacy or broken confidences
- Gossip or outright lies

employee over another. Lateral violence is not a rite of passage in the perioperative environment. The manager needs to identify the problem and address the issue.

The staff should be held accountable for maintaining professional relationships and for preventing the "eating of one's young," as has been the case for many generations. The staff must not be permitted to "dish it out" or be forced to "take it in."[10] The following is a list of behavioral signs of dissatisfied staff and indicate a need to be investigated and managed:

- *Excessive overtime and staff refusal to help out:* Cases that run overtime are sometimes caused by staff not performing assigned tasks and failing to prepare appropriately for caseload (foot-dragging).
- *Low productivity:* Turnover between cases is prolonged by staff coming back late from breaks and lunch. Work is unfinished or done poorly.
- *Constant complaining:* The manager needs to listen attentively to find the root cause.
- *High absenteeism and tardiness:* These can be signs that morale is very low.
- *Constant turnover of staff:* Dissatisfied personnel quit or transfer out when resolutions are not sought out or met.
- *Temperaments flare up easily:* Stress can result in acting-out behavior.

Downward Violence

Downward violence is any abusive behavior directed at lower ranked individuals by higher ranked individuals and includes abuses by a manager to staff, from a surgeon to manager, or surgeon to staff. A study was done of OR abuses that resulted in departmental transfers wherein 47% of transfer requests were sparked by management abuse toward staff.

When the disagreement is with a surgeon, the automatic assumption of the staff is that they do not have a fighting chance to say their piece nor does it matter what they say. This needs to be addressed as soon as possible after an incident.

Verbal abuse by surgeons is not acceptable under any circumstances, regardless of the event, and can cause serious problems in the OR. A surgeon has no right to terrorize the staff. Sometimes, bad behavior is a sign of incompetence and is an attempt to hide or smokescreen personal insecurity. This is true of any person.

Throwing items or other physical displays by the surgeon in the OR are unsafe and should be subject to discipline at the level of the medical staff officers. Failure to attain resolution at that level warrants a report and meeting with the CEO of the facility. Care is taken to follow chain of command; however, the conscientious manager cannot knowingly allow staff or patient endangerment by a surgeon, regardless of the volume of revenue to the facility. Standing up for what is right and just is hard, especially when one is standing alone. The staff will have a sense of respect for the manager who champions the cause of the department fairly and professionally.

Sometimes egos are factors and a small disagreement gets blown out of proportion. The staff should be assured that many surgeon complaints are not meant on a personal level but, instead, are directed specifically at a situation. Personal attacks can elicit anger initially and can cause grudges that last months or even years.

The manager, after hearing both sides, has the responsibility to mediate a truce but may have to involve the chief of surgery and the director of nursing service for the facility. Conflicts are costly to the organization in many ways but primarily because of the following factors:

- Staff replacement costs either in orientation of new personnel or in the use of agency workers to fill gaps left in staffing
- Additional man-hours to complete the schedule at the end of the day; staff frequently take a sick day when feeling overwhelmed and depressed. This is problematic when the person who called off is on call or late that night. Someone else on staff has to pick up the load, causing resentment to grow.
- Refusal to stay overtime because of lack of loyalty
- Increased errors and carelessness
- Legal issues, such as suits for harassment
- Poor productivity and low morale
- Lack of pride in the job can cause injury to the patient

What can the manager do about conflicts or verbal abuse? A few strategies can prove useful when facing this dilemma. Some ideas are as follows:

- The two people with the disagreement should have a face-to-face meeting away from the OR, perhaps in the manager's office or conference room.
- The manager should be present. Other support may include the chief of surgery, chief of staff, and the director of nursing service. If a physician representative is present, an additional nursing representative also should be present.
- Avoid blaming anyone. Remain objective, and maintain civil tones in all parties.
- Ask each party what would make the situation better on an individual level. Try to reach a compromise with this information. Sometimes a period of working apart allows both parties a chance to cool off.
- The surgeon should not have the right to demand an employee's resignation. Unfounded termination can result in a lawsuit against the facility, the manager, and the surgeon. The surgeon should not have power over an employee's job.
- Praise positive strides for a peaceful resolution. Be aware that some people are overjoyed by being unhappy. Some people have a bad day every day.
- Assure both sides that you will all reach a satisfactory conclusion together. Set some short-term goals and monitor progress.

Documentation

Records of performance reviews should be maintained in the human resources department and in the manager's file. Each employee should have a file that documents competency and practice attributes. Care is taken to document evaluations and anecdotal notes in professional terms because if a staff member files a grievance with higher administration or with a union, the records may be open to scrutiny. Inflammatory comments or slang references could be mistaken for inappropriate labeling of personnel and cause hard feelings.

The manager should evaluate personnel and have them perform self-evaluations in preparation for a face-to-face discussion about performance and performance improvement goals. The contents of the documentation should be the framework for discussion. The staff member should be permitted to retain a copy of all signed performance evaluations for his or her personal records.

Budgeting and Financial Responsibility

For the new nurse manager, preparing a budget for the first time can be intimidating. Before beginning, meet with the facility finance personnel, business manager, and another nurse manager

within the facility who may be willing to mentor this process. The materials manager can often shed light on the historical use of supplies, and the payroll department can provide information about salaries, performance reviews, and overtime. Computerized records can help with historical department activities and projection of future needs.

A review of previous copies of earlier budgets can be helpful. Most facilities have a specific fiscal year and begin the year with a budget overview meeting, at which time instructional packets are passed out. Computerized methods may include spreadsheets and graphs. Computer literacy and knowledge of financial programs is a must for organization of supplies and records.

After the initial budget is submitted and approved, plans should be under way to begin gathering information for the next fiscal year. Responsibility for the financial affairs of the department includes forecasting needs and growth. The budget in itself is a prime managerial planning tool, not an obstacle to progress.

Day-to-day financial management considerations may include several of the following budgetary factors:

- *Engage the staff in budget dialogue.* Do not use the budget as a weapon or threat, but emphasize the ways the staff can safeguard against waste and promote loss prevention. Include dialogue about first case starts, turnover times, and time management. Understand and discuss what is realistic in terms of safe patient care and efficiency for the type of facility and staffing.
- *Use the operational structure within the facility.* Seek information and advice from other managers, department heads, and purchasing departments. Set up formal and informal meetings to monitor the financial climate of the institution.
- *The cheapest materials may sometimes cost more in the long run.* Establish evaluation groups for new products. Graph out the pros and cons of each item tried. Solicit input from other departments that might interface with the product.
- *Encourage planning in ordering of stock.* Keep a standard number of supplies on hand and discourage "squirreling away" of items by staff members. Discourage inventory accumulation in the individual ORs. Staff should be aware of the costs of items used in the OR and not randomly open supplies that may be wasted.
- *Strive for standardization.* Custom packs and routine basic supplies help in this process. It is useful to include the surgeons in planning standardized custom packs. Implantable items such as orthopedic, ophthalmic, or plastic surgery devices could possibly be standardized.
- *Do not skimp on the education of the staff.* The staff needs to know the products and trends associated with the procedures for which they are required to provide patient care. Have regularly scheduled inservice programs, and have specialty leaders demonstrate proper assembly and use of equipment. New machines and supplies can be introduced in an enjoyable atmosphere instead of "on the fly," such as when a new item is foisted on the team in the middle of a procedure, which is an unsafe practice.

Operational Budget

The operating budget directly reflects the department's revenues and expenses. Caseload and man-hours are the prime considerations during the development of the **operational budget**. If cases are increasing, so are the numbers of hours and possibly overtime by staff. One method of minimizing the overtime costs is to have staggered staffing shifts. A team that starts later in the day could be assigned to break and lunch relief for the early starting rooms. At the end of the day the late-start team could be available to finish rooms that are still running at the end of the shift. In some facilities this decreases the need for a full second shift crew.

Most facilities provide a monthly departmental summary of expenditures that include the following line items:

- Noncapital purchases (usually less than $500)
- Charges for expenses such as laundry, preventive maintenance contracts, and repairs
- Supply and inventory charges (check the numbers and types of cases each month; are price increases expected? Is there a purchasing contract with a distributor or a buying consortium?)
- Wages and salaries with benefits (holidays and vacation time are calculated, overtime may be projected, and additional full-time equivalents [FTEs] may be needed)
- Educational funds for continuing education, degree-seeking courses, certification, and recertification

Each month the projected amount should be compared with the actual amount of each item. At first the process can seem confusing, but with time this practice becomes second nature. Some vendors charge on a net 30-day basis, and the actual charges do not appear until 1 to 2 months after the fact. A glance through 3 months at a time to compare and track charging trends is wise. Keep a notebook for observations by the month to help to sort out confusing items. Jot down phone numbers and problematic situations and ongoing questions.

Keeping track of the facility's monthly census may provide some clues as to the accuracy of the figures and whether they will be important for future budget preparation and identification of trends. As these data accumulate, they may demonstrate the need for a change in supplier. Keep good notes of positive and negative encounters with sales personnel. Always request a business card, and keep it on file for quick contact. A file should be started for each vendor used and notations made if they are associated with a hospital-wide buying contract.

A tablet computer, smart phone, or other portable electronic device is useful for tracking the budget and having portable information for meetings. The device can be synchronized and recharged with a desktop computer, and the information can be kept current at all times. Tablet computers have software that can be used for spreadsheets and document processing. Password protection for all devices is important in case of loss or theft. Some devices contain a global positioning system (GPS) to track their location.

Capital Budget

The **capital budget** is more concerned with improvements to the physical plant and purchases of large equipment. Patient care devices that are charged per use are considered capital equipment.

Surgeons frequently request equipment for the types of procedures they perform. Some surgeons have the opportunity to preview new equipment at seminars and conferences and then bring the brochures to the manager for future trial use. Sometimes new equipment previewed at medical conferences is discounted for participants of the event. If special capital items are planned for future purchase, it is useful for the manager to attend trade shows and medical conferences where these devices are displayed and demonstrated. New equipment brought in on trial must be checked by the biomedical department before use to validate safety in the OR.

Keeping an ongoing list or file with information about specifications and cost is useful at budget time when preparing requests for capital expenditures. Information that is useful in this process includes the answers to the following questions:

- What is the formal and generic name of the device? Is it available from more than one source?
- Does the device require special hookups or storage? Will we need to modify the physical plant?
- Who will use it and how often? Can it be used by more than one service?
- Who will educate the staff about its use?
- Is software necessary and included with upgrades? Is support available?
- What consumables are necessary, such as disposable leads or parts?
- What is the cost of its use to the facility and the patient? Will we make money on its use? Will we attract surgeons and patients?
- Is use of the device reimbursable by third-party payers?
- Will this device quickly become antiquated? Will we need more than one unit at some point?
- What is currently being used in its place? Are upgrades included?
- Who are the vendors (include contact person, phone number, business card, and e-mail address; date this entry because sales force changes are common)?
- Is it a new project or a replacement (one unit, or more)? Is a business plan needed to validate the purchase?
- Is a device available for trial? Is it possible to "rent to buy"? Would renting the device be more cost effective than purchasing it?
- Are any hazards or biologic injury associated with use? Is it U.S. Food and Drug Administration (FDA) approved?
- What are the costs (item, installation, PM contract, tax, shipping, maintenance; get a secured price quote)? Sometimes special prices are available if ordered through trade shows. Can you offer to be a demonstration site for a discounted cost?
- What education or credentialing is required to use it? Will dedicated staff be needed to manage the item in the OR?
- What is the warranty and service information?
- What is the delivery and turnaround time for repairs? Is a loaner available if a repair is needed?
- What are the costs of basic repairs and parts?
- Is product support available during the phase-in process?

Outdated or poorly functioning machinery is replaced during this process. The American Hospital Association has prepared a "life expectancy" guideline for most types of devices used in patient care. This resource is valuable in establishing a replacement program for dated items. The manager should project needs and develop plans for growth or improvement for a 5-year cycle of depreciation. Knowledge of current technology is a must to stay on top of new device knowledge. Some surgical services departments include anesthesia and central processing equipment with the OR and PACU capital budget.

New Product and Equipment Evaluation

The user of a product is best qualified to evaluate performance, safety, effectiveness, and efficiency. Before a decision is made to purchase or standardize a particular item, a clinical evaluation should be conducted to solicit feedback from team members whose work is affected by the product. This may involve the surgeons, anesthesia providers, and perioperative nurses and surgical technologists. Instruction should be provided on the correct use of the item before it is evaluated. Sales representatives may be permitted to assist in the trial of a product in the OR. Although they do not provide direct patient care, they offer suggestions and consult with the users during the product trial. Members of an interdisciplinary product selection committee might include:

- Pharmacists
- Nurse educators
- Biomedical staff
- Wound care team members
- Infection control nurses
- Occupational or physical therapists
- Nurse managers
- Nurses from the postsurgical areas

To be valid, feedback should be an objective evaluation of function, quality, and use. Does it meet a need? Does it solve a problem? Is it cost effective? Does it improve patient care? How does it compare with other brands? Several brands of the same product may be evaluated to select the most satisfactory one for the intended purpose and to standardize the inventory. Written evaluations are useful for the decision-making process after the trial period.

Many products are used only in the perioperative environment; however, some are also used in other patient care areas. Representatives from all user departments should assist the materials manager in selecting products. Most hospitals have a product evaluation committee for this purpose. A representative of the perioperative staff provides this committee with information regarding quality and effectiveness, based on feedback from user staff members.

Once a product has been purchased the user assumes responsibility for its safety and its proper use for its intended purpose. Problems with medications or patient care items should be reported to the FDA with the MedWatch system. The FDA tracks complaints and orchestrates recalls as appropriate.

Working with Sales Representatives

Sales representatives are important sources of information and support. Each facility should have a policy in place that addresses who has the authority to work with the sales personnel and under what circumstances they are permitted in the department. The sales personnel should register at the main information desk in the lobby of the hospital and wear proper identification at all times. They should not cause any disruption or compromise patient privacy in any way.

AORN has established a position statement about sales representatives in the OR that is useful for determining facility policies and procedures. Sales representatives should have a basic knowledge of sterile technique and should be able to enter the OR without disruption. AORN has developed a sales representative certification class to acquaint the sales force with the OR and its protocols. The following list provides guidelines for working with sales representatives:

- The facility should have specific policies in place to govern the activities of credentialed sales representatives. IDs are worn at all times. Attendance is documented and time-limited.
- Some facilities issue sales representatives scrub suits that are a different color from those of the staff for identification.
- Meetings are by appointment only. No meetings are to be scheduled with any of the staff without express permission from the manager.

- Physicians may not bring a sales representative into the department without going through proper channels.
- Facility security policies are followed at all times. Patient confidentiality is maintained.
- The sales representative may not render direct patient care at any time. The patient must have the opportunity to give informed consent to the presence of sales personnel.
- Specialized and highly trained manufacturer representatives may have indirect activities, such as calibration of pacemakers and defibrillators, as directed by the surgeon. These personnel should not be scrubbed in at any time.
- Only the products planned for the meeting are presented.
- No fliers or materials are to be distributed without permission of the manager.
- Trial devices are brought in only by request and are examined for safety by the facility's biomedical department.
- Disposable products for trial have appropriate lot numbers for reporting problems or malfunctions.

7 The Patient: The Reason for Your Existence

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Describe Maslow's hierarchy of needs.
- Describe some characteristics of diversity in a patient population.
- List the main elements of a patient-centered approach.
- Describe how the patient may perceive care.

KEY TERMS AND DEFINITIONS

Body mass index (BMI) Calculation that divides body weight in kilograms by height in meters squared (kg/m^2).
Comorbidity More than one disease entity in an individual that intersects and requires continual monitoring and treatment.
Domestic violence Abuse perpetrated in the home or living arrangement. Can be physical, psychologic, verbal, or nonverbal.
Homeostasis A balance of biochemical and physiologic systems within a person that sustains life in a disease-free state in the presence of environmental influences.
Paradigm Model used as a foundation for a conceptual framework.
Perception Use of the senses, cognition, and awareness to evaluate the collective stimuli of the environment.
Perpetrator Person who is suspected of committing a crime against another person.
Polypharmacy Use of multiple medications, either prescribed or self-administered.
Stress Internal perception of and response to stimuli in a positive or negative manner.
Victim Person who has been injured by the effects of the environment or suffered abuse by another person.

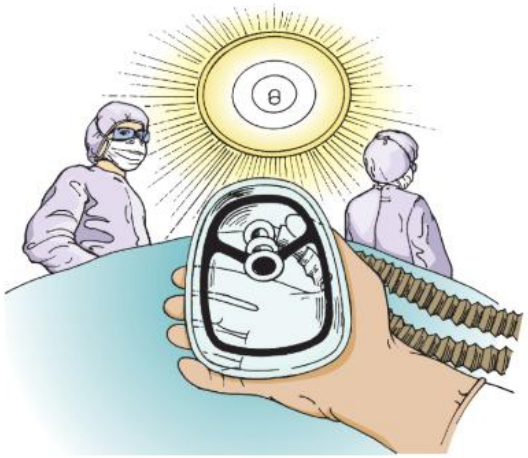
The Patient as an Individual

Patients are the reason for the existence of the health care team. They look to the perioperative team to fulfill their diverse needs during the preoperative, intraoperative, and postoperative phases of care (Fig. 7.1). The patient is always the center of attention, not just when under the operating room (OR) spotlight. A patient may be defined as an individual recipient of health care services.

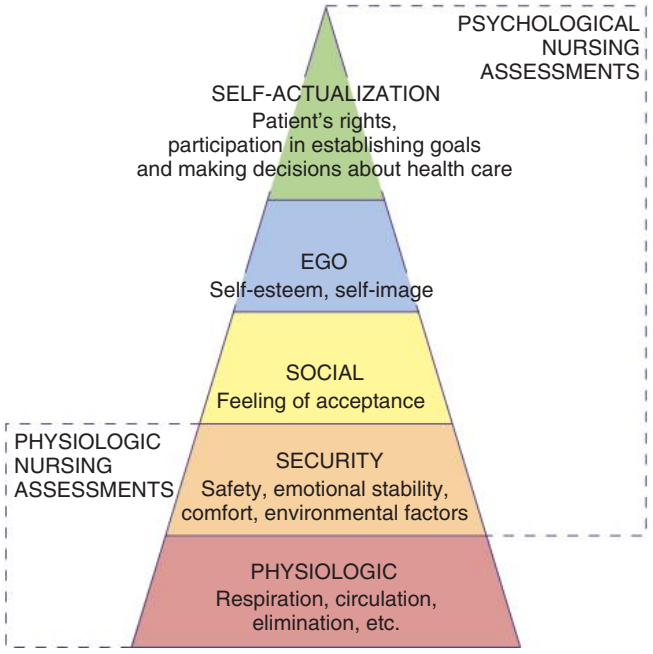
Extremes of age (pediatric and geriatric) and comorbid disease entities require individualization of the plan of care. To meet a patient's requirements and expectations effectively, personnel should have knowledge of the patient's needs, problems, and health considerations. From a perioperative perspective it is important to understand the effect a surgical procedure has on a patient's lifestyle. The following are some of the characteristics that individualize patients:

- They are unique with individual needs.
- They respond psychosocially on the basis of their personal values, beliefs, and ethnocultural background.
- They have the capacity to adapt to their internal and external environments.
- They have basic needs that must be met to maintain homeostasis.

Homeostasis is a consistent internal environment maintained by the patient's adaptive capabilities and has a physiologic and a psychologic component. From a physiologic aspect the patient's body strives to maintain equilibrium within normal limits through control mechanisms located in the endocrine glands and in the reticular formation in the brainstem. This stability depends partly



• **Fig. 7.1** The OR from the patient's perspective.



• **Fig. 7.2** Maslow's hierarchy of needs as related to surgical patient needs during perioperative care.

on the structural integrity of the body, the adequacy of its functions, and environmental influences.

Psychologic homeostasis is based on emotional acceptance and a rational understanding of events that influence health and wellness. Fear and anxiety are common stressors that alter a patient's psychologic response to the health care system.

Patients' Basic Needs

Needs are factors that must be controlled or redirected to restore altered function. Nursing diagnoses are based on knowledge and understanding of a patient's needs and how to fulfill them. The surgical patient faces a threat to the needs identified by humanistic psychologist and motivational theorist Abraham Maslow (1908–1970): physical, security, psychosocial, emotional, and spiritual.[1]

Hierarchy of Needs

In following Maslow's concept of a motivational hierarchy of needs to set priorities for care (Fig. 7.2), the basic lower level (physiologic needs) essential for survival must be met first. Satisfaction of the higher level needs for safety and security, belonging and acceptance, self-esteem, and self-actualization can then be met. Health care personnel should be concerned with a total picture of the patient's needs and consider all of them. In illness, needs can be influenced by factors such as location of the pathologic condition, type of surgical procedure, and effectiveness of therapy. In addition, priorities may shift with changing situations. Preoperatively, individual needs such as comorbidities, anxiety, nutritional status, and rehabilitation are addressed. Intraoperatively, the team concentrates on the patient's physiologic needs for oxygen and circulation and the prevention of shock and infection. Postoperatively, team members must prevent complications and encourage patient self-actualization. If the patient's needs are not met satisfactorily, undesirable consequences can occur.

To meet a patient's needs the health care team should be sensitive to the patient's feelings about the illness. A patient's reactions influence his or her behaviors and the staff's behavioral responses. An understanding of the patient's basic methods of coping is helpful to the caregiver in developing the plan of care (Table 7.1).

Behavior

Health and human behavior are interdependent and often age dependent. Regardless of age, individuals with physiologic problems experience some emotional change that influences their behavior. Patients react to a new interpersonal environment according to their learned behavioral patterns. The following list includes basic facts about behavior:

- The **perception** of interaction within the environment creates individual differences in personality, behavior, and needs.
- A person's physical and psychosocial behavior is a response to stimuli in an attempt to maintain homeostasis.
- Behavior is complex. Behavioral acts have multiple causes in addition to a major precipitating one.
- A person functions on many levels simultaneously. Many factors determine an individual's response in a given situation.

Behavior should be evaluated in light of the person's specific situation and pertinent social forces such as family, culture, and environment. Patients respond to crises or personal threats in different ways. Some persons face suffering and surgical intervention with extreme courage, dignity, and fortitude. Others may revert to extreme fear or helplessness, even when faced with a relatively safe procedure.

Overt behavior is not necessarily consistent with one's feelings but often reflects them most accurately. Patients often express frustration and fear behaviorally in an effort to cope with environmental stimuli.

Adaptation

In 1984, theorist Sister Callista Roy proposed adaptation as a conceptual model for nursing. Any deviation from a person's normal daily pattern of living necessitates adaptation through innate or acquired defenses. Adaptation may involve physiologic or psychologic changes.[2] Her **paradigm** as it applies to perioperative patient care includes the following factors:

1. The patient takes in stimuli and processes the information to produce a response.
   a. Effective adaptation is exhibited by a favorable response.
   b. Ineffective adaptation is exhibited by an unfavorable response.

TABLE 7.1 Common Coping Mechanisms

Mechanism	Meaning	Objective Assessment	Example
Denial	Rejects responsibility; unable or unwilling to accept the truth	Stammers; may or may not make eye contact; seems to be making excuses	"I do not have lung cancer."
Displacement	Shifts blame to a weaker substitute	Is submissive to power figures but critical and oppressive to subordinates	"My doctor never tells me anything. The laboratory must be wrong."
Identification	Acts like an admired hero or villain	Shows outward signs of indecisiveness and low self-esteem	"My sister and I both feel ill. We both have the same disease, I'll bet."
Projection	Attributes unacceptable behavior to others	Acts suspicious of others; assumes a defensive posture	"The cigarette manufacturer enticed me to smoke."
Rationalization	Justifies behavior with plausible statements	May be defensive or smug; tries to save face; can become hostile	"I became ill only because cancer runs in my family."
Reaction formation	Acts differently than he or she feels inside	Is confused, irrational; has mood swings; may seem overly conscientious and moral	"These are not tears of sadness; they are tears of joy because I will be dead soon."
Regression	Reverts back to a more primitive state of being	May assume closed, fetal position; has crossed arms and legs; looks downward, cries; has prolonged silences	"I want my mother."
Repression	Blocks unacceptable thoughts and feelings	Has a blank stare, a questioning look; no in-depth discussions	"I don't remember what my diagnosis is. Why am I here?"

2. The environment around and inside the patient is constantly changing. The patient responds either favorably or unfavorably to each change.
3. The health status of the patient integrates the whole person as he or she adapts to changes in internal and external forces.
4. The process of nursing is a science and the application of patient care is an art.

Both the mind and the body must adapt successfully for the patient to recover. Adaptation requires energy, ingenuity, and persistence. The adaptive process includes physiologic or psychologic changes that constitute an attempt to counteract stimuli so the individual can continue to function. If something interferes with this adaptation, the effects can be detrimental. Adaptation to illness includes three stages, as follows:

1. Transition from health: development of symptoms
2. Acceptance: coping and making decisions
3. Convalescence or resolution

Adaptation may be rapid or slow depending on the nature of the stimuli and on the patient's culture, learned responses, and developmental needs. Adaptations may be sensory, motor, or sensorimotor. The extent of adjustment needed is contingent on the type of illness, the magnitude of disability, and the patient's personality. More information about Roy's adaptation theory can be found online at www.currentnursing.com.

Stress

Stress can be defined as a physical, chemical, or emotional factor that causes tension, and it may be a factor in disease causation. It is the result of a perceived threat and is manifested by changes in physiologic and psychosocial behavior. Stress tolerance depends on the individual and on the stressor—its intensity, duration, and type (either localized or generalized, such as pain).

Stressful factors can originate from within the individual or from the external environment. Intrinsic factors, or those that originate within a patient, include the following:

- Hereditary or genetic factors, such as competency of the hormonal or enzymatic system.
- Nature of the illness or disease process. This may be influenced by nutritional or immunologic status.
- Severity of the illness or the presence of a stigma.
- Previous personal experiences with illness. Chronic illness has a disruptive effect on lifestyle.
- Age. Children feel threatened, whereas adolescents resent an interruption of activities and are painfully aware of body changes. Older people think about infirmity and death.
- Intellectual capacity. Misconceptions can lead to a knowledge deficit about the disease. Impaired cognitive function creates an inability to understand or comprehend.
- Disturbed sensorium. Hearing or sight loss intensifies a stressful experience.
- General state of personal well-being.

Extrinsic factors originate from external sources and include:

- Environment. The physical and social environment of the hospital is not the same as that of the home.
- Family role and status. Expectations and authoritative relationships affect lifestyle, attitudes, and communications.
- Economic or financial situation.
- Religion. Beliefs influence attitudes and values toward life, illness, and death. For example, Jehovah's Witnesses do not permit transfusion of whole blood or blood components. Orthodox Jews must follow dietary laws in any environment. The fatalistic attitudes derived from some religious beliefs give a person little control over his or her environment and can render a patient passive and apathetic.
- Cultural background, education, and social class. These factors are closely related to a patient's emotional responses and living habits. Significant cultural elements such as food habits, daily living patterns, hygiene, family organization, child care, and orientation to the past, present, and future should be analyzed in relation to culture. An ethnic community is really a larger

family. Roles taught by a cultural group influence the values, beliefs, and social interactions of its members. Also, responses to pain may vary according to cultural or ethnic background. Some groups commonly show an exaggerated emotional response, whereas other groups believe concealing suffering and feelings is more appropriate.
- Social relationships. Family, significant others, and friends help satisfy the need for reassurance and provide a sense of being cared about.

Stress is both physiologic and psychological. It can adversely affect appetite and bodily functions such as digestion, metabolism, and fluid and electrolyte balance. The secretion of adrenocortical hormones delays wound healing and decreases resistance to infection. In addition, the patient's emotional needs come to the surface during times of markedly increased stress, which mobilizes defense mechanisms for fight or flight. The patient's ability to adapt depends in part on options and effective intervention.[2]

Anticipatory apprehension, although normal to some degree, may diminish critical thinking and decision-making abilities and may also initiate an exaggerated response. Patients feel vulnerable when threatened with the loss of body parts, bodily function, or life. The assumptions of the OR itself—its noises, odors, and equipment—can be frightening for patients.[3]

Patients' Perceptions of Care

Studies have shown that a patient's perception of high-level care is based on participation in decisions. Patients are better educated and have higher expectations for better care. The patient's belief system defines what he or she considers to be good care.[3] Perceptions of caring behaviors vary according to the degree of illness, type of procedure, level of cognition, and setting. Most patients believe that proficient and efficient perioperative care includes assistance with pain control, warmth, comfort, and a safe environment. The caregiver is also perceived as a patient advocate and a communication link with the family or significant others.

Research has revealed that preoperatively a patient needs information about the surgical procedure, how it will be performed, and the type of anesthetic to be used. Intraoperatively, the patient assumes a passive role, entrusting care to the perioperative team.

Before administration of the anesthetic the patient may be acutely aware of surroundings and activities. Patients surveyed indicate that during this segment of intraoperative care they want to know what is happening as it takes place and desire reassurance from the circulator at their side. Patients expect the perioperative nurse to remain in physical proximity and act promptly in an emergency. During the check-in and time-out periods of patient identification and verification of the procedure, the patient is included in the dialogue as much as possible. Documentation of the patient's inclusion and responses should be part of the permanent record.

During and after the administration of the anesthetic, the patient places a strong sense of confidence in the team as a whole and has expectations of competence and efficiency. The professional nurse is considered a main source of protection during this period of vulnerability and should not leave the patient's side.

Postoperatively, patients expect the perioperative and perianesthesia nurses to monitor their condition closely and provide pain relief as needed. In continuation of the passive role, patients perceive the nurse as caring, knowledgeable, protective, and efficient. Patients respond favorably to the following scenarios:
- Provision of privacy and dignity
- Sensitivity to the inconvenience of hospitalization
- Frequent family updates during the surgical procedure
- Attention to personal and special needs
- Acceptance of personal individuality
- Friendliness
- Accurate and understandable information about tests and treatments

Family/Significant Others

A discussion of the patient is not complete without specific mention of the patient's family or others significant in his or her life. Illness often creates an emotional and financial burden on the family. They may experience considerable anxiety over the outcomes of surgery, the feelings of isolation, and the disruption of lifestyle. A family's reaction to illness and perception of care is as individualized as the patient.

Families need preoperative instruction to prepare for the postoperative outcomes and rehabilitation. They also need to be kept informed of the patient's progress during the surgical procedure and recovery period. Many surgeons have the circulating nurse call the waiting room when the procedure is started and periodically as the procedure progresses. Some facilities issue pagers so family members may leave the waiting room and not miss any updates. Time passes more slowly during waiting periods, and family members may fear something has gone wrong if the wait is longer than anticipated. Some family members may prefer to wait at home or at work. The surgeon should contact a spouse, family member, or significant other when the surgical procedure is over.

Discussions with anyone other than the patient concerning condition or personal information require the patient's permission as part of the Health Insurance Portability and Accountability Act (HIPAA) requirements concerning patient privacy. Details can be found at www.hhs.gov/hipaa.

The Patient with Individualized Needs

The debilitated, chronically ill, or age-extreme patient has an increased difficulty in combating the stress of surgery and anesthetic agents. Other problems or health considerations that predispose the patient to intraoperative or postoperative complications include substance abuse or other serious subclinical conditions not revealed during the preoperative assessment.

Preoperative diagnostic and laboratory studies assist in establishing diagnoses and in pinpointing areas of deficiency. Surgical intervention is often postponed until one or more physiologic conditions are improved or controlled (e.g., high blood pressure is lowered; cardiac dysrhythmias are corrected; or anticoagulation is controlled). Patients with more than one physical illness are considered comorbid. **Comorbidity** and the use of multiple drugs (**polypharmacy**) for their treatment complicates surgery and puts the patient at risk during anesthesia and surgical intervention. Preoperative therapy may be indicated to control diabetes, reduce obesity, or treat infection to decrease the risk for intraoperative or postoperative complications.

Patients of all ages and stages of development have different needs, and the ways of meeting these needs vary. A family-centered approach to care is valuable. Family cooperation is essential for communication with, interpretation for, and assistance with patients, particularly geriatric patients.

The Patient with Sensory Impairment or Physical Challenge

Some patients come to the perioperative environment with conditions unrelated to the surgical problem. Sensory and physically challenged patients commonly have increased anxiety and need a highly individualized plan of care; these patients also have the potential for a problematic postoperative recovery.

Sensory Impairment

Communication is essential to assess adequately the needs of challenged patients and to care for them. Team members should know about and understand the patient's limitations. Patients have a right to know what will happen during the surgical experience and to participate in decisions about their care.

The Rehabilitation Act of 1973 states that to receive federal funds an agency "must provide, when necessary, appropriate auxiliary aids to people with impaired sensory, manual or speaking skills to give them an equal opportunity to benefit from services." The complexities of each patient's situation should be evaluated and dealt with appropriately.

Language Barrier

A language barrier can be a complex challenge. Anxiety increases in proportion to one's inability to communicate in a stress-producing situation. The inability to understand or to express oneself verbally is frustrating, and the patient's behavior may reflect feelings of inadequacy or insecurity. Offer the patient something to write on, such as paper, an erase board, or a tablet, for communication.

Nonverbal body language through eye contact, pleasant facial expressions, and a gentle touch can comfort the patient who speaks a different language. Every effort should be made to obtain an interpreter to assist the patient and the health care team; many hospitals use interpreters for the ethnic groups within the community.

Some patients are reluctant to share confidential medical information with a relative or friend. The interpreter should be trusted and accepted by the patient and should be sensitive to the needs of the surgeon and caregivers. The patient needs to be adequately informed before giving consent for a surgical procedure and must provide permission for release of information concerning the procedure.

Hearing Impairment/Deafness

Hearing impairment varies from inner ear conduction changes that occur during the aging process and affect the distinction of some high-frequency consonant sounds to congenital profound sensorineural deafness. Conductive or sensorineural deafness may result from disease or injury to the ear at any age.

The degree of impairment determines whether the patient communicates through sign language, has a hearing-assistive cochlear implant, wears a hearing aid, or reads lips. Written information is always helpful, provided the patient is literate. Pictograms work well with most patients. An interpreter can assist with patients who use sign language.

The following steps should be observed when communicating with a patient who has a hearing impairment:

1. Make sure the room is quiet and well lit, with minimal distractions. Deaf patients may perceive extraneous sounds as buzzing or air-rushing. Deafness can be manifest in many degrees. Care is taken not to approach so quietly that the patient becomes startled.
2. Greet the patient without wearing a facemask and attract the patient's attention before speaking. Make eye contact.
3. Speak clearly and slowly in a moderate tone of voice, with visible but not exaggerated lip movements. Facial expressions, touch, and body gestures can help communicate feelings and instructions.
4. Be sure the patient understands and responds appropriately to questions.
5. To help explain your actions, show the patient any equipment (e.g., a safety strap) before placing it on him or her.
6. Allow the patient to wear a hearing aid in the perioperative environment, if possible. Try to know what type of device the patient uses and how to adjust the controls if it should start humming during the procedure. The team should know how to remove and deactivate the device if it could interfere with the planned procedure.

Visual Impairment/Blindness

Like deafness, blindness can be a part of the aging process, a congenital anomaly, or the result of an accident. Cataracts are a common cause of the loss of visual acuity; this condition may be inherited but is more often associated with aging. Vision is affected by the shape of the eye, other structural factors, and diseases and injuries.

Patients who are blind feel insecure in a strange environment; therefore the following steps should be observed when communicating with them:

1. Address the patient by name in moderate tones and then introduce yourself. Make some noise as you approach so as not to startle the patient.
2. Always speak to the patient before touching him or her. A gentle word followed by a gentle touch can be comforting.
3. For prevention of a distressful reaction to unexpected noises or sensations, the patient should be told what is going to happen before any physical contact.
4. Guiding the patient's hand helps him or her feel secure, such as when being moved onto the operating bed (OR bed).

A visually impaired patient should be permitted to wear spectacles in the perioperative environment as much as possible. If a general anesthetic is used, the spectacles should be placed in a container labeled with the patient's name and sent to the postanesthesia care unit (PACU) so they are available when the patient wakes. Contact lenses must be removed before administration of a general anesthetic because they may dry on the cornea or become dislodged.

Physical Challenge

Patients who are physically challenged need a highly individualized plan of care. Physical problems such as contractures, broken bones, spinal deformity, missing limbs, or pressure sores may make it difficult to position the patient on the OR bed. Patients with spastic muscle motion, as in cerebral palsy, need additional personnel around the OR bed for safety during transfer; otherwise the random body movement could cause the patient to fall.

Creative supports and positioning aids are needed, and additional assistance may be necessary to move the patient safely. Use alternating pressure pads, such as gel pads, as available. Exposure of the surgical site may be difficult to achieve.

Millions of people have some form of arthritis. Children with juvenile rheumatoid arthritis have many systemic problems as a result of the disease process, which continues into adulthood. The onset of this autoimmune disease can occur at any age and may result in stiffness, swelling, and deformity of the joints of the

hands, feet, and neck; inflammation of blood vessels; and tissue damage to organ systems. Joints need solid but padded support. Long-term treatment with nonsteroidal antiinflammatory drugs (NSAIDs) or corticosteroid therapy may affect bleeding intraoperatively and wound healing postoperatively.

Paralyzed patients, such as those with spinal cord injury, are unable to move. Patients with lack of voluntary muscle control, such as with cerebral palsy, must be protected from falls or injuries during transport or transfer. These patients may have decreased tactile sensitivity to heat and cold, so they must be protected from burns and hypothermia.

Impairment of Cognitive Function

Communicating with patients who have impaired cognitive function is sometimes difficult. Cognitive functions are based on intelligence and the ability to think, learn, remember, respond, and solve problems.

Explanations about procedures and the environment may seem confusing and frightening to these patients. Verbal communication should be attempted at the patient's level of understanding and response. Simple phrases and soft vocal tones can be reassuring. Some patients benefit from the presence of a significant other.

Patients with an autistic spectral disorder have a variety of cognitive levels. Understanding the individual characteristics of the patient's condition is useful during communications with the patient. Cooperation during the surgical procedure may be hard to attain, and preoperative sedation may be necessary. More information concerning autistic spectral disorder can be found at www.nichd.nih.gov/health/topics/autism.

The Patient with Alteration of Nutrition

Decreased intake and increased metabolic demands create nutritional problems in surgical patients. Drug therapy and procedure activities affect nutritional status; this should be considered when planning for a patient's nutritional needs. Table 7.2 describes the effects that certain drugs have on nutrition. With so many prescriptions, over-the-counter (OTC) drugs, and herbal substances on the market, patients should consult a pharmacist about possible side effects, nutritional effects, and long-term medication complications. The preoperative assessment may reveal risk factors associated with alterations of nutrition. Patients undergoing procedures of the mouth, face, head, and neck may have mechanical difficulty taking adequate nutrition orally. Some patients may have peripheral means of nutrition in place, such as feeding tubes, percutaneous gastric tubes, or central IV lines.

Malnutrition

Malnutrition in the surgical patient is caused by an inadequate intake or use of calories and protein preoperatively and/or postoperatively. The discrepancy between the intake of essential nutrients and the body's demand for them creates a state of impaired functional ability and structural integrity.[4]

Surgical patients are commonly kept without food preoperatively for safe anesthetic administration and postoperatively to prevent nausea and vomiting. Patients who are undernourished have less than 70% to 80% of ideal body weight (IBW) and suffer greatly from the lack of caloric intake. As a result of malnutrition the patient may experience the following side effects:

1. Poor tolerance of anesthetic agents
   a. Decreased metabolism of chemicals by the liver
   b. Inadequate excretion of toxins by the kidneys
   c. Unstable vital signs
   d. Hypothermia
2. Altered wound healing potential
   a. Decreased protein synthesis postoperatively
   b. Increased protein wasting and breakdown of skeletal muscle after severe traumatic injury
   c. Negative nitrogen balance, with a serum albumin value less than 3 g/dL and blood urea nitrogen (BUN) value less than 10 g/dL

TABLE 7.2 Drugs That Interfere with Nutritional Status

Drug	Effect on Nutrition
Aluminum hydroxide	Binds with other nutrients, causing phosphate malabsorption
Aminoglycosides	Reduce carbohydrate metabolism
Amphetamines	Suppress appetite, causing weight loss
Antacids	Alter gastrointestinal pH
Anticholinergics	Decrease gastrointestinal motility, causing malabsorption
Anticonvulsants	Can cause a decrease in calcium and vitamin D
Antihistamines	Stimulate appetite and can cause weight gain
Antihypertensives	Decrease gastrointestinal motility, causing malabsorption
Antineoplastics	Impair nutrient absorption
Antirheumatoids	Impair nutrient absorption
Benzodiazepines	Stimulate appetite, causing weight gain
Cathartics	Cause calcium and phosphate loss
Chloramphenicol	Inhibits protein binding
Cytotoxic agents	Suppress appetite, causing weight loss
Diuretics	Cause potassium loss (potassium-sparing diuretics are available)
Immunosuppressives	Suppress appetite, causing weight loss
Isoniazid	Causes pyridoxine deficiency
Neomycin	Interferes with bile acids, causing iron, sugar, and triglyceride malabsorption
Phenobarbital	Causes vitamin D deficiency
Phenothiazines	Stimulate appetite, causing weight gain
Phenytoin	Causes osteomalacia
Steroids	Deplete sodium
Tricyclic antidepressants	Stimulate appetite, causing weight gain

3. Decreased serum electrolyte levels associated with anorexia, bulimia, alcoholism, and other chronic metabolic disturbances
   a. Hypokalemia (low potassium level)
   b. Hypomagnesemia (low magnesium level)
   c. Hypocalcemia (low calcium level)
4. Increased susceptibility to infection from immunologic incompetence, with a total lymphocyte count less than 1500/mm^3
5. Sequential multisystem organ failure
   a. Dehydration
   b. Abnormalities in glucose regulation
   c. Abnormalities in clotting mechanisms
   d. Renal failure
   e. Cardiopulmonary failure
6. Increased risk for morbidity and mortality

Serum blood tests help determine nutritional status and include total proteins, albumin-to-globulin ratio, and BUN level. Body weight is also significant. The average adult patient needs a minimum of 1500 calories daily to prevent body protein catabolism.

Hypermetabolic states can double that requirement to 3000 calories daily. If caloric intake is less than body requirements, protein is converted into carbohydrates for energy. Protein synthesis then becomes insufficient for restoration of body tissues. Box 7.1 describes conditions that place a patient at risk for protein deficiency and malnutrition. Information about protein and dietary guidelines can be found at health.gov/dietaryguidelines.

Depleted reserves of essential elements must be replenished to replace tissue loss and expedite wound healing. Protein deficiency impairs collagen formation, thereby delaying the healing process. Water-soluble vitamins B complex and C are important for tissue repair and nervous system function. The fat-soluble vitamins A, D, E, and K are important for neurovascular activities.

The patient's depleted nutritional status lowers host resistance by impairing lymphocyte and neutrophil production. A definite relationship has been shown between hypoproteinemia and proliferative postoperative infection. Wound healing is impaired.

Metabolism

Metabolism is the phenomenon of synthesizing foodstuffs into complex elements and complex substances into simple ones in the production of energy. It involves two opposing phases:

1. *Anabolism:* The conversion of nutritive material into complex living matter; tissue construction.
2. *Catabolism, or destructive metabolism:* Breaking down or dissolution by the body of complex compounds, often with the release of energy.

• BOX 7.1 Factors That Increase a Patient's Risk for Protein-Based Nutritional Deficit

- Chronic illness
- Acute illness
- Stress
- Metabolic disease
- Sensory impairment
- Unconsciousness
- Polypharmacy
- Depression
- Immobility
- Edentulousness
- Lack of monetary resources to purchase protein-rich foods

Metabolic disorders such as diabetes and the stress response of traumatic injury can complicate the outcome of a surgical intervention. Hormonal responses to physical stress involve both anabolic and catabolic effects on the body, with catabolism being the predominant effect. The degree of metabolic reaction may depend greatly on the body's reserve of labile protein. The patient's preoperative nutritional state, the type and extent of the surgical procedure, and the effect of the surgical procedure on the patient's ability to digest and absorb nutrients affect immediate postoperative metabolism.

Catabolic responses are augmented by preoperative fasting, cathartic preparation, adrenocortical responses to tissue trauma during the procedure, blood loss, hypothermia, and alterations in fluid and electrolyte balance. Patients with burns, traumatic injury, absorptive disorders, or toxemia need careful nutritional replacement because they usually have a severe protein deficit. Hydration and renal function are closely observed and monitored in the perioperative environment.

Drugs also can have an adverse affect on metabolic balance. Broad-spectrum antibiotics limit a disease process, but in association with dietary inadequacy they can cause vitamin K deficiency in older patients by inhibiting the intestinal bacteria that produce that vitamin. Drug detoxification or excretion may be altered in patients with impaired kidney or liver function, leading to possible drug overdose.

Nutritional Supplements

Dietary management is used to correct metabolic and nutritional abnormalities before the surgical procedure. In some patients, special nutritional supplements are indicated to build up or compensate for a permanent metabolic handicap. Enteral feedings help maintain the integrity of the gastrointestinal mucosa. Successful therapy is indicated by weight gain, a rise in plasma albumin, and a positive nitrogen balance. A chemically defined elemental diet may be administered by the following routes:

- Oral intake
- Nasogastric tube for enteral nutrition
- Gastrostomy tube, with or without infusion pump, for enteral nutrition
- IV infusion of protein and dextrose through a peripheral vein for parenteral nutrition
- Central venous cannulation for hyperalimentation for parenteral nutrition

The Patient with Diabetes Mellitus

Diabetes mellitus is an endocrine disorder that affects glucose metabolism and the production of insulin in the beta cells of the pancreas. Insulin is a hormone that helps break down carbohydrates. If insulin is not produced in sufficient quantities or is of poor quality, carbohydrates are not metabolized and are excreted in the urine as glucose. Glucose molecules are large and damage the cellular structure of the renal tubules of the kidneys.

Usually genetic in origin, diabetes mellitus can be triggered in predisposed individuals by environmental stress.[5] Management of the surgical patient with diabetes depends on the type and control of the disorder, which is one of the following types[5]:

1. *Type 1:* Insulin-dependent diabetes mellitus. The pancreas produces little or no insulin, thus necessitating regular administration of insulin via injection. Onset may be at any age but usually occurs in juveniles (adolescents ages 12 to 16 years) and adults up to age 40 years.

2. *Type 2:* Non–insulin dependent diabetes mellitus. The pancreas produces varying amounts of insulin. Onset may be at any age but usually occurs after age 40 years in obese persons. Blood glucose levels are controlled by diet, weight loss, exercise, and the administration of oral antihyperglycemics, or injectable noninsulin drugs. In some cases, insulin therapy is necessary to lower blood glucose levels.
3. *Diabetes mellitus associated with other conditions or syndromes.* Impaired glucose tolerance may be the result of pancreatic or hormonal disease, drug or chemical toxicity, abnormal insulin receptors, or other genetic syndromes. The diabetes may be latent, asymptomatic, or borderline.
4. *SGLT2 inhibitors*: These drugs are new to the market and work by preventing the body from reabsorbing sugars through the kidneys. Empagliflozin (Jardiance) and dapagliflozin (Farxiga) are two examples.
5. *GLP-1 receptors:* This new group of injectable drugs work by lowering blood glucose levels and slows digestion. Examples include semaglutide (Ozempic), exenatide (Byetta), dulaglutide (Trulicity), and liraglutide (Victoza).

Stress caused by physical and emotional trauma, infection, or fever raises blood glucose levels and stimulates the pituitary and adrenal glands. The pituitary gland secretes adrenocorticotropic hormone (ACTH), which stimulates the production of glucocorticoids. These glucocorticoids in turn increase gluconeogenesis, the formation of glucose by the liver from noncarbohydrate sources. The resultant extra glucose enters the bloodstream.

Coincidentally, the adrenal glands secrete epinephrine, which accelerates the conversion of glycogen in the liver to glucose and also raises the level of blood glucose. More insulin is needed to metabolize this additional blood glucose. The primary goal in controlling diabetes is to maintain a stable internal environment, thereby averting a metabolic crisis.[5] Extreme care must be taken to prevent the following conditions:

1. Hyperglycemia and ketonuria
   a. A rise in blood glucose and ketones can precipitate severe fluid loss, causing dehydration and hyperkalemia from the release of potassium from cells.
   b. Some medications (e.g., cortisone) increase the level of blood glucose and antagonize the effect of insulin.
2. Ketoacidosis and acetonuria
   a. These conditions are caused by insulin insufficiency from natural causes or from a reduced or omitted insulin dosage.
   b. These conditions may result in coma and ultimately death if allowed to progress untreated.
3. Hypoglycemia and hypoglycemic shock
   a. These conditions are caused by too much insulin.
   b. They are of faster onset than ketoacidosis.
   c. Hypoglycemia is especially dangerous. It can occur during major surgical procedures because of the omission or delay of oral intake.
   d. These conditions can cause brain damage and put stress on the cardiovascular system.

Prevention of these states depends on the following factors:

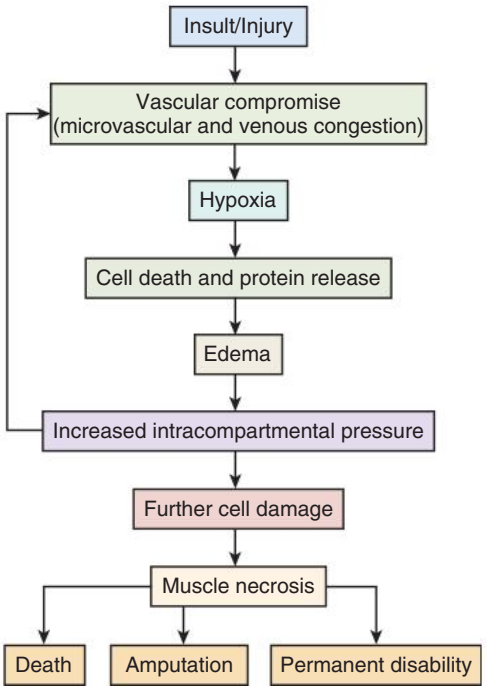
- Physician's treatment of choice for diabetes
- Severity and type of disorder
- Existence of complicating conditions
- Type of surgical procedure.
- Blood glucose should be monitored throughout the perioperative care period and maintained between 80 and 110 mg/dL, if possible. Preoperative blood glucose A1C should be less than 7%.[6] All diabetic patients undergoing a surgical procedure should discuss NPO (nil per os, nothing by mouth) status, diabetes medication time, and dose amount with the surgeon. Each individual will have a different plan; some patients will be instructed not to take any medication or reduce the dose.
- Patients undergoing general anesthesia may have different intraoperative and postoperative blood glucose numbers. According to the Society for Ambulatory Anesthesia (SAMBA), patients had fewer adverse outcomes when blood glucose levels were maintained between 140 and 180 mg/dL for 24 hours or until the patient was stable to resume a presurgical regimen. Patients with blood glucose levels over 200 mg/dL were at risk for complications and higher mortality rates.[6]

The preoperative assessment of patients with the potential for impaired glucose metabolism includes laboratory testing for fasting and postprandial blood glucose levels, urinalysis, complete blood count, BUN values, and serum electrolyte determinations. A chest x-ray study and electrocardiogram (ECG) also are advisable.

Common Complications

The balance between caloric intake and glucose metabolism is disrupted during the perioperative experience. Patients with type 2 diabetes usually withstand a surgical intervention without crisis. Intraoperative metabolic control may be more difficult in patients with type 1 diabetes who have marked unpredictability and greater extremes in blood glucose levels. Lengthy major surgical procedures with extensive tissue trauma present the greatest challenge to regulation. Patients with diabetes are prone to the following conditions:

- Dehydration and electrolyte imbalance
- Infection
- Inadequate circulation from neurovascular disease, which causes deficient tissue perfusion (Fig. 7.3)
- Hypertension
- Hyperlipidemia that affects both coronary and peripheral arteries; peripheral edema can lead to gangrene



• **Fig. 7.3** Outcomes of tissue injury in the OR.

- Delayed wound healing as a result of increased protein breakdown or compromised circulation; glycogenesis, the breakdown of glycogen to glucose in the liver, diverts protein from tissue regeneration
- Neuropathy or nervous system disorders, which cause motor and sensory deficit
- Nephropathy, which affects small blood vessels in the kidneys
- Retinopathy, which affects small vessels in eyes, and blindness
- Neuropathic musculoskeletal disease; severe bone destruction may cause neuropathic fractures
- Neurogenic bladder, which causes incontinence; urinary tract infections are common
- Hypothermia related to metabolic disorders

Diabetes causes many bodily changes that increase in frequency with duration of the disease. Physiologic dysfunctions, as listed in Table 7.3, make a person with diabetes a potentially high-risk patient.

Special Considerations

Scheduling of elective surgical procedures early in the day for patients with diabetes minimizes the period during which oral intake is restricted. Assessment of these patients can minimize potential risks:

1. Capillary blood should be tested preoperatively for fasting serum glucose. The results provide baseline data for assessment of postoperative control.
2. The preoperative insulin dose may be reduced or eliminated to guard against hypoglycemia or insulin shock during the surgical procedure.
3. Continuous IV access is vital throughout the surgical procedure in case of a metabolic problem. An infusion of dextrose in water may be started to begin administering the daily carbohydrate requirement before the patient comes to the OR.
   a. Optional methods of management for patients who are insulin dependent are determined by the severity of the disease, the preoperative control regimen, and the type of surgical procedure. Insulin may be added to the infusion or administered via subcutaneous injection. Amounts are determined by serum glucose levels. Patients with insulin pumps should consult the surgeon and be advised to keep the pump working or disconnect the device. If the pump is disconnected, the anesthesia provider will administer necessary medication.
   b. Adequate hydration must be maintained because a rising blood glucose level upsets osmotic equilibrium. Electrolytes may be added to maintain metabolic status.
   c. Fluid intake and output must be monitored to maintain hydration without fluid overload.
4. A metabolic crisis in an unconscious patient is difficult to detect without frequent blood tests. Therefore during long surgical procedures, blood glucose levels are monitored for hyperglycemia or hypoglycemia. Glucometers accurately measure capillary blood glucose levels. Monitoring is necessary to ascertain the patient's requirements for insulin, glucose, or both.
5. Nasogastric suction may cause acidosis, dehydration, or electrolyte imbalance.
6. Antiembolic stockings are usually worn by the patient during the surgical procedure and postoperatively as a precaution against thrombophlebitis and thromboembolism. Some surgeons use sequential compression leg wraps to prevent deep vein thrombosis during long periods of immobility.

TABLE 7.3 Physiologic Dysfunctions in Patients at High Risk with Diabetes and Obesity

Diabetes Mellitus	Obesity
Integumentary System	
Skin that may be dry, itchy	Hirsutism in women
Loss of fat from adipose tissue	Excess subcuticular fat
Injuries that heal slowly	Injuries that heal slowly
Musculoskeletal System	
Neuropathic skeletal disease with bone destruction	Osteoarthritis
Leg pain, neuropathy	Chronic back pain
Muscular wasting	Strain on joints and ligaments
	Joint pain
	Diminished mobility
Cardiovascular System	
Increased heart rate	Myocardial hypertrophy
Predisposition to coronary artery disease	High blood pressure
Predisposition to thrombophlebitis	Arteriosclerosis
Peripheral edema	Venous stasis
	Varicose veins
Respiratory System	
Predisposition to infection	Shortness of breath
	Decreased tidal volume
	Decreased lung expansion
Renal System	
Nephropathy	Vascular changes in kidneys
Increased excretion	Decreased intestinal mobility
Neurogenic bladder	Predisposition to liver and biliary disease
Gastrointestinal System	
Secretion of glucose by liver	
Neurologic System	
Neuropathy	
Sensory impairment	
Retinopathy and blindness	
Endocrine System	
Poor or nonexistent insulin production	Predisposition to diabetes mellitus
Poor metabolic control	Pituitary abnormalities
Increased production of cortisol by adrenal glands under stress	Poor metabolic control
Electrolyte imbalance	Dysfunctional uterine bleeding

7. Skin integrity must be guarded to avoid breakdown.
   a. Strict aseptic and sterile techniques are extremely important to the infection-prone patient with diabetes.
   b. To protect bony prominences and prevent pressure sores, foam padding or a gel mattress should be placed on the OR bed for surgical procedures expected to take more than 2 hours.
   c. Hyposensitive tape is used to affix dressings.
   d. If an active warming device is used, the patient's skin should be monitored for contact burns.

The Obese Patient

Obesity is prevalent in our society. The condition is referred to as morbid obesity when weight exceeds 100 lbs (45.4 kg) over the ideal weight and the patient's **body mass index (BMI)** exceeds 25 to greater than 30 kg/m^2. Patients may be offended or embarrassed by use of the term *obese.* In discussing the subject of weight the patient may respond better if kinder terms such as *weight problem* or *weight difficulties* are used. The term *morbid* is used to describe from 110% to greater than 120% of IBW and its serious effect on health and lifestyle.[7] It may be of one of two origins:

1. *Endocrine:* Usually associated with biliary, hepatic, or endocrine disease.
2. *Nonendocrine:* Commonly associated with excessive caloric intake.

Common Complications

Surgical patients who are 10% or more overweight have an increased incidence of morbidity and mortality caused by concomitant systemic diseases and physical problems.[7] The degree of morbidity varies with the severity of the obese condition. The physiologic dysfunctions of obesity are listed in Table 7.3.

Obesity predisposes an individual to several conditions, including:

- Increased demand on the heart. Pulse rate, cardiac output, stroke volume, and blood volume increase to meet the metabolic demands of the adipose tissue (fat). Eventually this overload leads to myocardial hypertrophy (enlargement of the heart), and congestive heart failure may result. Coronary artery disease also is common.
- Hypertension (high blood pressure). Vascular changes in the kidneys are associated with hypertension and affect the elimination of protein wastes and the maintenance of fluid and electrolyte balance.
- Varicose veins and edema in the lower extremities. Poor venous return results from pressure on the pelvic veins and the vena cava. Venous stasis can ultimately contribute to thrombophlebitis and thromboembolism. Some surgeons use sequential compression leg wraps or antiembolic stockings to aid venous return and prevent deep vein thrombosis during long periods of immobility.
- Pulmonary function abnormalities. Hypoxemia, or inadequate oxygen in blood, may be associated with decreased tidal volume or poor gas exchange caused by excessive weight on the thoracic cavity. Patients who are obese are susceptible to postoperative pulmonary infection and pulmonary embolism.
- Respiratory compromise sleep apnea is common.
- Diseases of the digestive system, such as liver or gallbladder disease. Diverticulosis is not uncommon.
- Osteoarthritis. This condition may limit mobility of the spine and joints and may in fact contribute to excessive wear on joint cartilage.
- Diabetes mellitus. Type 2 diabetes.
- Malnutrition. Although obese patients are overweight, they may have a protein deficiency or other metabolic disturbance such as hyperlipidemia.

Special Considerations

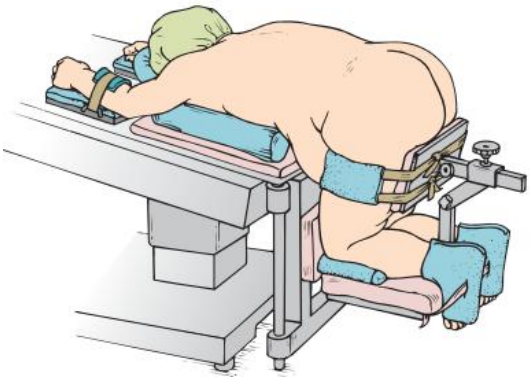
The physical size of an obese patient presents problems for the OR and PACU teams. Safety precautions against injury to the patient and staff, falls, and burns must be emphasized. Problems include the following situations:

1. Transporting and lifting the patient. Size-appropriate wheelchairs and stretchers should be used. Mechanical patient lifters are desirable. If these are not available, extra people are needed to ensure safety in lifting.
   a. Stretchers and OR beds must be weight appropriate and stabilized. Many standard OR beds cannot support more than 300 to 350 lbs. With the population becoming heavier, facilities are purchasing beds to accommodate obese patients. The manufacturer's instructions should be consulted. OR beds should be tagged with clearly visible weight restrictions. Larger weight loads can be borne by beds especially designed for obese patients.
   b. In moving the patient from the stretcher to the OR bed the wheels should be locked and it should be suggested that the patient sit up. The back of the patient's gown should be untied, and the patient should be asked to feel for the side of the OR bed so that he or she does not move too far and fall over the opposite side. Additional personnel should stand at the opposite side of the bed to prevent falls.
   c. Safety belts should be long enough to provide secure limitation of unwanted mobility. When the patient is supine the circulating nurse should place a small pillow under the patient's knees to relieve low back strain. The safety belt is placed over the thighs 2 to 3 inches above the knees. The circulating nurse should be able to slide one hand between the safety belt and the patient to ensure that no pressure is on the patient. A second safety belt may be needed for the lower legs if the patient's calves occupy the spaces closest to the edges of the bed because of the inability to close the legs when supine.
2. Keeping bodily exposure to a minimum as with all patients. Gowns are often small and may cause obese patients to feel self-conscious. Protecting the patient's privacy and dignity is the responsibility of the entire team.
3. Induction, intubation, and maintenance of anesthesia.
   a. On rare occasions, venous cutdown may be necessary to establish an IV line if peripheral veins are difficult to access. Some anesthesia providers may use a central line for better venous access.
   b. Mobility of the cervical spine to hyperextend the neck for intubation may be limited. The anesthesia chapter of this text (see Chapter 24) discusses neck and throat considerations for complex intubation. Some patients may need awake intubation.
   c. Inefficient respiratory muscles, poor lung/chest wall compliance, and increased intraabdominal pressure in the supine position reduce ventilation capability.
   d. Inefficient ventilation lowers the concentration of gases entering the alveoli of the lungs, which prolongs induction time.
   e. Continuous uptake by adipose tissue necessitates higher concentrations of anesthetic agents to maintain anesthesia.

Drug dosages are calculated by body weight in kilograms (2.2 kg = 1 lb). The circulating nurse should double check that the patient's weight is listed in kilograms on the chart for the anesthesia provider.

f. The recovery period may be prolonged because adipose tissue retains fat-soluble agents and because the poor blood supply in this tissue eliminates agents slowly.

4. Positioning, prepping, and draping on the OR bed.
   a. Extra personnel may be necessary to assist with positioning.
   b. Massive tissue and pressure areas must be protected. Protuberances must be padded to prevent bruising and pressure injuries (Fig. 7.4). Tissue folds, breasts, and genitalia should not be compressed. Alternating pressure reduction surfaces such as gel pads should be used. Rolled blankets are not appropriate padding because once compressed, they do not disperse the body weight and become a source of localized pressure.
   c. Ventilation and circulation must be ensured.
   d. When an electrosurgical unit is used, the patient's dispersive electrode is applied on a flat, dry, smooth surface and is not surrounded by overlapping skinfolds because tissue could be burned by accumulated radiofrequency energy.
   e. An additional person may need to help hold the legs during Foley catheter insertion in a female patient.
   f. More than one skin prep tray or applicator may be needed to accommodate large body habitus. Great care is taken to be sure that alcohol-based prep solutions do not accumulate in skin folds. This could be a fire hazard, because this area will not dry at the same rate as surface areas.
5. Increased operating time because of mechanics of the surgical procedure.
   a. In an open procedure, the accessibility of deep organs (e.g., gallbladder) may be a problem.
   b. Large instrumentation may contribute to surgical trauma and postoperative pain.
6. Thromboembolic complications, which may occur because of venous stasis; erythrocytosis, which increases the viscosity of the blood; and a decrease in fibrinolytic activity.[7] Anticoagulants such as subcutaneous heparin may be given prophylactically.
7. Delayed healing because of poor vascularity of adipose tissue. Obese patients have an increased incidence of postoperative wound infection and disruption caused by dead space in the adipose tissue.
   a. A sterile, closed drainage system is often used to drain accumulated fluid, thereby facilitating healing.
   b. It is harder to eliminate "dead space" in wound closure.



• **Fig. 7.4** Positioning an obese patient for spinal surgery on an Andrews frame.

Additional information about working with obese patients, including BMI charts, can be found at www.niddk.nih.gov.

The Patient with Cancer

Oncology is the study of scientific control over neoplastic growth. It concerns the etiology, diagnosis, treatment, and rehabilitation of patients with known or potential neoplasms. A neoplasm is an atypical growth of abnormal cells or tissues that may be a benign or malignant tumor.

Both malignant and benign neoplasms consist of cells that divide and grow uncontrollably at varied rates. The stimulus for growth can be intrinsic (e.g., hormonal) or extrinsic (e.g., exposure to external elements). Neoplastic overgrowth or the invasion of surrounding tissue causes dysfunction and may eventually cause the death of the patient.

Cancer is a broad term that encompasses any malignant tissue change and is potentially curable.[8] Treatment and prognosis are based on the type of cancer and the extent of the disease. Each type differs in its symptoms, behavior, and response to treatment.

The exact cause of cancer is unknown, but it is the second leading cause of death in the United States. Cancerous tumors can be caused by exposure to chemical toxins, ionizing radiation, chronic tissue irritation, tobacco smoke, ultraviolet rays, environmental hazards, viral invasion, and genetic predisposition. Studies have shown that immunosuppression may contribute to the incidence of cancer by altering biochemical metabolism and cellular enzyme production. Other research has shown that dietary influences, such as nitrates, salt-cured or smoked foods, and high-fat diets, may contribute to cancer in certain individuals.

Oncologists study the cause (epidemiology) of cancer and the diagnosis, treatment, and rehabilitation of patients with cancer. Moreover, patients are demanding that their surgeons give attention to the reconstruction of body image and rehabilitation to a useful life. Therefore the management of patients with cancer must be accomplished through the efforts of a multidisciplinary team of oncologic surgeons in conjunction with pathologists, radiation oncologists, pharmacists, immunologists, medical oncologists, and others. In addition to physical care, nurses in all patient care settings provide psychological support for cancer patients and their families.

Cancer Risk Avoidance Behaviors

Patient education should include information about avoiding cancer-causing behaviors and how to minimize the risk for cancer. Behaviors to discuss include the following[8]:

- Avoiding smoking and exposure to smoke. The U.S. Department of Health and Human Services reports that exposure to cigarette smoke is responsible for 83% of all cases of lung cancer. Secondhand smoke, referred to as *environmental tobacco smoke,* has been implicated in the development of cancer in nonsmoking people who are exposed to smoke on a regular basis.
- Increasing dietary intake of fiber and low-fat foods. Antioxidants such as vitamins A and C may reduce an individual's risk for development of cancer. High-fat diets have been implicated in the development of breast, colon, and prostate cancers. According to reports of the American Cancer Society, 20% of cancer deaths are related to dietary causes and are possibly preventable. A desirable weight should be maintained, and obesity should be avoided. Excessive alcohol intake also should be avoided.

- Minimizing sun exposure, especially between the hours of 10:00 AM and 4:00 PM.[8] Sun exposure has been shown to be the major cause of skin cancer, especially melanoma. Severe sunburn in childhood may be linked to the development of skin cancer later in life. Certain medications, such as tranquilizers, antidiabetic agents, diuretics, antiinflammatory agents, and antibiotics, can predispose an individual to sunburn. Certain cosmetic products, such as tretinoin (Retin-A) and α-hydroxy acid, are extremely reactive to sunlight and can increase the risk for sunburn within 30 minutes of exposure. Tanning booths also can be hazardous to the skin. A waterproof, broad-spectrum sunscreen with a sun protection factor (SPF) of at least 30 should be applied whenever sun exposure is likely.[8] Sun-blocking products of SPF 30 to 100 are preferred and should provide protection from both ultraviolet A and ultraviolet B (UVA, UVB) rays. (UVA rays can increase the damage caused by UVB rays.) Sunscreen should be applied at least half an hour before going outdoors and reapplied according to the directions.
- Having regular checkups, especially yearly checkups, after 40 years of age. Knowing the warning signs of cancer may promote prompt diagnosis and treatment. Signs to consider in young children include frequent swelling (lymphadenopathy) or bruising, unexplained headaches or fevers, dramatic weight loss or gain, and localized pain.
- Self-examining the skin, breast, and testes, may reveal early signs of cancer. These self-examinations should be performed monthly.

Extent of Disease

Carcinoma in Situ

In carcinoma in situ, normal cells are replaced by anaplastic cells, but the growth disturbance of epithelial surfaces shows no behavioral evidence of invasion and metastasis. This cellular change is noted most often in stratified squamous and glandular epithelium. Carcinoma in situ is also referred to as *intraepithelial* or *preinvasive cancer.* Common sites for in situ carcinoma include the following:

- Uterine cervix
- Uterine endometrium
- Vagina
- Anus
- Penis
- Lip
- Buccal mucosa
- Bronchi
- Esophagus
- Eye
- Breast

Localized Cancer

Localized cancer is contained within the organ of its origin.

Regional Cancer

In regional cancer the invaded area extends from the periphery of the organ or tissue of origin to include tumor cells in adjacent organs or tissues (e.g., the regional lymph nodes).

Metastatic Cancer

In metastatic cancer the tumor extends by way of lymphatic or vascular channels to tissues or organs beyond the regional area.

Disseminated Cancer

In disseminated cancer, multiple foci of tumor cells are dispersed throughout the body.

Cancer Treatment Modalities

Cancer is a systemic disease. Therapy is curative if the disease process can be totally eradicated, but the success of therapy depends largely on early diagnosis. Tumors are classified according to location, regional spread, and systemic extension for determination of the most effective therapy. When a cure is not possible, palliative therapy relieves symptoms and improves quality of life; however, it does not cure the disease. Additional information about surgery in patients with cancer can be found at www.cancer.org. This site provides concise descriptions suitable for students and patients and is a useful tool for patient education.

Adjuvant Therapy

Surgical resection, endocrine therapy, radiation therapy, chemotherapy, immunotherapy, hyperthermia, stem cell, targeted therapy, blood transfusion, or combinations of these procedures are used to treat cancer. The surgeon or oncologist determines the most appropriate therapy for each patient. In determination of the most appropriate therapy the following factors are considered:

- Type, site, and extent of tumor and whether lymph nodes are involved
- Type of surrounding normal tissue
- Age and general condition of the patient, including nutritional status and whether other diseases are present
- Whether curative or palliative therapy is possible

Before beginning therapy a patient with cancer undergoes an extensive pretreatment workup. Each form of cancer therapy has certain advantages and limitations. Several factors affect a patient's response to treatment: host factors, clinical stage of malignancy, and type of therapy. The patient is followed carefully to determine the effectiveness of treatment at routine intervals.

Surgical Resection

Surgical resection is the modality of choice to remove most solid tumors. The resection of a malignant tumor is, however, localized therapy for what may be a systemic disease. Each patient is evaluated and treated individually, and the surgical procedure is planned appropriately for the identified stage of disease. Depending on localization, regionalization, and dissemination of the tumor, the surgeon selects either a radical curative surgical procedure or a salvage palliative surgical procedure.

Surgical debulking (cytoreduction), in which the tumor is partially removed, may be the procedure of choice for some types of surgically incurable malignant neoplasms. With surgical debulking the intent is not to cure but to make subsequent therapy with irradiation, drugs, or other palliative measures more effective and thereby extend survival. In planning the surgical procedure the surgeon considers the length of expected survival, the prognosis of surgical intervention, and the effect of concurrent diseases on the postoperative result.

Accessible primary tumors are often treated with excision. An extremely wide resection may be necessary to avoid recurrence of the tumor. The pathologist is able to make judgments about questionable margins by evaluating frozen sections while the surgical procedure is in progress. The pathologist's findings guide the surgeon during resection so residual tumor is not left in the patient. The specimen is also tested after permanent section fixation in the

pathology laboratory. Final results are available in 2 to 3 days. Additional discussion about cancer diagnostics is found in Chapter 22.

Many surgical procedures are performed for ablation of tumors with primary resection. In addition, a lymphadenectomy (removal of local lymph nodes) may be performed as a prophylactic measure to inhibit the metastatic spread of tumor cells by lymphatic channels. These nodes are tested to determine the extent of tumor cell spread. Other modalities of therapy may be administered preoperatively, intraoperatively, and/or postoperatively to reduce or prevent a recurrence or metastasis.

Considerations for Intraoperative Care

Malignant tumor cells can be disseminated with manipulation of tissue. Because of their altered nutritional and physiologic status, patients with cancer also may be highly susceptible to the complications of postoperative infection. To minimize these risks the following specific precautions are taken in the surgical management of patients with cancer:

1. The skin over the site of a soft tissue tumor should be handled gently during hair removal and antisepsis. Vigorous scrubbing could dislodge underlying tumor cells; this is avoided with the use of "no-touch" techniques. With vascular tumors, manipulation during positioning or skin preparation could cause vascular complications such as emboli or hemorrhage. The no-touch technique means that the tumor is handled as little as possible during its removal.
2. Gowns, gloves, drapes, and instruments may be changed after a biopsy (e.g., a breast biopsy) before incision for a radical resection (e.g., a mastectomy). The tumor is deliberately incised to obtain a biopsy for diagnosis.
3. Instruments placed in direct contact with tumor cells may be isolated in a basin immediately after use. Even when the tumor appears to be localized, most cancers have disseminated to some degree. Therefore some surgeons prefer to use each instrument once and then discard it.
4. Some surgeons prefer to irrigate the surgical site with sterile water instead of sterile normal saline solution to cause the destruction of cancerous cells via lysis. This practice is common during mastectomy.
5. As a prophylactic measure, antibiotics are administered 1 hour preoperatively, with potential redosing intraoperatively for long procedures, and for 24 hours postoperatively to provide an adequate antibacterial level to prevent wound infection.
6. Time-honored precautions such as handling tissue gently, keeping blood loss to a minimum, and avoiding an unduly prolonged surgical procedure influence the outcome for the patient.

During a long surgical procedure the circulating nurse conveys periodic messages to the patient's family members or significant others to reassure them that their loved one is receiving care from a concerned perioperative team. Events to report to the family could include start time, completion of the main surgical procedure, such as tumor removal, and when closure begins. A quick call as the patient leaves the OR for the PACU can be reassuring to the family.

Cancer Therapy

Patients may have many treatments of a varied nature before they come to the OR for formal tumor resection. Many treatments for cancer require surgical implantation of a drug delivery device or tissue preparation before actual therapy can take place. The team should have an understanding of the entire treatment regimen the patient is undergoing in conjunction with surgery. The following methodologies have many different types of effects on the patient's physiology and can alter response patterns during surgical intervention. Some of these treatments require combined chemical, radiation, and multiple surgical procedures to be effective.

Endocrine Therapy

Tumors that arise in organs that are usually under hormonal influence (e.g., breast, ovary, and uterus in female patients; prostate and testes in male patients) may be stimulated by hormones produced in the endocrine glands.

Cellular metabolism is affected by the presence of specific hormone receptors in tumor cells: estrogen or progesterone in females and androgens in males. In some patients, surgical removal of the gonads may be incorporated in the procedure.

Certain breast, endometrial, and prostatic cancers depend on sex hormones for growth and maintenance. Therefore the recurrence or spread of disease may be slowed with therapeutic hormonal manipulation. Endocrine manipulation does not cure, but it can control dissemination of the disease if the tumor progresses beyond the limits of effective surgical resection or radiation therapy.

Hormonal Receptor Site Studies

Identification of the hormonal dependence of the primary tumor through studies of the receptor site is a fairly reliable way of selecting patients who will benefit from preoperative or postoperative endocrine manipulation. After a positive diagnosis of cancer, either with a frozen section biopsy or pathologic permanent sections, the surgeon will probably request a receptor site evaluation of a primary breast, uterine, or prostatic tumor. The tissue specimen removed by surgical resection should be sent to the pathology department fresh or in saline solution. It should not be placed in formalin preservative solution because doing so alters the receptor cells enough to negate the hormonal study.

Endocrine Ablation

Since 1896, surgeons have described positive clinical responses in patients with metastatic breast cancer after treatment with endocrine ablation, the surgical removal of endocrine glands. If the surgeon plans to eliminate endocrine stimulation surgically in a patient with a known hormone-dependent tumor, all sources of the hormone should be ablated chemically, hormonally, or surgically.

- *Bilateral adrenalectomy and oophorectomy.* Both adrenal glands or the ovaries may be resected to prevent the recurrence of endocrine-derived cancer. These may be removed as a one-stage surgical procedure (i.e., bilateral adrenalectomy/oophorectomy). If two separate surgical procedures are preferred, the bilateral oophorectomy precedes the bilateral adrenalectomy, except in menopausal women in whom only the latter surgical procedure may be indicated.
- *Bilateral adrenalectomy and orchiectomy.* After prostatectomy for advanced carcinoma of the prostate, both testes may be removed (i.e., bilateral orchiectomy) to eliminate androgens of testicular origin. Bilateral adrenalectomy also may be indicated.
- *Hormonal therapy.* Hormones administered orally or by injection can alter cell metabolism by changing the systemic hormonal environment of the body. For hormones to be effective, tumor cells must contain receptors. Hormones must bind to these receptors before they can exert an effect on cells.

- *Antiestrogen therapy.* Patients with medical contraindications to endocrine ablation may receive antiestrogen therapy. An estrogen antagonist deprives an estrogen-dependent tumor of the estrogen necessary for its growth. Nafoxidine and tamoxifen (Nolvadex) are synthetic nonsteroidal drugs that inhibit the normal intake of estrogen at estrogen receptor sites; they are taken orally.
- *Corticosteroids.* Prednisone, cortisone, hydrocortisone, or some other preparation of corticosteroids may be administered as an antiinflammatory agent, along with the chemotherapeutic agents given to control disseminated disease.

Photodynamic (Laser) Therapy

For photodynamic therapy (also referred to as *photoradiation*), an argon tunable dye laser is used to destroy malignant cells by photochemical reaction. A photosensitive drug, either hematoporphyrin derivative (HPD) from cow's blood (Photofrin; porfimer) or purified dihematoporphyrin ether, is absorbed by malignant and reticular endothelial cells. HPD is primarily used in esophageal or endobronchial tumors. This treatment is contraindicated in the presence of esophageal varices.

The photosensitive drug (2 mg/kg) is injected IV by venipuncture or Hickman catheter 40 to 50 hours before the photodynamic therapy and is taken up by cells to make them fluorescent and photosensitive. It remains longer in malignant cells than in normal cells before being excreted from the body. When exposed to light from an argon laser, the tunable rhodamine B dye laser produces a red beam of approximately 630 nm. An additional laser treatment can be given 96 to 120 hours post initial treatment without the need for further injection. Debridement of initial treatment site is necessary 2 to 3 days after each treatment as necrotic tissue begins to shed.

Other dyes, such as dicyanomethylene, may produce different wavelengths. HPD in cells absorbs the laser light, which leads to a photochemical reaction that causes tissue-oxygen molecules to release cytotoxic singlet oxygen and destroy tumor cells. Depending on tumor site, the laser can be delivered interstitially, endoscopically, externally, or retrobulbarly.

Photodynamic therapy may be used to debulk tumors of the eye, head and neck, breast, esophagus, gastrointestinal tract, bronchus, prostate, and bladder. The tunable dye laser also may be used to diagnose tumor cells. The OR should be darkened or have shades to block outside daylight during the laser treatment.

The patient is cautioned to avoid exposure to sunlight or other sources of UV light both after injection of the dye and postoperatively. Photosensitivity is the primary side effect of the dye and may last 4 to 6 weeks. Patients should be advised to wear sunscreen and sunglasses for at least 30 days posttreatment. Some patients have adverse reactions to bright household lights. Patients with liver impairment may experience photosensitivity for more than 90 days.

Radiation Therapy

Radiation is the emission of electromagnetic waves or atomic particles that result from the disintegration of nuclei of unstable or radioactive elements. The treatment of malignant disease with radiation may be referred to as radiation therapy, brachytherapy, or radiotherapy. Ionizing radiation is used for this type of therapy, which involves the use of high-voltage radiation and other radioactive elements to injure or destroy cells. Like surgical resection and photodynamic therapy, radiation therapy is localized therapy that is applicable for a limited number of specific tumors. Supplemental information on radiation therapy can be found online at www.cancer.gov/cancertopics/factsheet/Therapy/radiation.

Ionizing Radiation

Ionization is the physical production of positive and negative ions capable of conducting electricity. Ionizing radiation is radiation with sufficient energy to disrupt the electronic balance of an atom. When disruption occurs in tissue cells or extracellular fluids, the effect can range from minor changes to profound disturbances. Radiation may come from particles of the nuclei of disintegrating atoms or electromagnetic waves that have no mass. Types of ionizing radiation include the following:

- *Alpha particles:* Alpha particles are relatively large particles that have a slight penetrating power. They are stopped by a thin sheet of paper. They have dense ionization but can produce tremendous tissue destruction within a short distance.
- *Beta particles:* Beta particles are relatively small, are electrical, and travel with the speed of light. They have greater penetrating properties than do alpha particles. Their emissions cause tissue necrosis, and they produce ionization, which has destructive properties.
- *Gamma rays and x-rays:* Gamma rays and x-rays are electromagnetic radiations of short wavelength but high energy and are capable of completely penetrating the body. They affect tumor tissue more rapidly than normal tissue. These types of rays are stopped by a thick lead shield. Protons that range in energy from 30 kV to 35 million eV are available for the treatment of various cancers. Gamma rays are emitted spontaneously from the nucleus of an atom of a radioactive element.

Effects of Radiation on Cells

Cancer cells multiply out of normal body control; they are in a state of active uncontrolled mitosis (the nuclear division of the cytoplasm and nucleus). Radiation affects the metabolic activity of cells. Cells in an active state of mitosis are most susceptible.

Over time, gamma rays and x-rays cause a cessation of cell growth and a regression of the tumor mass. Cells die and are replaced by fibrous tissue.

The sensitivity of a tumor to radiation varies. Some tumors can be destroyed with a small amount of radiation, whereas others require a large amount. The sensitivity of the tumor cells is determined by the sensitivity of the normal cells from which the tumor cells are derived.

The effects of radiation therapy also depend to a large extent on tissue oxygenation. As a tumor grows the periphery is well oxygenated but the central portion becomes necrotic and poorly oxygenated. The number of cells killed with radiation therapy is directly related to the amount of tissue and oxygen within the tumor; therefore the hypoxic effect is a factor in determining the therapeutic dosage of radiation.

Radiation cannot be limited solely to the area being treated. The danger of injuring normal surrounding tissue is a limiting factor in the dosage and selection of the most appropriate type of radiation therapy. A factor in dosage is the ratio of tumor tissue to the surrounding normal tissue. The dosage is computed in roentgen-absorbed doses (rads). A rad is the unit used to measure the absorbed dose of radiation. One rad is the amount of radiation required to deposit 100 ergs of energy per gram of tissue.

Radiophysics or instruments such as Geiger counters or scintillation probes are used to determine the dose of radiation delivered to a specific tissue site; the dose is measured by distance from the source and duration of exposure. Doses are measured in rads to

determine whether the dosage is adequate for therapy but not so excessive that it could cause damage to normal tissues.

The penetration of radiation energy is calculated from the rate of decay or disintegration, known as half-life. Half-life is the time necessary for half of the radioactive element to disintegrate and lose half of its activity through decay.

Sources of Radiation

Although the effects of the different types of radiation therapy are similar, their sources and applications do differ. Some sources are implanted into the body in direct contact with tumor tissue, whereas other sources use an external beam to pass the radiation through the body to the tumor.

- *Radium:* Radium is a radioactive metal. Research chemist Marie Curie (1867–1934) and her husband, Pierre (1859–1906), a physicist, discovered and named this metal in 1898. Several years earlier, Mme Curie had been given the task of discovering why pitchblende would record its image on a photographic plate. She and her husband knew this material emitted more radiation than justified by the known minerals contained in it. It took 6 years of painstakingly difficult work for the Curies to isolate radium as a pure element and to learn of its radioactive properties. Their research eventually led to the use of radium in the treatment of malignant tumors.
  - Metallic radium is unstable in air. Radium chloride or bromide salts emit fluorescence and heat. One gram gives off 134 calories per hour. Alpha and beta particles and gamma rays are products of its disintegration. The half-life of radium is approximately 1620 years; half the remaining life is lost in another 1620 years, and so on. The final product is lead.
- *Radon:* Radon is a dense radioactive gas liberated as the first by-product of the disintegration of radium. Mme Curie discovered this gas and first named it *emanation.* Radon is collected by an intricate process in radiopaque glass or gold capillary tubing, and the seeds for implantation are then cut and sealed. The dosage is computed according to the hours of insertion into tissue. It is measured in millicurie-hours. The half-life of radon is 4 days; its total life is approximately 30 days.
- *Radionuclides:* A radionuclide is an element that has been bombarded with radioactive particles in a nuclear reactor. A radionuclide shows radioactive disintegration and emits alpha and beta particles or gamma rays. Radionuclides that emit beta particles and gamma rays are used primarily for treatment of malignant tumors. Therapeutic radionuclides also may be referred to as radiopharmaceuticals. Historically they were known as *radioactive isotopes,* or *radioisotopes;* these terms are still found in the literature. Cesium, cobalt, iodine, iridium, and yttrium are the most commonly used elements for therapy.

Radionuclides are controlled by the Atomic Energy Commission and are released only to individuals trained and licensed to use them. Available in liquid or solid forms, they may be ingested orally, infused intravenously, instilled into a body cavity, injected or implanted into a tumor, or applied to the skin externally. The ionizing radiation emitted has an action on tissue similar to that of radium, but radionuclides differ from radium in the following ways:

- The half-life of radionuclides is short. Radionuclides disintegrate at varying rates depending on their type. Each element has a specific half-life that varies from a few hours (e.g., the 6 hours of technetium-99) to 8 days (iodine-131) to 5.3 years (cobalt-60).
- Irradiation with radionuclides does not spread so much into adjoining tissue; therefore a stronger dose can be used in a malignant tumor. Radiation is not absorbed by bone and other normal body tissues. It can be more easily shielded for safe handling. The surgeon and other personnel get less radiation exposure in placing or removing radionuclides.

As with exposure to radium and radon, exposure to radionuclides is always potentially dangerous. Radiation may treat cancer, but it can also cause a malignant neoplasm.

Implantation of Radiation Sources

All radiation sources for implantation are prepared in the desired therapeutic dosages by personnel in the nuclear medicine department. Many types of sources are used to deliver maximum radiation to the primary tumor. No single type is ideal for every tumor or anatomic site.

Interstitial Needles. Interstitial needles are hollow sheaths and are usually made of platinum or Monel metal. Radium salts or radionuclides are encased in platinum or platinum-iridium short units or cells, which in turn are sealed in the metal sheath of the needle for implantation into tumor tissue. A needle may contain one or several short units or cells of the radiation source, depending on the length of needle to be used. Needles vary in length from 10 to 60 mm, with a diameter of 1 to 2 mm. The choice of length depends on dosage and on the area involved. Dosage is measured in milligram-hours, which can be converted to rads.

The interstitial needles, which usually contain cesium-137, are implanted in tumors near the body surface or in tissue accessible enough to permit their use (e.g., vagina, cervix, tongue, mouth, neck). In certain patients, stereotactic techniques are used to implant needles for the irradiation of brain tumors.

In the interventional suite or OR these needles are inserted at the periphery of and within the tumor. One end of the needle is pointed, and the other end has an eye for a heavy (size 2) suture. Needles are threaded to prevent loss while in use and to aid in removal. After the surgeon inserts the needles, the ends of the sutures are tied or taped together and then taped to the skin in an adjoining area or secured to buttons. Depending on the anatomic site, a template may be used to position and secure the needles.

A template consists of two acrylic plates separated by rubber O-rings and held together with screws. The plates have holes for insertion of the interstitial needles. The template remains in place until the needles are removed. Depending on the planned dosage to the tumor bed, needles are usually left in place for 4 to 7 days.

Interstitial Seeds. Sealed radionuclide seeds may be implanted permanently or temporarily. Because they have a short half-life, gold seeds are permanently implanted, most commonly into the prostate, lungs, or pancreas. Seeds that contain cesium-137, iridium-192, or iodine-125 and are implanted directly into tumor tissue are removed after the desired exposure.

Seeds are useful in body cavities, in localized areas, and in tumors that are not resectable because of their location near major vessels or the spinal cord. Because they are small, the seeds can be placed to fit a curved area without necessitating immobilization. However, they may move about with much motion.

Radionuclide seeds are 7 mm or less in length, are 0.75 mm in diameter, and have a wall 0.3 mm thick. The length of the seed depends on the desired dosage. Seeds can be inserted with or without an invasive surgical procedure. They may be strung on a strand of suture material or placed in a hollow plastic tube with sealed ends. With a needle attached, the strand or tube is woven or pulled through the tumor. Seeds in a plastic tube may be inserted through a hollow needle, such as a catheter through a trocar. Empty tubes may be inserted in the OR and afterloaded (i.e., the seeds are put

into the tube at a later time and place). A microprocessor-controlled machine that pulls wire attached to radioactive material through the tube may be used for remote afterloading.

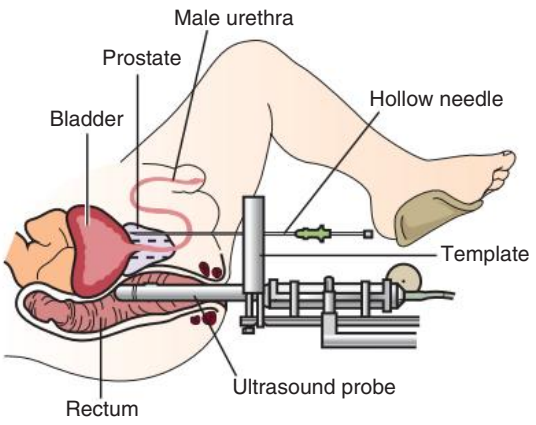
Brachytherapy

The term *brachytherapy* (also known as internal beam radiation) comes from a Greek term meaning "short-range treatment." Tiny titanium cylinders that contain a radioactive isotope are implanted to deliver a dose of radiation from the inside out that kills cancer cells while sparing healthy tissue. Brachytherapy is performed for many types of cancers, including breast, uterus, and prostate (Fig. 7.5).[7] Brachytherapy, an internal application with sealed sources of radionuclides, has almost totally supplanted the use of radium and radon. For example, the gamma rays of cesium-137 have greater penetrating power than radium does.

Brachytherapy is useful for delivering higher cell-killing doses in shorter periods than with conventional radiation treatments. The capsules are placed with ultrasound scan guidance. A rapid delivery system that uses a catheter with a balloon on the tip has been developed to treat breast cancers smaller than 3 cm. The catheter is placed into the breast tissue during tumor excision, and the balloon is expanded with water. Twice per day for 4 to 5 days a high-dose radiation pellet is placed inside the catheter to treat the tissue. When the treatment period is complete, the catheter and pellet are removed. Patient selection includes those with clear margins of the tumor and with fewer than three affected lymph nodes. Additional information about brachytherapy suitable for students and patients can be found online at www.radiologyinfo.org/en/info.cfm?pg=brachy. The information can be used for patient education.

Intracavitary Capsules. A sealed capsule of radium, cesium-137, iodine-125, yttrium-192, or cobalt-60 may be placed into a body cavity or orifice. The capsule may be a single tube of radioactive pins fixed in a tandem loader or a group of individual capsules, each of which contains one radioactive pin. Commonly used to treat tumors in the cervix or endometrium of the uterus, a capsule is inserted via the vagina for treatment of the uterine body.

In a patient with cervical cancer an instrument such as an Ernst applicator is used. A metal or plastic tube with radioactive pins is inserted into the uterus. Metal pins are used in conjunction with heat. The tube is attached to two vaginal ovoids, each of which contains a radioactive pin, that are placed in the cul-de-sac around the cervix. This type of application delivers the desired dosage in a pear-shaped volume of tissue, which includes the cervix, corpus, and tissue around the cervix but spares the bladder and rectum from high doses of radiation.



• **Fig. 7.5** Placement of radioactive cylinders for brachytherapy.

A blunt intracavitary applicator is used to position the parts. The applicator is held securely and remains fixed to ensure proper dosage to the tumor without injuring the normal surrounding structures. For stabilization the surgeon may suture the applicator to the cervix; vaginal packing is also used. Two different methods of application are used for inserting the radiation source: afterloading techniques and preloading techniques.

Afterloading Techniques. Afterloading techniques afford the greatest safety for OR personnel. In the OR a cold, unloaded, hollow plastic or metal applicator, such as the Fletcher afterloader, is inserted into or adjacent to the tissues that will receive radiation. After x-ray verification of correct placement, the radiation source is loaded into the applicator at the patient's bedside.

Preloading Techniques. Preloading techniques necessitate insertion of the "hot" radiation capsule in the OR by the surgeon. OR personnel should not be permitted in the OR during this procedure. To deliver a uniform dose to the desired area the surgeon inserts an adjustable device designed to hold the radiation source in proper position in the tissues (e.g., the Ernst applicator). The bladder and rectum are held away from the area with packs to avoid undesired irradiation.

For calculation of the necessary dosage, the surgeon uses x-rays of the pelvis to check the position of the radiation source and measure its distance from critical sites.

All preparations for insertion are made by surgical team members before they leave the room. (They wait in the substerile room during insertion.) Preparations include setting the sterile table with vaginal packing, antibiotic cream for packing, radiopaque contrast media for radiographic studies, and a basin of sterile water; placing the x-ray cassette on the OR bed and notifying the radiology technician; obtaining the radiation source; positioning the patient; and putting a radiation notation on the patient's record and a card on the stretcher.

Intracavitary Colloidal Suspensions. Sterile radioactive colloidal suspensions of gold or phosphorus are used as palliative therapy to limit the growth of metastatic tumors in the pleural or peritoneal cavities. Radioactive colloidal gold-198 is most commonly used; it has a half-life of 2.7 days. It also may be instilled within the bladder.

The effect of these suspensions is from the emission of beta particles, which penetrate tissue so slightly that radioactivity is limited to the immediate area in which the colloidal suspension is placed. A trocar and cannula are introduced into the pleural or peritoneal cavity, and the colloidal suspension is injected through the cannula from a lead-shielded syringe. After use, these instruments are stored in a remote area until the decay of radioactivity is complete.

External Beam Radiation Therapy

Ionizing radiations of gamma rays or x-rays generated from machines are used externally to alter tumor cells within the body. This type of radiation therapy is noninvasive.

A maximum dose of radiation is concentrated on the malignant tumor underneath the skin, with a minimum dose to surrounding tissue. The angle of approach is changed a number of times during treatment to spread the amount of radiation to normal tissue over as wide an area as possible. Both orthovoltage equipment (low-voltage equipment that produces 200 to 500 kV) and megavoltage equipment (e.g., cobalt-60 beams and linear accelerators or betatrons) are used for external beam radiation therapy.

With some cancers, external radiation may be the only therapeutic modality used. Determination of the dosage of radiation that will provide the optimal cure with an acceptable balance of complications is difficult. With the advent of stereotactic techniques and the use of megavoltage equipment, intense rays can deliver cancer cell–killing doses without permanently injuring normal tissue and causing skin irritation. Even so, for many tumors most oncologists recommend a combination of radiation therapy and surgical resection; radiation therapy may be administered preoperatively and/or postoperatively or intraoperatively. External radiation therapy also may be combined with internal sources, such as intracavitary radiation capsules, to build up the dosage to large tumor areas.

Intraoperative Radiation Therapy

During a surgical procedure a single high dose of radiation may be delivered directly to an intraabdominal or intrapelvic tumor or tumor bed to provide an additional palliative or localized means of control. Normal organs or tissues can be shielded from exposure. Radiation also may be used after resection of the bulk of the tumor.

An orthovoltage unit may be installed in a lead-lined OR for intraoperative radiation therapy. The sterile Lucite cone is placed directly over the tumor site. All team members leave the room during treatment. In some hospitals the patient is transported from the OR to the radiation therapy department. After exposure to a megavoltage electron beam, the wound may be closed in the treatment area or the patient may be returned to the OR for further surgery or wound closure. The open wound is covered with a sterile drape during transport, and sterile technique is used for closure.

Stereotactic Radiosurgery

Gamma knife technology was developed in Sweden in the early 1950s by surgeon Lars Leksell and Borje Larsson, PhD. They experimented with guiding devices and proton beams. Cobalt-60 was found to be most effective in the treatment of brain tumors and was selected as the energy source for the gamma knife. In 1975 the device was used for treatment of brain tumors in humans.

With stereotactic radiosurgery, fiberglass fixation pins are used to apply a base ring (the Leksell head frame) to the patient's head preoperatively. Two small rods are placed in the ear canals to stabilize the head frame during fixation. Care is taken not to injure the ear canal or tympanic membrane during this process. A calibrated ring is affixed to the frame to form X, Y, and Z coordinates to localize the brain lesion. The frame and ring sit within a larger helmet that aims the radiation at the tumor.

The gamma knife delivers highly concentrated doses of gamma rays to inoperable or deep-seated vascular malformations or brain tumors 1 to 10 cm^3 in size. The localized area is determined with precision stereotaxis. The neurosurgeon places the patient's head, with the Leksell head frame and localizing ring, into the collimator helmet so the focusing channels direct 201 pinpointed cobalt-60 beams to the tumor. (The radiation sources are housed in a large spherical chamber that is housed within a special room.)

The patient is placed on a sliding bed that accommodates and aligns with the helmet as it enters the spherical chamber. The gamma knife process lasts 3 to 4 hours. During the procedure the patient is in video and voice communication with the perioperative team. All personnel leave the room during treatment because of the intensity of the radiation and its cumulative effects.

Safety Rules for Handling Radiation Sources

The cardinal factors of protection from radiation sources are distance, time, and shielding. For both personnel and patients the following principles of radiation safety apply to handling all types of radioactive materials:

- The intensity of radiation varies inversely with the square of the distance from it (i.e., double the distance equals one quarter the intensity). Personnel should stay as far from the source as is feasible.
- Radiation sources (e.g., needles, seeds, capsules, suspensions) are prepared by personnel in the nuclear medicine department. Personnel prepare these sources behind a lead screen. Their hands are protected with lead-lined gloves, if possible, or special forceps during handling.
- Radiation sources are transported in a long-handled lead carrier so they are as close to the floor and as far away from the body of the transporter as possible. The lead carrier should be stored away from personnel and patient traffic areas while it is in the OR suite.
- When radiation sources are delivered to the OR, each needle, seed, or capsule is counted by the surgeon with the radiation therapist. This number is recorded.
- Glutaraldehyde solution is poured into the lead carrier to completely submerge the radiation sources. When ready for use the radiation source is transported in the lead carrier into the OR. The needles, seeds, or capsules are removed from the lead container with sterile long-handled instruments and are rinsed thoroughly with sterile water.
- All radiation sources are handled with special long, ring-handled forceps from behind a lead protection shield. Radiation sources should never be touched with bare hands or gloves. Radiation sources are never handled with a crushing forceps because the seal of hollow containers can be broken. A groove-tipped forceps designed for this purpose is used.
- Radiation sources are handled as quickly as possible to limit the time that personnel are exposed to radiation.
- All radiation sources are accounted for before and after use, and any loss is immediately reported to the OR nurse manager. Nothing should be removed from the room. To locate a lost radiation source a radiation therapist or nuclear medicine department technician is called to bring a Geiger counter. A Geiger counter has a radiation-sensitive gauge with an indicator that moves and a sound that increases when near radioactive substances. A Hazmat team may be summoned.
- A radiation documentation sheet is completed and put in the patient's chart. The surgeon fills in the amount, exact time of insertion, and time the source is to be removed. Each nurse who cares for the patient on the unit signs this sheet just before going off duty, thereby passing responsibility for checking the patient and radiation source to the nurse who relieves. For checking needles, the sutures attached to each needle are counted.
- The patient's bed and door to the room are conspicuously labeled with a radiation-in-use sign.
- The radiation source is removed by the surgeon at the exact time indicated so the patient is not overexposed.
- Radiation is neither seen nor felt; therefore the rules are carefully observed. Exposure is monitored and minimized.

Effects of Radiation Therapy on the Perioperative Patient

The patient may be undergoing several treatment modalities and may experience the specific tissue and systemic effects of each. The

perioperative nurse should understand how radiation affects the patient and how it affects the attainment of desired outcomes. The plan of care should include consideration for the potential side effects of radiation therapy.

Chemotherapy

Either alone or in combination, a variety of chemotherapeutic agents are capable of providing measurable palliative remission or regression of primary and metastatic disease, with a decrease in the size of the tumor and no new metastases. In some instances a complete response, with the disappearance of all clinical evidence of the tumor, is achieved.

The trend is toward earlier and greater use of adjuvant chemotherapy. More than one agent may be administered to enhance the action of another cytotoxic or antigenic substance. Adjuvant therapy is designed to maximize the benefits of each agent in the combination while avoiding overlapping toxicities. The following factors are important in determining the ability of tumor cells to respond to chemotherapy:

- *Size and location of the tumor.* The smaller the tumor the easier it is to reach cells. The mechanism for the passage of drugs into the brain differs from that for other body organs.
- *Type of tumor.* For example, cells of solid tumors in the lung, stomach, colon, and breast may be more resistant than cells in the lymphatic system.
- *Combinations of adjuvant therapy.* In select patients, chemotherapy may be used as an adjunct to all other types of therapies. Precise scheduling of dosages is necessary to attain effective results.
- *Specific biochemical requirements of the tumor.* Agents are selected according to the appropriateness of their structure and function. More than one agent is usually given.
- *State of life cycle of the cancer cells.* Cancer cells and normal cells go through the same life cycle phases. An understanding of this phenomenon is necessary for understanding chemotherapy.

Indications for Chemotherapy

Patients who are at risk for or who have systemic signs of advanced or disseminated disease (generally indicated by extranodal involvement) may be candidates for preoperative, intraoperative, or postoperative chemotherapy.

Preoperative Chemotherapy

The objective of preoperative chemotherapy may be to shrink the tumor sufficiently to permit surgical resection. Adjuvant radiation therapy may be used in combination with chemotherapy to increase tumor regression and necrosis. Agents also may eliminate subclinical microscopic metastatic disease.

Intraoperative Chemotherapy

After the initial incision is made, a Tenckhoff catheter is inserted through the midline abdominal wall for instillation of a heated chemotherapeutic solution suspended in a dextrose-based peritoneal dialysate. Additional active suction drains are inserted in the lower abdomen for drainage of the solution. These drains remain in place for postoperative drainage. A temperature probe is attached to the Tenckhoff catheter, and several liters of chemotherapeutic solution are infused at 43° C. Because the dialysate causes fluid shifts in the peritoneal cavity, the anesthesia provider closely monitors the patient's urinary output with a Foley catheter. If necessary, medication is given to increase output.

At the conclusion of the instillation the intended surgical procedure, usually some form of cytoreduction, is performed. The Tenckhoff catheter and the active drains are left in place for future treatments.

Postoperative Chemotherapy

Surgical resection followed by regional chemotherapy often can control local disease to keep a tumor in remission. Residual metastatic disease may be treated with systemic chemotherapy to cure the patient or to prolong life. Multiple doses may be given over a long period (several months to a year or more) to delay or eliminate recurrence of the tumor.

The Patient with Chronic Comorbid Disease

Patients come to the OR for surgical procedures unrelated to a chronic cardiopulmonary or pulmonary disease. Even for unrelated surgeries the presence of these conditions may present a high risk for physiologic complications.

Cardiovascular Disease

The surgeon is particularly concerned about hemostasis and the potential for hemorrhage in a patient who is taking an anticoagulant medication. A patient who takes a daily dose of 81 mg of aspirin prophylactically may be instructed to discontinue its use for 2 weeks preoperatively. Anticoagulation is commonly prescribed for patients who have cardiac stents in place or a history of embolic disease, such as atrial fibrillation, pulmonary embolus, or deep vein thrombosis.

The anesthesia provider regulates the medications of patients who have an unstable blood pressure. Blood pressure is also monitored and maintained with appropriate medications in patients with a history of hypertension or hypotension. Tissue perfusion and oxygenation are critical to wound healing and depend on the circulatory status of the patient.

Pulmonary Disease

Any chronic condition that compromises pulmonary function presents a potential risk for a patient undergoing general inhalation anesthesia. Bronchoconstriction, edema, and excess mucus production cause uneven airway narrowing that creates a ventilation-perfusion mismatch. Severe hypoxemia, an abnormal deficiency of oxygen in arterial blood, can trigger life-threatening dysrhythmias and respiratory failure.

Adequate ventilation is difficult in patients with asthma, chronic bronchitis, and pulmonary emphysema. Chronic obstructive pulmonary disease, which includes these conditions, is characterized by diminished inspiratory and expiratory capacity of the lungs. It is aggravated by cigarette smoking and air pollution. Smokers are advised to stop smoking at least 3 weeks preoperatively and are taught to use a spirometer postoperatively to clear respiratory secretions.

Deep-breathing and coughing exercises may be helpful postoperatively. A mechanical ventilation or intermittent positive pressure breathing apparatus may be necessary postoperatively to assist or control respiration. Patients who have trouble breathing are usually highly anxious and need emotional support.

The Patient with Induced or Acquired Immunosuppression

The immune system creates local barriers and inflammation to protect the body from invasion by pathogenic microorganisms and foreign bodies. Humoral and cell-mediated responses develop if these first-line defenses do not provide adequate protection. The body's natural lines of defense are described in Chapter 14 of this text.

The humoral response produces antibodies to react with specific antigens. The cell-mediated response mobilizes tissue macrophages in the presence of a foreign body. Immunocompetence is the ability of the immune system to mobilize and deploy its antibodies and other responses to stimulation by an antigen. Immunocompetence may be threatened by a disease, a virus such as hepatitis B or human immunodeficiency virus (HIV), or an immunosuppressive agent. Patients with immunocompromise have a weakened or deficient immune response with a resultant decreased resistance to infection.

Immunosuppression

Immunosuppressive agents include corticosteroid hormones, which are given to prevent or reduce the inflammation caused by certain diseases. They are often prescribed for patients who have an autoimmune collagen disease (e.g., rheumatoid arthritis, systemic lupus erythematosus, scleroderma) or an autoimmune hemolytic disorder (e.g., idiopathic thrombocytopenic purpura or acquired hemolytic anemia). They also are given to patients with adrenal insufficiency and after organ transplantation to combat rejection. Antineoplastic cytotoxic agents for chemotherapy and radiation therapy, which are used to reduce malignant tumor cells, also may cause immunosuppression.

Common Complications

The manifestations and clinical characteristics of the patient with immunocompromise depend on the specific disease and the affected organ or system. For example, systemic lupus erythematosus can affect every organ system in the body. Adrenal insufficiency, as caused by Addison's disease, may be characterized by generalized systemic reaction. In contrast, organ transplantation or a malignant tumor may affect a single organ.

Special Considerations

Many patients with immunocompromise have skin rashes or lesions, painful joints, poor nutrition, and generalized malaise. They need physical and emotional support throughout the perioperative care period. Aseptic and sterile techniques are important considerations for all surgical patients but are especially crucial for individuals with immunosuppression and immunocompromise, who are at high risk for development of a postoperative infection.

Acquired Immunodeficiency Syndrome

Patients with acquired immunodeficiency syndrome (AIDS) test positive for HIV in serum and exhibit one or more signs and symptoms of an opportunistic disease, including pneumonia, fungal or parasitic infection, and malignant neoplasms.

HIV can remain inactive and undetected in the body for many years before seroconverting and causing the immunodeficiency illness known as AIDS. During this time, no outward signs of HIV infection are noted, but the patient can transmit the virus through blood, body fluids, or sexual contact.

Both males and females, including infants and children, may be HIV positive or diagnosed with AIDS. HIV was once thought to be transmitted only through homosexual behavior among men, IV drug use, or tainted blood transfusions. The virus is now known to be transmitted also through heterosexual contact, and an infected mother may transmit the virus to her fetus.

The diagnosis of an HIV infection is confirmed with at least two separate tests. One positive test result is not a conclusive diagnosis, and the test is usually repeated for clarity. Initial testing with the enzyme-linked immunosorbent assay (ELISA) is performed to detect the presence of HIV antibodies in the blood. The diagnosis is confirmed with either the Western blot test or the indirect immunofluorescence assay.

If test results are seropositive for HIV infection, the patient does not necessarily have AIDS. HIV invades and destroys T lymphocytes. During this process the patient's immune system is disabled. The normal T lymphocyte level is 1000/mm^3; the severity of an HIV infection is measured by the level of T lymphocyte cells in the patient's blood. When the T cell level decreases to between 200 and 500/mm^3, the patient has had seroconversion to an immunodeficient state and is considered to have AIDS.

HIV infection and AIDS have no known cure. Some medications are available to delay seroconversion in HIV infection and to prolong the life of a patient with seroconversion to AIDS. Pharmacologic therapy may include broad-spectrum antibiotics, antivirals, antidiarrheals, vitamins, and antineoplastics.

Common Complications

A patient with HIV infection may have night sweats, unexplained fevers, dry cough, weakness, diarrhea, weight loss, and swollen lymph glands. A patient with seroconversion to AIDS may have multiple opportunistic infections and malignancies concurrently and generalized poor health. Extreme muscle and tissue wasting are common.

Many patients with AIDS have multiple external and internal lesions. The skin may have open wounds with infectious exudate or large, swollen, purple lesions associated with Kaposi's sarcoma (a malignant multifocal neoplasm of reticuloendothelial cells that spreads in the skin and metastasizes to the lymph nodes and viscera). Large, painful masses of lymph tissue may be present in the neck, axilla, and groin. Mechanical obstruction caused by Kaposi's lesions in the esophagus may prevent swallowing of food. Intestinal lesions may prevent the absorption of nutrients or cause bowel obstruction.

Constant anorexia, nausea, vomiting, and diarrhea may prevent adequate intake by mouth. Nutritional supplementation with hyperalimentation may be indicated to meet a patient's high caloric needs. Hyperalimentation is discussed in Chapter 29.

AIDS causes the body to be susceptible to opportunistic infections because of the lowered resistance of the immune system. Opportunistic infections are caused by microorganisms that normally are nonpathogenic in a healthy individual. The mucous membranes of the mouth and genital areas may have herpesvirus lesions or white patches of candidiasis, a yeastlike fungus. Neurologically, the patient may have recurrent episodes of cryptococcal meningitis or toxoplasmosis, which causes persistent motor dysfunction and mental changes.

The patient with AIDS experiences a continual cycle of acute and chronic respiratory infections. *Pneumocystis jiroveci* pneumonia is the most common lung infection, followed by multiple-drug–resistant tuberculosis. The patient may be in a perpetual state of respiratory distress. Central and peripheral cyanosis may be present. The respiratory effort expends high energy levels, which causes the patient's condition to deteriorate rapidly.

Special Considerations

Patients with AIDS may be in poor physical condition, depending on how the body systems have been affected. Most systems are eventually involved. The plan of perioperative care should incorporate the following considerations:

1. Moving the patient from the transport stretcher to the OR bed may require additional personnel for total lifting. The patient may not be able to move because of weakness or pain in the joints, muscle and tissue wasting, and superficial skin lesions.
2. Bony prominences and areas of decreased muscle mass and devascularized tissue must be protected throughout the positioning process and surgical procedure. Blankets, restraints, monitoring devices, electrosurgical dispersive electrodes, drapes, instruments, and routine care devices may cause inadvertent harm to the patient despite the team's best efforts to protect the patient from injury.
3. IV line insertion, induction of anesthesia, and maintenance of the airway may be difficult. A suitable vein for infusion may be hard to identify because of former IV drug use or large areas of epidermal Kaposi's sarcoma. In extreme cases the only IV site may be a central venous catheter. Endotracheal intubation may be contraindicated because of potential hemorrhage from Kaposi's lesions in the trachea. Placement of an esophageal stethoscope or rectal temperature probe may rupture other internal Kaposi's lesions with the same result.
4. Postoperative wound healing is delayed or absent because of poor nutrition, decreased circulation, poor tissue integrity, and a continued immunodeficient condition.

Patients with AIDS may have been rejected by their families, especially if the virus was transmitted through a route not accepted or understood by family members. The diagnosis of AIDS may be the first time the family is made aware of the patient's alternative lifestyle. Psychologic support systems may consist of a small circle of friends, who also may be infected with HIV or have AIDS. Preoperative consideration should be given to power of attorney, living will, and the potential for future do-not-resuscitate (DNR) status.

Continual counseling should be emphasized in the postoperative discharge plan to include provisions for physiologic care and support. The patient, family, and significant others should be educated about the potential routes of transmission, such as exposure to blood and body fluids through sexual contact or shared IV needles. The virus is also potentially transmissible through shared razors, toothbrushes, and tweezers because of the possibility of blood contamination. Dishes and eating utensils are considered safe when washed in hot soapy water, rinsed, and dried.

Education should include learning about physical activities that do not pose a risk for transmission, such as hugging, shaking hands, and sitting close.

Confidentiality is a concern because of the nature of the routes by which HIV can be transmitted. It is about the patient's right to privacy. Testing for HIV is not a routine preadmission laboratory procedure. If a patient is tested, the results should be placed in the appropriate section of the patient's chart with other laboratory results, not displayed on the front of the chart. Reporting of the results should be governed by institutional policy and treated in the same manner as all patient confidentiality issues.

Dissemination of confidential patient information to inappropriate people is a breach of duty to the patient's privacy and may be subject to legal action. Physicians and nurses may face disciplinary action such as license suspension or revocation by the boards of medicine or nursing, as indicated.

Perioperative patient care personnel should provide care to all patients with equal professionalism, compassion, empathy, and positive regard despite any personal feelings about a patient's lifestyle or disease entity. Nonjudgmental care is essential for the psychologic wellness of patients with AIDS.

The Patient Who Is a Victim of Crime

Violent crime is prevalent in society. As health care professionals we manage the care of the **victims** of crime and sometimes the accused **perpetrators**. Victims and perpetrators involved in the same incident may present to the same emergency department (ED) within moments of each other. Both are entitled to the same care and legal considerations, including privacy and basic tenets of respect.

The perpetrator is considered innocent until proven guilty in a court of law. Both patients have equal rights to patient advocacy, regardless of the circumstances of their injuries. All members of the health care team need to be in control and aware of subjective feelings and place personal biases and prejudices in proper perspective when caring for these individuals.

Crimes can involve drugs, domestic abuse, shootings, stabbings, gang violence, mugging, sexual assault, and hit-and-run motor vehicle accidents. Injuries can occur to bystanders at a crime scene, such as a robbery, drive-by shooting, or gang fight. All patients who arrive at the ED may provide potential forensic evidence for law enforcement officials and should be carefully processed according the facility policy.

On Arrival to the Emergency Department

Physical assessment is performed immediately on contact with the health care system by paramedics and continued on arrival to the facility by additional medical personnel. The level of consciousness is evaluated and the ABCs (airway, breathing, and circulation) are prioritized and stabilized. The first concern is to preserve life, followed closely by the concern to preserve the chain of evidence.

Patients with severe injuries may need to bypass the ED and go directly to the OR.

Notation should be made of psychologic affect. Many crimes are associated with drug abuse, and the administration of medications in the hospital could interact with drugs ingested on the street. The use of street drugs should be carefully ruled out with toxicology screens because they may alter baseline laboratory tests, interfere with lifesaving treatment, and potentiate anesthetics used during emergency surgery.

Unusual odors such as chemicals, alcohol, gasoline, or other volatile substances should be investigated and documented. Chemicals can be hazardous in the OR, where fires can be triggered by electrosurgical devices in the presence of volatile materials.

Baseline vital signs, x-rays, scans, antibiotic prophylaxis, tetanus toxoid, pain control, and hemostasis are some of the prime concerns for stabilization. Facility spokespeople should handle all media interviews, and respect for patient privacy should be provided. Standard precautions are strictly followed at all times concerning all body substances.

Consent for treatment is required and should be obtained as soon as possible. This is important as the chain of evidence is constructed. The chain of evidence incorporates documentation of all material and observational findings associated with the victim, the suspected perpetrator, and the incident. An unconscious

person is given full treatment regardless of consent status until family can be consulted.

Forensic Evidence in the Operating Room

Forensic evidence is critical for the reconstruction of events in a crime or suspected illegal activity. All forensic evidence is preserved according to institutional policy and procedure and is relinquished only to the appropriate authorities. The documentation of handling and disposition of evidence is referred to as a chain of evidence. This chain is maintained by requiring the signatures of everyone who comes into contact with forensic evidence. The goal is to attempt to validate that the evidence has not been tampered with before reaching the appropriate law enforcement agency.

Any potential evidence discovered during physical assessment should be carefully documented and secured until it can be turned over to appropriate law enforcement authorities. The Fourth Amendment to the Constitution of the United States provides equal protection against unreasonable search and seizure. Items found during intentional searching of a conscious patient without consent may be interpreted as unreasonable search and are potentially not admissible in court.

Illegal substances or weapons discovered during the routine course of assessment that have not been obtained through unreasonable means may be used as evidence in some states. They are packaged dry and in an impervious container to prevent injury. Gloves are worn in handling evidence. Nothing is washed, wiped clean, or discarded. A clear chain of evidence is often difficult to maintain in a crisis, but every attempt is made to document the disposition of evidence and the location from which it was taken.

Assessment and Documentation of the Crime Victim

Data collection begins with emergency medical service and police reports. If a patient with a suspicious injury, such as a gunshot or stab wound, arrives at the ED by some other means, the police should be notified. Critical information about the injury includes where, when, and how the injury occurred and should be documented. Direct quotation of the patient's words is preferred. Differences between accounts of the incident by the patient and other observers should be carefully noted. Variance in reporting by a potential victim may mean that an accused perpetrator is innocent.

Patients who are critically injured may be taken directly to the OR. The perioperative nurse should document physical injury patterning on the OR nurses' notes before evidence, such as bloody handprints, is washed away during the skin preparation process. Most ORs have cameras or photographic staff available. Injuries should be photographed in the lighting of the OR for clarity.

Patients may not be able to communicate vital information, such as when the last meal was eaten, whether they have allergies, or whether medications are taken on a routine basis for some condition. Family may not be available to give a medical or surgical history. It is critical to communicate to the team every detail discovered during the preparation of the patient for surgical intervention. Close observation for responses to treatment and physiologic clues is important for the provision of safe care.

The patient's clothing may provide important information for the police and should be preserved intact if possible. This can be complex if the patient must come to the OR for lifesaving intervention. If clothing must be cut off, care should be taken to avoid cutting through bullet holes or stab wounds.

Keep in mind that the patient may have sharp objects in his or her clothing that could injure a caregiver. If possible, the patient should be placed on a separate bed sheet before clothing is removed and the fabric of the clothing should be cut along the seams. Hairs, carpet fibers, and other environmental information may be contained in folds of fabric and should be left with the clothing for the forensic examiners. The sheet forms a wrapper for the clothing before it is placed in an approved receptacle.

Clothing should not be placed in airtight containers or plastic bags because that may cause degradation of biologic matter. A paper bag may be used provided the bag has not been used before and the moisture of the clothing is not going to seep through the surface. Contamination of the outer aspect of the paper bag is a hazard to the examining teams and the law officials. Underclothes of sexual assault victims must be carefully preserved in the same manner. Storage and handling of these items should be well documented, and signatures are required when the items are turned over to proper authorities. Some facilities provide tamperproof evidence tape to seal the package and prevent altering of contents.

The patient's skin is observed for bruising, swelling, and open wounds. Characteristic marks, such as finger-shaped or hand-shaped injuries, tire marks, and repetitive patterning such as stripes, should be documented. The locations of the marks should be indicated on a human-like diagram in the patient's record. Whenever possible, the injuries should be photographed. This may require separate consent.

The study of ballistics is the scientific matching of a particular weapon to its projectile. As a bullet travels down the barrel of a gun, it picks up characteristic markings. Bullets that are removed from a patient should be handled with care so the ballistic markings are not altered. Placement of bullets or metallic evidence in a metal specimen basin could alter the longitudinal design of the identifying marks. Only plastic containers should be used. No solution should be added. Blood evidence could be washed off from either the victim or the perpetrator.

The presence of gunpowder and its distribution pattern around a bullet entrance wound on skin or clothing is important in determination of muzzle-to-body distance. The closeness of the gun barrel determines the amount of skin damage on impact. Small-caliber bullet wounds have a smaller inverted entrance and larger everted exit points. Some bullets are designed to flatten on entry and may exit the body after traveling through several layers of soft tissue or organs. If contact is made with bony structures, the bullet may remain embedded in the body. Fragmentation bullets are designed to burst into tiny pieces as they enter the body and may embolize. Close examination of the victim's back may reveal a gaping bullet exit wound or additional injuries that were initially unnoticed.

Wounds should be copiously irrigated with sterile saline solution. Some surgeons request antibiotic solution. Antibiotic solutions are described in Chapter 14.

Absence of an exit wound may indicate the presence of a nonexploded fragmentation bullet. A retained malfunctioning fragmentation bullet could be deadly during an emergency surgical procedure. The explosive mechanism could inadvertently activate, causing injury to a member of the OR team.

Victims may present with obvious injuries but may also have concealed damage. The initial assault may have been a gunshot or a stab wound, but incidental injury may include blunt trauma caused by falling to the ground. Some victims also have been beaten with fists or solid objects, causing damage to underlying organs and structures. A plain x-ray (i.e., flat plate, scout) of the torso can reveal free air in the abdomen as diagnostic of perforated organs.

Crime victims are at high risk for misdiagnosis of secondary head injury or ruptured viscus. This may be further complicated if the victim is pregnant. Two patients may be affected: the mother and her unborn child. **Domestic violence** is a leading cause of death for pregnant women. Obstetric-gynecologic staff may need to be included in the surgical team.

Broken bones are misdiagnosed less frequently because of the use of routine radiography. The victim of a hit-and-run driver often suffers a fractured tibia and fibula at the height of the car's bumper. The measurement of the point of impact enables investigators to determine whether the vehicle was traveling at a constant rate of speed or braking at the time of the collision. Thorough head-to-toe assessment is followed by a complete review of all body systems. Every aspect of the physical examination and treatment becomes part of the evidence discovery process.

The Patient Who Is a Victim of Sexual Assault

Patients who have been raped or sexually assaulted begin treatment in the ED. Victims with severe injuries or multiple traumas are treated in the OR. Although frequently used, the term *rape* is a legal conclusion, not a medical diagnosis. Rape is a felony and one of the most underreported crimes. More victims are reporting sexual assaults, rape, and harassment because of the "Me Too Movement" (www.metoomvmt.org). Victims can find local organizations that provide services, support, and safety measures. Sexual offenses include marital rape, sexual battery, felonious sexual penetration, sexual imposition, and corruption of a minor. *Sexual assault* is the appropriate term for both male and female victims.[9]

In reality, 1 of every 3 females is sexually assaulted during her lifetime. Only 1 in 10 ever reports it. One of every 7 males experiences some form of sexual assault. The number of reported assaults is growing with public awareness and safe reporting methods. More than 80% of the assailants are known to their victims.

The rape crisis center should be involved in every aspect of care for both sexes. Female rape trauma victims should always be examined by the gynecology staff, preferably female. Victims of sexual assault may fear examination or physical contact by members of a specific sex. Females may wish to have a female examiner. A male also may prefer a female examiner, especially if his assailant was male. This holds true of the OR team: The patient may have a sexual prejudice that needs to be respected. Sensitivity to the needs of the victim is important, and documentation and preservation of evidence should be maintained. Sexual assault is a crime of violence and power.[9]

Physiologic and psychologic stabilization is critical. Additional physical injuries, such as gunshot or stab wounds, may complicate care related to sexual assault. Medical history, such as current medications, immunizations, and allergies, should be assessed. Postassault douching, bathing, urination, or defecation may have altered evidence and are taken into consideration. Genital trauma should be closely evaluated. Edema and damage to the genitals of a female may require the use of a pediatric speculum.

Considerations for the Patient with Sexual Trauma

The psychologic affect of a sexual assault victim can range from flat to hyperreactive. The victim should be approached with patience and understanding. Minors may be accompanied by their natural or court-appointed guardians. Quick, brisk moves by a caregiver can create undue emotional stress. The caregiver should always wear gloves to depersonalize touch and should allow the victim to guide his or her hands during the physical assessment to provide an element of self-control. Feelings of loss of control and violation increase the victim's anxiety. A calm demeanor can provide a sense of security for any victim of crime, but particularly for a sexual assault victim. The OR should reflect a sense of stability and prevent nonessential noise.

Preoperative assessment of a female sexual assault victim should include past sexual, menstrual, and contraceptive history. The possibility of existing or resultant pregnancy should be considered. A blood test for beta human chorionic gonadotropin should be drawn. Hormonal pregnancy prophylaxis (the "morning-after pill") may be used within 72 hours of the assault to induce menses and is 95% to 98% effective in preventing implantation of a fertilized ovum. Some women may desire the morning-after pill or abortion counseling at a later date. Approximately 1% of sexual assaults result in pregnancy.

During the examination the victim's pubic hair should be combed into a clean white envelope. A few clippings of the victim's pubic hair and the comb should be sealed inside with the examiner's signature, date, and time on the outside. The assailant's hair may be present and is valuable as evidence. Examination with an ultraviolet Wood's lamp should be performed because prostatic secretions and seminal fluid appear fluorescent even when dried. Dried scrapings of blood and secretions from under fingernails and around genitalia should be saved in an appropriate container. Dried semen can be used to verify an assailant's identity by DNA. Toluidine blue dye that stains acidic tissue may be used on the genitals to identify DNA, RNA, or injuries such as tears for both males and females.[9]

A colposcope with a green filter can be used to examine and photograph vaginal tears. The green filter is useful for identification of vascular structures as a direct contrast to reddened or bleeding tissue. Speculum, proctoscopic, or bimanual pelvic examinations are performed with only sterile water as lubrication. Oral, vaginal, or anal mucosal smears, swabs, and washings should be fixed according to laboratory protocol. Maintain the chain of evidence at all times.

Commercial rape-evidence kits are available for the collection of specimens, preservation of evidence, and documentation of physical findings. Baseline blood tests for HIV, hepatitis B virus (HBV), hepatitis C virus (HCV), and syphilis should be performed, with follow-up tests in 4 to 6 months. Cultures for gonococci also should be obtained. Antibiotic prophylaxis may be indicated. Women should be tested for pregnancy that was present before the rape. Treatments can be harmful to the developing embryo or fetus.

The Patient Who Is a Victim of Domestic Violence

Victims of domestic violence may be male or female. Most are female and have a common set of specific injuries. Many beatings go unreported because of fear of retaliation, low self-esteem, and embarrassment over enduring repeated abuse. Other victims claim they love the abuser and want to keep the family together. A battered woman may feel she deserved the beating and may

avoid going to the ED unless she experiences symptoms she interprets as life-threatening.

Signs of physical abuse are commonly found around the face and head and consist of multiple abrasions, contusions, chipped teeth, fractured facial bones, epistaxis, and blackened eyes. Often the woman is pregnant for the first time, which is a common theme in 8% to 15% of gravid females suffering abusive treatment. Domestic violence occurs in all socioeconomic groups, but poverty and unemployment may precipitate the event.

The victim of domestic abuse or violence may be afraid to report the event to the police. ED personnel are not bound by law to report domestic violence. Many victims' may lie about how the injuries occurred out of fear of future violence. Sometimes the abuser is the person who brought them to the ED and is present. Personnel may ask in private if injuries are caused from violence. Reporting domestic violence in adults depends on the individual case and safety of the victim. ED nurses should completely and accurately document the event and if possible photograph the injuries with the patient's permission. Assure the victim that all information is confidential. Referral can be made to a battered women's shelter as necessary. Most shelters have a 24-hour crisis intervention.

The Patient Who Is a Victim of Child Abuse

Children are the most helpless victims, and more than 1750 die each year as a result of abuse or neglect. Of reported cases of child abuse deaths, 70% are younger than 3 years of age.[10] Child abuse can occur in any socioeconomic group and may take the form of psychologic, physical, or sexual abuse. Other forms of victimization include neglect of physical, psychologic, and medical needs. The National Child Abuse Hotline (1-800) 4-A-Child offers confidential reporting 24 hours a day, 7 days a week for reporting suspected abuse. Health care workers are mandated to report all forms of child abuse because children cannot help themselves.

Infants and young children are unable to ask for help and are dependent on adults and health care workers to recognize abuse and neglect, treat them for it, and report it. Many injuries and illnesses are characteristic of abuse. However, many forms of abuse are discovered incidentally when a child is brought to the ED, clinic, or physician's office for an unrelated illness. OR personnel may discover signs of abuse when performing simple procedures, such as myringotomy. Health care personnel should be educated to observe for unspoken signals from these helpless victims.

The first signs of child abuse may be discovered while obtaining the child's history from the adult caretaker, parent, or guardian. Clues to look for include discrepancies about injury patterns, visits to multiple hospitals, lack of a consistent medical history, delays in seeking treatment, and visible evidence of old untreated injuries in various stages of healing. Observation of the child's affect can be misleading. Some children may be overcooperative with painful procedures or display extremes of affection.

A child who has known only abuse may show no response to the environment or fail to thrive. The abused child may cling to the abuser or exhibit avoidance behavior. Response patterns can be unpredictable at times. Patient assessment should compare the physical and psychologic development stage of the child with expected normal findings. Further discussion of normal childhood development is found in Chapter 8.

Examples of physiologic developmental discrepancies include long-bone fractures in nonwalking infants or head injuries (whiplash-type) associated with violent shaking such as retinal and cerebral hemorrhage.

Violent shaking is a common form of abusive treatment between the ages of 6 weeks and 4 months during episodes of crying. Abusers may feel that shaking a crying infant is more acceptable than actually hitting. Crying may cease during the shaking because of brain edema, and the abuser may repeat the action because it made the baby stop crying. Clinical signs of trauma-induced brain injury are loss of consciousness, seizures, vomiting, and apnea. Brain injury also is caused by nutritional deficit and is manifest by personality change, learning disability, and diminished functional skill.[10]

Visible injuries such as circumferential bruising around wrists or ankles from being held down are sometimes noted. Multiple clusters of similarly shaped discolored skin markings could indicate repeated strikes with a belt or stick. These are sometimes found to be in various stages of healing. Questionable burns may be found on soles of feet, backs of hands, or inside thighs. A scalded stocking pattern may be identified on a child who has been dipped in hot water. Children who accidentally burn themselves by grabbing hot objects usually have burns on the palms of the hands or irregular splash-shaped burns from pulling a pan off the stove. Venereal disease in a child is usually the result of sexual abuse.

Some pathologic conditions commonly mistaken for child abuse include dermatologic conditions, bone diseases, coagulation disorders, infections, skin discoloration (mongolian spots), and folk healing remedies. Birthmarks can appear bluish and give the impression of bruising in various stages of healing.

Some questionable marks can be caused by clothing dyes or inks. Most of these markings can be removed with rubbing alcohol. Phytodermatosis is a skin discoloration that occurs when lime, lemon, celery, or herbal preparations are rubbed into the skin and exposed to sunlight. These phototoxic reactions can appear like hand marks if an adult was squeezing lemons or limes for summer beverages.

Folk remedies include coining, which involves rubbing a coin over an afflicted area. This sometimes causes striped bruises that resemble strap marks. To avoid erroneous reports of child abuse, the examiner should perform a careful history and physical examination, including appropriate laboratory studies. When in doubt, consult with a specialist who can critically evaluate suspicious injury or illness.

Recognition of child abuse during physical assessment may not be instantly obvious. If the injury or illness does not match the explanation, the child may be a victim of abuse and the incident should be further investigated. In every state a health care worker who suspects child abuse is mandated to report it to child welfare authorities.

Outcomes of Victimization

Regardless of the victim's age or social status the postassault, postvictimization results can be devastating. Sequelae to victimization may include posttraumatic stress disorder (PTSD), augmented attention-deficit disorder with or without hyperactivity (ADD/ADHD), psychosis, depression, and continued feelings of victimization. Children may experience secondary enuresis and encopresis as a form of regression and display inappropriate sexual behaviors toward adults or other children.

Anger may be projected toward pets and smaller siblings in the form of cruelty and abuse. Abused children may grow up to become abusers. Nightmares are common in all ages. Coping mechanisms become distorted, and conversion reactions can be

confused with somatic complaints. Unfortunately, death is sometimes the final outcome of violent crime.

Prevention of violent crime is not always an option. Health care workers become aware of the event after the fact. Referral agencies are available to provide emergency shelter and temporary solace. Encouraging adult victims to report violent acts and follow through with prosecution is equally as important as treating physical injury. The victim who is fearful and unwilling to prosecute is at high risk for being victimized again. Minor victims are helpless and unable to report their injuries without help. Health care workers are required to report confirmed or suspected child abuse to proper authorities. Follow institutional policy and procedure in this regard.

End-of-Life Care

Although perioperative patient care personnel are most often involved with patients who have a favorable prognosis, they also care for patients of all ages who have a catastrophic illness and are undergoing surgery to palliate or relieve a specific problem. The procedure may be palliative rather than curative. Included in this category are patients with the following conditions:

- Malignant diseases that result in severe debilitation and terminal illness
- Severe traumatic disabilities that necessitate lengthy hospitalization, such as after high spinal cord injury or extensive burns
- End-stage renal disease, or patients waiting for an organ transplant
- Patients with a DNR order

Maximum patient comfort and the relief of physiologic disturbances are primary concerns. All of these patients need highly individualized care. The manner in which patients are told the diagnosis and prognosis obviously has a great effect on their hope for recovery. Patients who have been thoroughly and considerately informed are easier to talk to, accept therapy more readily, and have greater trust in and communicate more openly with caregivers.

Each patient deals with such a diagnosis in his or her own way. Although it is not always so, many people consider the diagnosis of cancer a death warrant and react accordingly. To be supportive, the caregiver should mentally review Elisabeth Kübler-Ross's (1926–2004) stages of dying: denial, isolation, anger, bargaining, depression, and acceptance. (These stages do not always occur in this sequence.) More information about death and dying can be found at www.ekrfoundation.org/.

Emphasis is placed on the present, with a focus on the patient's strengths and attributes and how best to use them. Finding hope is difficult when facing a radical, disfiguring procedure. Listening to the patient is particularly important.

Death of a Patient in the Operating Room

Although it is an uncommon occurrence, a patient may die while on the OR bed or shortly after reaching the PACU or intensive care unit (ICU). When this happens the perioperative manager should be notified immediately. Ideally the family and significant others are informed by the surgeon or the surgeon's designee. It may be appropriate to have organ procurement personnel discuss organ donation with the family if death is imminent and to request permission to proceed with plans for potential organ procurement. If circumstances warrant, an autopsy may be necessary.

In the event of a high-profile accident or event, the facility's public relations personnel should be the contact with the press or news media. Perioperative or perianesthesia personnel should not provide information about any patient to any person not authorized in the patient's care. A breach of confidentiality is a serious ethical consideration and is especially contained in the event of a police investigation or medical malpractice suit.

Coroner's Cases

In some states the body of a patient who dies in the OR or who does not awaken from general anesthesia automatically becomes the property of the coroner. Patients who die as a result of or in the commission of a crime become the property of the coroner. Family consent for autopsy is not necessary in these situations. The coroner must give approval for organ procurement and has the right to overrule the wishes of the family.

Individual state law and institutional policy determine the postmortem care of the patient's body. For example, all drainage tubes, implants, and catheters may need to be left in place for removal and examination at autopsy. All medication vials and IV solution containers should remain with the body.

The body of a patient who dies under these circumstances is also considered the property of the coroner, but postmortem care is more complex. Critical medical-legal issues should be considered if the patient was a suspected victim or perpetrator of violence or was injured in a suspicious manner. All information about the patient's condition, personal effects and attire, and materials discovered during the surgical procedure are considered forensic evidence.

Postmortem Patient Care

A death may occur as a result of shock after extensive traumatic injuries, exsanguination after rupture of an aortic aneurysm, unsuccessful cardiopulmonary resuscitation after cardiac arrest, or other causes. The circulator's responsibilities after intraoperative death include the following:

1. Provide after-death care for the body as appropriate or ensure that forensic protocol is followed before releasing the body to authorities or the morgue.
   a. Follow institutional policy and procedure.
   b. Be sure identification is correct.
   c. Place the patient supine in correct alignment with one pillow under the head. This minimizes pooling fluids in dependent tissue.
   d. Secure the patient's personal effects.
   e. Do not wash the body if it is considered part of forensic evidence.
2. Arrange for transportation of the body from the OR to the morgue, or release it to an appropriate authority.
   a. Release the body from the OR according to institutional policy and procedure.
   b. Avoid exposing other patients, visitors, and family to removal of the body.
   c. If the religious or cultural preference of a patient or family is known, an appropriate member of the clergy or a spiritual adviser may be consulted concerning after-death practices.
3. Complete the intraoperative chart and additional documentation as required by institutional policy.

Policy may allow the family to view a loved one before the body is transported to the morgue. The room in which the viewing takes place should be clean, presentable, and private. The perioperative nurse (or designee) should remain with the family

and lend support. Parents may wish to hold a deceased child. Chairs and facial tissues should be available in the room. If forensics are involved, the nurse should not leave the patient's body unattended at any time.

Care is taken not to make statements to the family that sound cliché, such as the following examples:

- "It was God's will" or "God has a plan."
- "Your loved one is in a better place now."
- "God needed an angel."
- "Everything happens for a reason."
- "Things will work out for the best."
- "Time will heal."
- "You have to be strong for your remaining loved ones."
- "Your loved one wouldn't want you to be sad."
- "At least your loved one is not in pain anymore."
- "You shouldn't be so sad. It is for the best."
- "At least your loved one lived a good life."

After a death in the OR, from whatever cause, team members should be given time to express their grief and deal with their feelings about the event. Tears and sadness are normal responses and should not be criticized. The team members should be supportive of each other, including the surgeon and the anesthesia provider.

Perioperative Pediatrics

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Describe pediatric patient care in terms of developmental stages.
- Identify age-specific considerations in the care of pediatric patients.
- List several procedures that are performed on pediatric patients.

KEY TERMS AND DEFINITIONS

Acholic Stool is pale because of absence of bile pigment.
Atresia Interruption in the continuity of a tubular anatomic structure, such as the trachea or esophagus.
Cloaca Congenital malformation in females in which the vagina, urethra, and anus open into a single orifice from the body.
Congenital Physiologic condition that is present since birth.
Contralateral Opposite side.
Cryptorchidism Testicles fail to descend into the scrotal sac.
Imperforate Opening that failed to form at the terminal end of a natural orifice.
Intussusception Intestinal condition in which the bowel slides backward into itself, causing obstruction, pain, and necrosis.
Ipsilateral Same side.
Neonate Newborn.
Puberty Period of transition between childhood and adulthood when secondary sex characteristics develop. Commonly ages 8 to 13 years for girls and ages 10 to 15 years for boys.
Rule of Tens A measure of neonate physiology in preparation for a surgical procedure: 10 weeks of age, 10 g of hemoglobin, 10 lbs of body weight.
Urachus Anatomic connection between the umbilicus and the bladder that usually closes and seals after birth.
Volvulus Kinked segment of midgut that causes bowel obstruction.

The surgical problems peculiar to children from birth to postpuberty are not limited to any one area of the body or to any one surgical specialty. Malformations and diseases affect all body parts and therefore may require the skills of any of the surgical specialists. However, pediatric surgery is a specialty in itself and is not adult surgery scaled down to infant or child size. Indications for surgery include congenital anomalies, acquired disease processes, and trauma. Many of these conditions are treatable or curable with surgical intervention.

Indications for Surgery

Congenital Anomalies

A **congenital** anomaly is a deviation from normal structure or location in any organ or part of the body that is present from birth. It can alter function or appearance. Multiple anomalies may be present at birth. If an anomaly does not involve vital life functions, surgical intervention may be postponed until the results can be maximized and the risks of the surgical procedure are minimized by growth and development of body systems.

If a newborn has a poor chance of survival without a surgical procedure, the risk is taken within hours or days after birth. Defects in the alimentary tract are the most common indication for an emergency surgical procedure during the newborn period, followed in frequency by cardiac and respiratory system defects.[1] Mortality in the newborn is influenced by three uncontrollable factors: the multiplicity of anomalies, prematurity, and birthweight.

The presence of three or more physical congenital anomalies is referred to as the VACTERL association or syndrome, which includes the following anomalies:

*V*ertebral defect, such as spina bifida or myelomeningocele
*A*nal malformation, such as **imperforate** anus
*C*ardiac anomaly, such as patent ductus arteriosus or ventricular and atrial septal defects
*T*racheoesophageal fistula
*E*sophageal **atresia**
*R*enal anomaly, such as horseshoe kidney and renal dysplasia
*L*imb defect, such as short radius syndrome or syndactylism

Another acronym used to describe multiple congenital defects is the CHARGE association or syndrome. These defects may be accompanied by facial clefts and dysphagia. The CHARGE syndrome includes several of the following defects:

*C*oloboma (split iris) defect in the eye
*H*earing impairment caused by structural defects
*A*tresia choanae
*R*etardation or intellectual disabilities caused by brain anomalies
*G*enitourinary defects
*E*sophageal defects

Acquired Disease Processes

Among acquired disease processes, appendicitis is the most common surgically corrected childhood disease. Malignant tumors occur in infants and children but with minimal frequency compared with occurrence rates for adults. Benign lesions are surgically excised, usually without further difficulty to the child.

Trauma

Accidental injury is the leading cause of death in children. In 2019 the Centers for Disease Control and Prevention reported that more than 2400 children die of accidents daily throughout the world. In children ages 1 to 5 years, drowning, burns, motor vehicle accidents (MVAs), falls, choking, and poisoning top the list of death caused by accidents in all income groups. In the teenaged years, leading causes of death include MVAs, suicide, homicide, firearm accidents, disease, drowning, childbirth, poisoning, and fire. Males die of accidents more frequently than do females.

The margin for error in diagnosis and treatment of a child is less than that for an adult with a comparable injury. A child's blood volume is low compared with body size, and even a small loss of blood can be critical. Because the child's chest cavity is small, an abdominal or chest injury can be critical. Diagnosis is made quickly, and the patient is sent to the operating room (OR) if indicated. Examples of common injuries include blunt intestinal trauma caused by seat belt use on small children and head injuries caused by improper use of infant car seats. Other injuries, such as lacerations, fractures, or crushing injuries of hands and arms, may result in nerve, vessel, tendon, bone, and other soft tissue damage.

Considerations in Perioperative Pediatrics

Surgeons who perform pediatric surgery should have knowledge of the embryologic, psychologic, physiologic, and pathologic problems peculiar to the newborn, infant, and child. Knowledge has advanced pediatric surgery in the following ways:

- Recognition of differences between pediatric patients and adults.
- Accurate diagnosis and earlier treatment, which facilitates a more favorable outcome, especially in the fetus and preterm **neonate**. Neonatology is a growing subspecialty of pediatrics.
- Understanding of preoperative preparation of the patient and family.
- Availability of total parenteral nutrition (TPN) and other measures of supportive care for perioperative pediatric management.
- Advances in anesthesiology, including new agents, perfection of techniques of administration, and an understanding of the responses of pediatric patients to anesthetic agents.
- Refinements in surgical procedures and instrumentation.
- Understanding of postoperative care. Larger facilities have neonatal and pediatric intensive care units.

The nursing process is tailored to meet the unique needs of each pediatric patient. Assessment and nursing diagnoses are based on chronologic, psychologic, and physiologic factors specific to each patient. The plan of care should reflect consideration for age and reflect interventions modified according to the child's developmental stage as identified in Table 8.1.

Three developmental theorists, Erikson, Piaget, and Lovinger emphasized that although the child has reached a certain age or physical size, psychologic growth is the baseline parameter by which communication is measured.[2] Understanding individual differences enables the perioperative team to develop a positive rapport with the patient and family, which facilitates attainment of expected outcomes.

Not every patient of a particular age-group meets standardized height and weight criteria; children may be short or tall or thin or heavy for their age. Children approaching **puberty** have varied growth spurts and physical development. Although norms have been established by age-groups, the plan of care should reflect consideration for individual differences.

Chronologic Age

The patient's chronologic age is a primary consideration in the development of the plan of care. An age-related baseline is a useful beginning for effective assessment of pediatric patients. The CDC offers an assortment of information for caregivers, parents, and families concerning childhood milestones, concerns, educational programs, and reference materials.[2] Tools and information can be downloaded from the website (www.cdc.gov). Parents take comfort in knowing their children are being cared for in an age-appropriate manner and not like miniature adults. Use of a pediatric focus with babies and children creates an atmosphere specifically geared toward safety and may minimize risks such as medication dosage errors.

In concert with the care of adult patients and Universal Protocol for patient safety in the OR, a pediatric checklist should be used. No child exactly meets all criteria in chronologic versus emotional age. Authors may vary in small age increments; however, no author can state that all children fit all templates exactly because each is an individual. The following terminology is used to approximately categorize ages of pediatric patients:

1. *Embryo:* Not compatible with life: 1 day to 3 months' gestation
2. *Fetus:* In utero after 3 months' gestation
3. *Newborn infant, referred to as a neonate:*
   a. *Potentially viable:* Gestational age more than 24 weeks; birthweight more than 500 g; capable of sustaining life outside the uterus (as defined by the World Health Organization)
   b. *True preterm:* Gestational age less than 37 weeks; birthweight 2500 g or less
   c. *Large preterm:* Gestational age less than 38 weeks; birthweight more than 2500 g
   d. *Term neonate:* Gestational age 38 to 40 weeks; birthweight greater than 2500 g, usually between 3402 and 3629 g

TABLE 8.1 Psychologic Developmental Stage Theories

Chronologic Age Ranges (Approximate)	DEVELOPMENTAL STAGE BY THEORIST			Characteristics of Psychologic Development
	Erikson	Piaget	Loevinger	
Birth-18 months	Trust vs. mistrust	Sensorimotor	Presocial	Learns to view self as being separate from the environment; begins to develop the concept of hope; learns to develop attachments to others; dependent on caregiver for warmth, security, nourishment, nurturing, and stimulation; begins to use sounds and short words to communicate ideas; may view hospitalization as abandonment
19 months-3 years	Autonomy vs. shame/doubt	Preoperational	Symbiotic	Develops a two-way relationship with primary caregiver; suffers separation anxiety when isolated from established relationships; has short trials of independence; personality becomes introverted or extroverted; establishes a sense of will; uses sentences for communication; has fear of immediate threats; does not project thoughts beyond the present situation
4-6 years	Initiative vs. guilt	Preoperational	Impulsive	Asserts a separate identity; begins to have fear of real and imagined situations; senses peer acceptance or rejection; is concerned about disfigurement; may act out feelings; believes that every action has a purpose, either reward or punishment; learns to be self-protective; fears death or nonexistence; death is not always understood as being permanent; develops short-term self-control; uses compound sentences to communicate; mimics terminology used by fantasy characters
7-11 years	Industry vs. inferiority	Concrete operational	Conformist	Imitates actions and attitudes of peers and heroes; is aware of the differences of others and identifies with a particular social group; fears loss of self-control; understands the world in moderate detail; prefers honest explanations and reassurance of safety; does not want to be treated like a baby; strives for competency in daily tasks; can distinguish between fact and fantasy; has a greater understanding of death and its permanence; wants to be accepted as an individual; communicates well verbally and with basic writing skill
12-16 years	Identity vs. role confusion	Formal, operational	Self-aware, conscientious	May change opinion in response to stereotypes; develops close relationships; understands values, rules, and ideals; begins to feel more important as an individual; fears alienation; body image is extremely important; is capable of abstract thought and reasoning; has a sense of aesthetic beauty; can merge sensory information and logic to derive a conclusion; prefers privacy and confidentiality; may question authority; is aware of opposite sex; may explore sexual activity; dreams about future lifestyle; wants to prove self-worth; globally communicates verbally and in writing
17 years-adulthood	Intimacy vs. isolation	Formal, operational	Individualistic	Becomes aware of and accepts the interdependence of humankind; may feel some hostility toward authority; sometimes torn between the desire to be totally independent and dependent; seeks companionship of opposite sex; may be sexually active; refines interpersonal skills; demands privacy and confidentiality; plans for independent lifestyle as approach; refines verbal and written communication skill

(if less than 2500 g, the neonate is considered small for gestational age [SGA])

e. *Postterm:* Gestational age extended by more than 8 weeks

4. *Neonatal period:* First 28 days of extrauterine life
5. *Infant:* 28 days to 18 months
6. *Toddler:* 18 to 30 months
7. *Preschool age:* 2½ to 5 years
8. *School age:* 6 to 12 years
9. *Adolescent:* 13 to 18 years

Perioperative Assessment of the Pediatric Patient

Pediatric Psychosocial Assessment

Assessment of psychologic development is based on age-related criteria (see Table 8.1) but includes assessment of individual differences. Comparison of established norms and assessment data is

helpful in developing the plan of care. Environmental and parental influences can cause variance in affect, attitude, and social skills. Environmental influences on psychologic development include ethnic, cultural, and socioeconomic factors.

The age of the patient may indicate the level of involvement with the environment. For example, an infant may have exposure only to immediate family members for external stimuli, but a preschool child may have daily experience with children in preschool and other children. Coping and social skills may be developed, depending on the child's developmental stage.

Parenting practices may directly influence the way the patient responds to caregivers and the perioperative environment.[2] Pediatric patients respond differently in the presence of parents or guardians. Infants may be more cooperative if a parent is present. Conversely, an adolescent may want to show independence by asking the parent to leave the room. These actions may be completely opposite if the child has been abused or neglected. Lack of parental nurturing can cause a global deficit, including poor development of language and cognitive skills. Understanding the patient's level of psychologic development can help the caregiver communicate more effectively with the pediatric patient throughout the perioperative experience. Interaction should be according to the child's individual developmental level regardless of chronologic age.

Pediatric Physical Assessment

The physiologic assessment of pediatric patients is compared with national averages when baseline norms are established. Physiologic development is influenced by genetics, nutrition, health status, and environmental factors.[2] The physical assessment may reveal conditions that can adversely affect the outcome of a surgical procedure. Comparison of the patient's age, size, and psychologic development with established norms may enable the caregiver to assess for deficiencies in size or weight that may indicate a potential health problem.

Unexplained marks or bruises may be signs of physical abuse. Health care personnel are required to report suspected child abuse. Photographs are useful in the documentation of physical findings. Abused children may be afraid of punishment for revealing the origin of an injury. Some physical findings suggestive of abuse discovered during the physical examination or surgical skin preparation may include, but are not limited to, the following:

- Burns and scalding marks
- Genital injuries, such as tears or sexually transmitted diseases
- Human or animal bite marks
- Patterned bruises or skin tears
- Rope-like stricture marks
- Cranial damage or ruptured vessels in eyes

A small, frail child may have a congenital cardiac deformity or a malabsorption syndrome. Abuse or neglect may be manifested as a nutritional deficit. An extremely thin, malnourished adolescent may be intentionally bulimic or anorexic in response to a psychologic body image problem. An obese child may have an endocrine disease or a psychologic disturbance that causes overeating. These issues are important considerations because most dosages of medications given to pediatric patients are based on body weight in kilograms. Absorption and metabolism of medications are influenced by the same physiologic parameters that govern nutritional status.

Metabolism and Nutritional Considerations

Infants have relatively greater nutritional requirements than do adults for minimizing loss of body protein. The resting metabolic rate of an infant is two to three times that of an adult, which results in rapid metabolic imbalances in infants. Neonates require 100 to 200 calories per kilogram of weight per day to maintain homeostasis. The potential for complications increases proportionately with the duration of fluid restriction because infants are prone to hypovolemia and dehydration.

The neonate's body weight represents 70% to 80% fluid. Fluid weight is directly related to body fat content. Preterm infants have less body fat and consequently lose fluids easily. Other fluid losses are associated with urinary loss, gastrointestinal loss, insensible loss through respiration, and surgical loss by evaporation via the skin and drains. Fluid replacement for babies is calculated according to body weight, as follows:

- *Preterm:* 120 to 50 mL/kg/24 hr
- *Term neonates:* 100 mL/kg/24 hr
- *Infants more than 10 kg:* 1050 mL/kg/24 hr

Procedures performed on infants and toddlers should have priority on the surgical schedule so that these patients can return to a normal fluid and feeding routine as quickly as possible.

Infants may be given regular formula or a varied diet up to 6 hours before anesthesia and clear liquids, usually dextrose in water, up to 2 hours before the surgical procedure. A satisfactory state of hydration is thus maintained, and milk curds are absent from the stomach. Infants may be breastfed up to 4 hours before the surgical procedure. Breast milk has fewer or no curds and empties faster from the stomach than formula. Infants should not miss more than one or two feedings. Oral intake is resumed promptly after the infant recovers from anesthesia.

Toddlers and preschool children may be permitted clear liquids up to 2 to 4 hours preoperatively. Intake of clear oral fluids in small amounts decreases the level of gastric acid contents by stimulating gastric emptying and diminishes the hunger-deprivation response.

Children older than 5 years may have nothing by mouth (nil per os [NPO]) after midnight or 6 hours before induction of anesthesia. Exceptions may be necessary for children with fever, diabetes, or other special problems. For these children, clear liquids with supplemental glucose may be ordered to be given orally up to 2 hours preoperatively. Avoid colored liquids that could be mistaken for blood or other body substance if the child vomits.

Older children may require slower progression of oral dietary intake postoperatively and are maintained with supplemental intravenous (IV) therapy that includes protein and vitamins. Vitamins K and C may be given to patients of any age-group.

Fluid and Electrolyte Balance Considerations

The newborn is not dehydrated and withstands major surgical procedures within the first 4 days of life without extensive fluid and electrolyte replacement. The renal system is easily overloaded with the administration of IV fluids. The newborn has a lower glomerular filtration rate and less efficient renal tubular function than does an adult. (Renal function improves during the first 2 months of life and approaches adult levels by age 2 years.) During the time of an average surgical procedure on a newborn, a total of 10 to 30 mL of fluid may be administered. Usually 2.5% to 5% dextrose in half-strength normal saline solution is infused.

Administration of excessive IV dextrose solution is avoided in infants younger than 1 year because they maintain lower glycogen stores. During physiologic stress the patient easily becomes hyperglycemic. Hyperglycemia acts as an osmotic diuretic and causes increased urinary output and dilutional hyponatremia. The increased urine volume can be a false indicator of renal and hemodynamic status. Seizures and neurologic damage may result.

Seizures may be clinically undetected while the infant is under general anesthesia because the pharmacologic agents act as anticonvulsants.

Infants have a relatively larger ratio of body surface area to body mass than do adults. When they become dehydrated, which can occur rapidly, bodily functions are disturbed, as is the acid-base balance. Plasma proteins differ in concentration from those of an adult. Fluid and electrolyte replacements are necessary. In children older than 1 year, isotonic solutions, such as normal saline or lactated Ringer's solution, are given IV per kilogram of body weight.

Urinary output is directly related to body size and age. Neonates can concentrate 400 mOsm/L initially and 500 mOsm/L progressively over the first few days compared with 1200 mOsm/L in the average-size adult. This concentration and excretion of the solute load result in 2 to 4 mL/kg/hr urinary output. Older children (toddlers and preschoolers) produce 1 to 2 mL/kg/hr of urine when adequately hydrated. Urine measurement in children is difficult to monitor without a Foley catheter.

The hemoglobin level is lowest at 2 to 3 months of age (Table 8.2). The blood volume of the average newborn is 250 mL, approximately 75 to 80 mL/kg of body weight (Table 8.3). A subtle sign of blood loss is a narrowed pulse pressure less than 20 beats per minute. Significant blood loss requires replacement. Blood is typed and crossmatched in readiness. Although blood loss is small in most cases, a loss of 30 mL may represent 10% to 20% of circulating blood volume in an infant. The small margin of safety indicates the need for replacement of blood loss exceeding 10% of circulating blood volume. When replacement exceeds 50% of the estimated blood volume, sodium bicarbonate is infused to minimize metabolic acidosis.

Hypotension in an infant is not apparent until 50% of the circulating volume is lost. Hypotension is usually caused by myocardial depression from anesthetic agents, primarily inhalation anesthesia. The infant's myocardium has fewer contractile muscle fibers and more noncontractile connective tissue than found in an older child or adult and therefore lacks myocardial force to maintain cardiac output. The cardiac output depends on the heart rate. Any decrease in heart rate directly affects blood pressure and body tissue perfusion.

IV infusions should be administered with the following precautions:

- Dehydration should be avoided. Therapy for metabolic acidosis, should it develop, is guided with measurement of pH, blood gas values, and serum electrolyte levels.
- Blood volume loss should be measured as accurately as possible and promptly replaced. In an infant, rapid transfusion of blood may produce transient but severe metabolic acidosis because of citrate added as a preservative.
- IV fluids and blood should be infused through pediatric-size cannulated needles or catheters connected to drip chamber adapters and small solution containers. Umbilical vessels may be used for arterial or venous access in newborns less than 24 hours after birth. In extreme circumstances the umbilical vein can be accessed through a small infraumbilical incision and cannulated from inside the peritoneal cavity for rapid infusion. Scalp veins are used frequently on infants.

If venous access cannot be quickly established, intraosseous infusion may be indicated for fluid replacement or the administration of emergency anesthesia. Intraosseous infusion (IO) may be indicated when vascular collapse is evident and no other route is available. Most medications, blood, and blood products can be given via this route, but chemotherapy is not advised. Contraindications for IO use are specific to the planned site. IO cannot be used in a fractured limb, a site of previous orthopedic implant, a previously used IO site, or place where there is known infection.

In adults the lateral proximal humerus is used for insertion. In pediatrics the anterior proximal tibia, below the growth plate, is used (Fig. 8.1). The position on the tibia is identified by placing the index finger centrally, below the patella, between the medial and lateral borders. An antiseptic solution of choice is used to cleanse the site before insertion and sterile technique is used. Local anesthetic without preservative may be used. Lidocaine 2% is common.

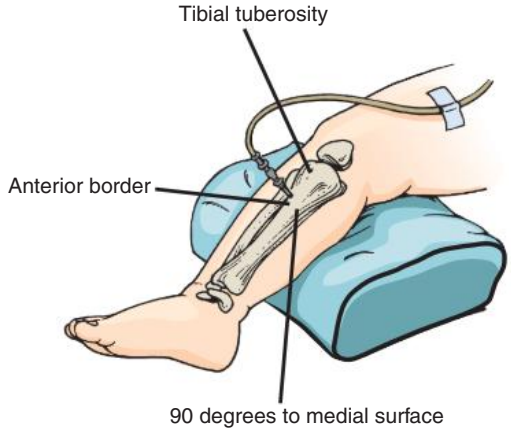
IO is a direct venous route into the medullary canal for fluid replacement and medication delivery. A specialized power driver

TABLE 8.2 Pediatric Hematologic Value Ranges

Age	Hemoglobin (g/dL)	Hematocrit (%)	Leukocytes (mm^3)	Platelets (mm^3)
Cord blood	13.7-20.1	45-65	9000-30,000	350
2 weeks	13-20	42-46	5000-21,000	260
3 months	9.5-14.5	34-41	6000-18,000	250
6 months-6 years	10.5-14	33-42	6000-15,000	250
7-12 years	11-16	34-40	4500-13,500	250

TABLE 8.3 Pediatric Blood Volume

Age	Blood Volume (mL/kg)
Neonate	75-100
6 weeks-2 years	80
2 years-puberty	70-75



• **Fig. 8.1** Intraosseous Infusion into Tibia. Insertion site for needle placement is in anterior midline 1 to 3 cm below tibial tuberosity. Note that the needle is perpendicular to medial surface and that tubing is secured on the thigh.

is used to insert the stainless steel catheter and stylet at a 90 degree angle to the bone. After entering the medullary canal, the stylet is removed and the catheter is aspirated to assure the correct position within the marrow space. Once it is confirmed in the correct location, a plastic hub and stabilizing sheath maintain the position of the delivery device. The plastic hub uses a needleless connector to minimize the risk for needlesticks during the connection of medication lines. A Hep Lock device can be used for intermittent infusions. Pressurized pumps can be used, but care is taken to prevent excessive pressure over 250 to 300 mm Hg that will cause the machinery to shut down. Some physicians prefer to use manual pressure bags to regulate flow rates.

Potential complications include, but are not limited to, extravasation of infused fluids, infection caused by contamination, cellulitis, and compartment syndrome (if extravasation occurs). Embolic events are possible, but extremely rare.

A cutdown on an extremity vein, usually the saphenous vein, may be necessary for toddlers and older children. An extremity should be splinted to immobilize it. A 150 or 250-mL solution drip chamber, sometimes referred to as a burette, buretrol, Metriset, or Soluset, is used to help avoid the danger of overhydration. This chamber is available in sizes that range from 50 to 250 mL from manufacturers such as Abbott, Braun, and Baxter. Adapters are set for accurate control of the desired flow rate.

Body Temperature Considerations

Temperature regulation is controlled in the anterior hypothalamus. Cooling causes vasoconstriction for the conservation of body heat. Extremes of cooling cause shivering in infants older than 3 months that generates body heat and increases metabolic needs, causing a 200% to 500% increase in oxygen consumption.

Neonates (especially preterm), infants, and children have wider average body temperature variations than do adults. Infants younger than 3 months do not have a shiver response because of immature neurologic development. They are at significant risk for hypothermia. Body temperature in the newborn tends to range from as low as 97° F to 100° F (36.1° C to 37.7° C). Temperature begins to stabilize within this range 12 to 24 hours after birth if the environment is controlled. A relatively high rate of heat loss in proportion to heat production in the infant results from an incompletely developed thermoregulatory mechanism. The ratio of body fat to lean mass with only a thin layer of subcutaneous brown fat for insulation puts the newborn at risk for hypothermia.

Extensive extracorporeal membrane oxygenation (ECMO) also causes rapid dissipation of heat from the body. A hypothermic newborn or infant metabolizes anesthetic agents more slowly and is susceptible to postoperative respiratory depression and delayed emergence from anesthesia. The first signs of significant hypothermia in a pediatric patient younger than 1 year are a heart rate less than 100 beats per minute, metabolic acidosis, hypoglycemia, hyperkalemia, elevated blood urea nitrogen levels, and oliguria.

Oxygen consumption is at a minimum when abdominal skin temperature is 97° F (36.1° C). A room temperature 5° F (–15° C) cooler than that of abdominal skin produces a 50% increase in oxygen consumption, creating the hazard of acidosis. These factors account for the pediatric patient's susceptibility to environmental changes. The following events can result in heat loss:

- *Evaporation.* When skin becomes wet, evaporative heat loss can occur. Excessive drapes can cause sweating. As sweat evaporates, it elicits a cooling effect.
- *Radiation.* When heat transfers from the body surface to the room atmosphere, radiation heat loss can result.
- *Conduction.* Placement of the pediatric patient on a cold operating bed causes heat transfer from the patient's body to the surface of the bed.
- *Convection.* When air currents pass over skin, heat loss by convection results. Cold, wet diapers and blankets can cause heat loss by conduction.

Neonates, infants, and children are kept warm during the surgical procedure to minimize heat loss and prevent hypothermia. Body temperature tends to decrease in the OR because of cooling from air conditioning and open body cavities. Room temperature should be maintained as warm as 85° F (29.4° C). Continuous core body temperature monitoring should be performed (skin temperature sensors may be sufficient for short procedures). Other precautions should also be taken, as follows:

- A hyperthermia blanket or water mattress may be placed on the OR bed and warmed before the infant or child is positioned. It is covered with a double-thickness blanket. The temperature is maintained between 95° F and 100° F (35° C to 37.7° C) to prevent skin burns and elevation of body temperature higher than the normal range. Excessive hyperthermia can cause dehydration and convulsions in the anesthetized patient.
- A radiant heat lamp should be placed over the newborn to prevent heat loss through radiation. Warming lights with infrared bulbs may be used if a radiant warmer is not available. These lights should be approximately 27 inches (69 cm) from the infant to prevent burns; the distance should be measured. Halogen bulbs can cause serious burns because of the extreme heat. Plastic wrapping material also provides insulation around the newborn to prevent heat loss by conduction but can cause heat loss by evaporation.
- Wrapping the head (except the face) and extremities in plastic or Webril helps prevent heat loss in infants and small children. An aluminum warming suit or blanket may be used for toddlers and older children. Forced-air warming blankets also are effective in maintaining core temperature. Booties or socks can provide good results.
- Rectal, esophageal, axillary, or tympanic probes are used to measure core temperature. A probe placed into the rectum should not be inserted more than 1 inch (2 or 3 cm) because trauma to an infant through perforation of the rectum or colon can occur. Urinary catheters with thermistor probes may be useful if urinary catheterization is indicated. Tympanic temperature measurement can be inconsistent with measurements taken elsewhere in the body and should not be the only parameter with which determination of body temperature is made.
- Drapes should permit some evaporative heat loss to maintain equalization of body temperature. An excessive number of drapes, which can retain heat and be heavy on the body, are avoided. Combinations of paper, plastic, and cloth drapes may cause excessive fluid loss through diaphoresis and absorption into the drapes.
- Solutions should be warm when applied to tissues to minimize heat loss by evaporation and conduction. The circulating nurse should pour warm solutions immediately before use. Check the manufacturer's recommendations for warming prep solutions. Some iodine-based solutions become unstable when heated. The concentration of iodine increases when the fluid portion evaporates.

The scrub person moistens sponges in warm saline solution before handing them to the surgeon. Irrigant for urologic procedures should be warmed to body temperature except where contraindicated. Room temperature solutions may be indicated where heated solutions may increase bleeding by vasodilation (i.e., brain).

- Blood and IV solutions can be warmed before transfusion by running tubing through a blood and fluid warmer. Carbon dioxide (CO_2) for insufflation during laparoscopy can be warmed this way.
- Blankets should be warmed to place over the patient immediately after dressings are applied and drapes are removed. The patient should be kept covered whenever possible before and after the surgical procedure to prevent chilling from the air conditioning.

Indicators of Thermoregulatory Status

Hyperthermia (i.e., core temperature of the body over 104° F [40° C]) during the surgical procedure can be caused by fever, dehydration, decrease in sweating from atropine administration, excessive drapes, and drugs that disturb temperature regulation, such as general anesthetics and barbiturates. If the patient is febrile preoperatively, the surgical procedure may be delayed to allow reduction in temperature and to permit fluid administration. If an immediate surgical procedure is necessary and fever persists, anesthesia is induced and external cooling is used. IV fluids may be given at room temperature instead of warmed during administration.

Beginning signs of hypothermia include initial tachycardia and tachypnea as the body tries to compensate by circulating warmed blood throughout the body. As chilling progresses, the pediatric patient becomes bradycardic, with shallow respirations as a result of slowed metabolic processes.

A sudden rise in temperature during the surgical procedure may indicate malignant hyperthermia. Immediate cooling with ice and cool fluids is necessary. More detailed information about malignant hyperthermia is described in Chapter 31.

Cardiopulmonary Status Considerations

The heart rate fluctuates widely among infants, toddlers, and preschool children and varies during activity and at rest (Table 8.4). Infants younger than 1 year tolerate a heart rate between 200 and 250 beats per minute without hemodynamic consequence. Heart rhythm disturbance is uncommon unless a cardiac anomaly is present. Cardiopulmonary complications manifest as respiratory compromise more commonly than as cardiac dysfunction. After age 5 years, cardiopulmonary response to stress resembles that of a young adult.

Cardiac and respiratory rates and sounds are continually monitored in all age-groups with precordial or esophageal stethoscopy. Blood pressure, vital signs, electrocardiogram results, and other parameters as indicated also are monitored throughout the surgical procedure (see Table 8.4). A pulse oximeter can be placed on the palm of the hand or on the midfoot of a newborn or small infant. Smaller patients experience oxygen desaturation easily. A disadvantage of pulse oximetry is that it cannot detect instantaneous drops in oxygen saturation. It gives readouts of levels that have already occurred. Because of increased carboxyhemoglobin levels, it may be ineffective for patients who have had smoke inhalation or carbon monoxide poisoning. A pulse oximeter reading of 80% is clinically diagnostic of central cyanosis. Hypoxemia can cause bradycardia to decrease oxygen consumption of the myocardium.

TABLE 8.4 Pediatric Vital Sign Ranges

Age[a]	Heart Rate/ Minute Awake	Heart Rate/ Minute Asleep/at Rest	Respirations/ Minute Asleep/at Rest	Blood Pressure Systolic (mm Hg)
Newborn (2-3 kg)	100-205	80-160	30-60	60-76
Infant 1-12 months (4-10 kg)	110-180	90-160	30-53	72-104
Toddler 18-30 months (12-14 kg)	98-140	80-120	22-37	86-106
Preschool 3-5 years (16-18 kg)	80-120	65-100	20-28	89-112
School Age 6-9 years (20-32 kg)	75-118	58-90	18-25	97-115
10 years (33 kg)	60-100	60-90	18-22	102-120
Adolescent 14 years (50 kg)	60-100	50-90	12-20	110-131

[a]Weights from the National Institutes of Health (NIH) represent a combined estimate of weight for girls and boys.

Data from American Heart Association, PALS, Dallas, TX, 2016, The Association.

Infants are particularly susceptible to respiratory obstruction because of their anatomic structure. They are primarily obligate nasal breathers. They have small nares, a relatively large tongue, lymphoid tissue present, and a small-diameter trachea, which causes disproportionate narrowing of the airway. The pharynx is funnel-shaped and allows secretions to pool and obstruct the airway. A cylindric thorax, poorly developed accessory respiratory muscles, and increased volume of abdominal contents limit diaphragmatic movement. The chest is more compliant and collapses easily.

Pediatric Infection Risk Considerations

Newborns and infants are susceptible to nosocomial infection. Many preterm infants who have respiratory distress and circulatory problems survive because of advances in perinatal medicine, which has increased the population of infants who are at high risk and debilitated with reduced humoral and cellular defenses to infection. Aseptic technique is essential in handling neonates and all other pediatric patients.

An elective surgical procedure should be delayed in the presence of respiratory infection because of the risk for airway obstruction. Intubation of inflamed tissues may cause laryngeal edema. Coryza, inflammation of mucous membranes of the nose, is often a sign of an infectious respiratory disease.

Frequent use of antibiotics may lead to antibiotic resistance in some microorganisms. Many types of antibiotics are used to treat infection; however, prevention via aseptic and sterile techniques is more beneficial to the patient.

Pediatric Pain Management Considerations

Infants and children are sensitive to pain with the same intensity as adults. Their pain may be intense, but infants, toddlers, and preschool children are unable to describe its location and nature with specific terms, although they have some limited pain-descriptive vocabulary around the age of 18 months.

Neonates and infants can be assessed for pain with physiologic parameters such as heart rate and oxygen saturation and with facial expressions such as brow bulge, eye squeeze, and nasolabial furrow and body movements.

Another method of measuring pain is the FLACC behavioral pain assessment scale (*F*ace, *L*egs, *A*ctivity, *C*ry, and *C*onsolability) developed by nurses and physicians at C.S. Mott Children's Hospital at the University of Michigan Health System in Ann Arbor. The chart measures and scores five categories of behavior in pediatric patients ages 2 months to 7 years in relationship to pain (Table 8.5).

School-age children may refer pain to a part of the body not involved in the disease process. Fig. 8.2 describes the Wong-Baker FACES pain rating scale that can be used to determine the severity of pain experienced by a pediatric patient. Insecurity and fear in an older child may be more traumatic than the pain itself. Children should be observed for signs of pain (i.e., vocalizations, facial expressions, crying, body movements, physiologic parameters). Children also differ from adults in their response to pharmacologic agents; their tolerance to analgesic drugs is altered (Table 8.6).

Most pediatric medication errors occur because children vary significantly in body weight. The number of near-misses is almost 7 times greater in children than in adults. Many errors are as high as 10 times the usual dose because of decimal placement mistakes in calculation. Considerations in pediatric medication should include the following points:

- Children cannot determine and communicate their own responses to drugs with reliable precision.
- Parents often do not understand drug administration instructions.
- Data are minimal about pediatric responses to medication.
- Few clinical trials are used to support drug use for children, although the drugs are commonly used.
- Pediatric dosage forms and packaging are not available in all drugs used for children.
- Children have unpredictable disease states and organ responses to drugs.
- Reactions in children may not reflect the responses exhibited by adults.

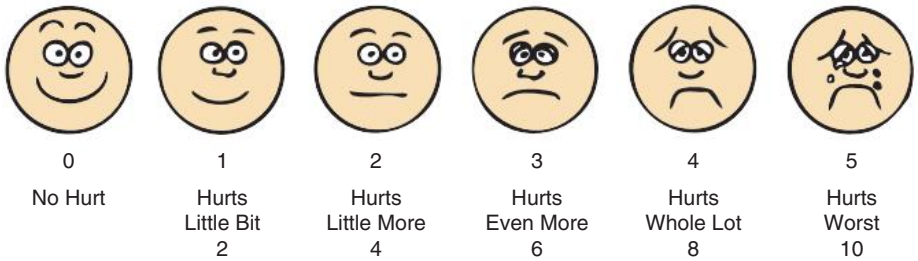
Prevention of pediatric medication errors should include, but is not limited to, the following activities:

- Be sure the pediatric patient's weight is recorded in grams or kilograms (as appropriate for age and size) on the chart because weight-based dosages require accurate measurement for calculation.
- Do not abbreviate dosages or volumes.

TABLE 8.5 Pain Assessment in Pediatric Patients 2 Months to 7 Years Old: FLACC Behavioral Pain Assessment Scale

	SCORING		
Categories[a]	0	1	2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant quivering chin, clenched jaw
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers; occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging or being talked to, distractible	Difficult to console or comfort

[a]Each of the five categories is scored from 0 to 2, resulting in a total score between 0 and 10. The FLACC scale was developed by Sandra Merkel, MS, RN; Terri Voepel-Lewis, MS, RN; and Shobha Malviya, MD, at C.S. Mott Children's Hospital, University of Michigan Health System, Ann Arbor, MI. Copyright © 2002, The Regents of the University of Michigan.



• **Fig. 8.2** Wong-Baker FACES Pain Rating Scale. Explain to the child that each face is for a person who feels happy because he has no pain (hurt) or sad because there is some or a lot of pain. Face 0 is very happy because he does not hurt at all. Face 1 hurts just a little bit. Face 2 hurts a little more. Face 3 hurts even more. Face 4 hurts a whole lot, but Face 5 hurts as much as you can imagine, although you do not have to be crying to feel this bad. Ask the child to choose the face that best describes his or her own pain. Rating scale is recommended for persons age 3 years and older. TABLE 8.6 Pediatric Sedation and Pain Management

Drug and Dosage	Duration	Considerations in Administration
Acetaminophen		
10-15 mg/kg PO	3-8 hours	Dose Dependent
10-20 mg/kg rectally	4-6 hours	Analgesia for minor procedures; antipyretic; absorption is delayed in infants, so dose should not be repeated for 6 hours; no effect on coagulopathy; no respiratory depression; may be combined with narcotic for major procedures
Codeine		
0.5-1 mg/kg PO	3-6 hours	Moderate pain relief; not given IV; can be given with acetaminophen
Diazepam		
0.05-0.03 mg/kg IM or IV	2-4 hours	Sedation and seizure control; can cause respiratory depression, jaundice, and vein irritation at IV site
0.2-0.3 mg/kg PO	4-12 hours	Administer 45-60 minutes before procedure
Not used for continuous infusion: 0.2-0.5mg/kg rectal		
Fentanyl		
1-2 mcg/kg IM or IV	30-60 minutes	Excellent pain and anxiety relief; metabolized slowly in smaller children and infants; reversible with naloxone; short half-life; can cause respiratory depression, nausea, and vomiting; PO lozenge provides sedation but causes high incidence of preoperative nausea and vomiting
Continuous infusion: 0.5-2 mcg/kg/hr		
PO lozenge is available 200 mcg, 400 mcg, 600 mcg, 800 mcg, 1200 mcg, 1600 mg		Consume over 15 minutes. Check appropriate dose.
Hydromorphone		
0.5-4 mg per dose every 4 hours IM, IV, or PO	4-5 hours	Not used for infants and young children; used for adolescents; side effects include CNS and respiratory depression, hypotension, bradycardia, increased intracranial pressure, and peripheral vascular dilation
Ibuprofen		
4-10 mg/kg PO, IV or rectally[a]	3-4 hours	Can cause gastrointestinal bleeding; may affect platelet aggregation
Ketamine		
0.5-1.5 mg/kg IV IM 2-5 mg/kg PO 5-10 mg/kg	5-60 minutes 15-90 minutes 30-120 minutes	Can cause respiratory depression, hallucinations, emergence delirium and behavioral changes
Meperidine		
1-1.5 mg/kg IM, IV, PO, or SQ	3-4 hours	Excellent pain relief; reversible with naloxone; can cause respiratory depression, suppression of intestinal motility, and hypotension; may cause nausea and vomiting; not used in increased intracranial pressure; poor sedation; not a good premedicant
Continuous IV infusion: titrate up to:0.5-0.7 mg/kg/hr		
Midazolam		
0.05-0.1 mg/kg IV	30-60 minutes	Short half-life; may cause respiratory depression; excellent amnesic; sedation of choice for most pediatric patients
0.1-0.15 mg/kg mg/kg IM	2-6 hours	
0.25-0.75 mg/kg PO		
Intra nasal 0.2-0.3mg/kg		
Continuous infusion: 0.1 mg/kg/hr		

TABLE 8.6 Pediatric Sedation and Pain Management—cont'd

Drug and Dosage	Duration	Considerations in Administration
Morphine		
0.08-0.1 mg/kg IM, IV, or SQ; not well absorbed PO	4-5 hours	Excellent pain relief; reversible with naloxone; can cause respiratory depression, suppression of intestinal motility, and hypotension; may cause nausea and vomiting; not a good premedicant
Continuous infusion: 0.25-2 mg/kg/hr		
Average dose: 0.06 mg/kg/hr		
Pentobarbital		
2-6 mg/kg IM, PO, or rectally	3-4 hours	Causes sedation and hypnosis; short acting
Sufentanil		
1-2 mcg/kg IV; nasal spray, sublingual	1-2 hours	Is 10 times more potent than fentanyl; very short half-life
Propofol		
125 mcg-2 mg/kg	Maintenance requires constant infusion.	Bronchodilator, causes sedation and no analgesia, short acting; contains egg lecithin

[a]Additional values can be found in: *Davis's drug guide for nurses,* ed 16, Philadelphia, 2019, F.A. Davis Company.
CNS, Central nervous system; *IM,* intramuscularly; *IV,* intravenously; *PO,* by mouth; *SQ,* subcutaneously.

- Clarify any questionable drug, dose, or route.
- Check for allergies. Observe the pediatric patient for new signs of allergy if a new medication is added to the regimen.
- When the drug is measured in decimals, be sure to use a zero at the left of the decimal to signify the fraction (e.g., 0.2 mg rather than .2 mg). Do not use a zero at the right of the decimal (e.g., 5 mg rather than 5.0 mg). Errors happen when someone does not see the decimal.
- Use generic names of drugs as a routine.
- Be sure to have clear signatures and contact numbers for the person prescribing the drug.
- Avoid verbal orders if possible.
- Know the medication and its actions before giving the drug.
- Know the medication delivery devices before using them (e.g., infusion pumps).

Preoperative Psychologic Preparation of Pediatric Patients

The pediatric surgical patient should be considered as a whole person with individual physical and psychosocial needs assessed in relation to the natural stages of development. Equally important are the adjustment and attitude of the parents toward the child, the illness, and the surgical experience. Parental anxiety about the impending surgical procedure may be transferred to the child. Emotional support and education of the patient and the parents are important aspects of preoperative preparation to help them cope.

When an event is threatening, the patient changes cognitive and behavioral responses to deal with the specific demands of the situation. Most adults face stress with more control when fear of the unknown is eliminated. Therefore parents need to be informed of events that will occur and to be taught how to care for their child preoperatively and postoperatively. If children are informed of sensations to be experienced, cognitive control of the event may occur. Children do not differ from adults in this respect. However, understanding varies with age.

The following are general considerations:

1. Correction of a congenital anomaly as soon after birth as possible may be better psychologically for both the infant and the parents. The infant younger than 1 year does not remember the experience. Parents gain confidence in learning to cope with a residual deformity as the infant learns to compensate for it. Fear of body mutilation or punishment may be of paramount importance to a preschool or young school-age child.

   Children from 2 to 5 years of age have great sensitivity and a tenuous sense of reality. They live in a world of magic, monsters, and retribution, yet they are aggressive. School-age children have an enhanced sense of reality and value honesty and fairness. Their natural interest and curiosity aid communication. These children need reassurances and explanations in vocabulary compatible with their developmental level. Words should be chosen wisely. Negative connotations should be avoided, and the positive aspects should be stressed. The nurse should talk on the child's level about his or her interests and concerns.
2. Anxiety in the school-age child may be stimulated by remembrance of a previous experience. Many children undergo two or more staged surgical procedures before the deformity of a congenital anomaly or traumatic injury is cosmetically reconstructed or functionally restored. Familiarity with the nursing staff reassures the child. Ideally the same circulating nurse who was present for the first surgical procedure should visit preoperatively and be with the child during subsequent surgical procedures.

   Fear of the unknown about general anesthesia may become exaggerated into extreme anxiety with fantasies of death. The school-age child and adolescent need facts and reassurances. General anesthesia should not be referred to as "putting you to sleep." The child may equate this phrase with the euthanasia of

a former pet that never returned home. Instead the nurse should say, "You will sleep for a little while" or "You will take a nap." Tell the child about the "nice nurses" who will be in the "wake-up room after your nap." Parents should be encouraged to also display confidence and cheerfulness to avoid transmitting anxiety.

Parents should be honest with their child but maintain a confident manner. The perioperative nurse should do the same. However, a school-age child should not be given information not asked for; questions should be answered, and misunderstandings should be corrected. The nurse should be especially alert to silent, stoic, noncommunicative children, many of whom have difficult induction and emergence from anesthesia. Children who have lost a sibling or friend to death often fear hospitalization.

3. Some facilities hold parties or get-togethers for children and their parents before or after admission to explain routines and procedures before the surgical experience. At other facilities personnel take children to the OR with their teddy bears so that they can see the different attire, lights, tables, anesthesia machine, and other equipment that might interest them. A child-size anesthesia mask becomes a toy that they are allowed to handle and place on the teddy bear. A clear plastic mask is less psychologically traumatic to a child than is an opaque black rubber mask. An effective method of explaining procedures to children is to use the child's teddy bear and dress it as the child will look postoperatively. For example, a bandage is put on the bear if the child will have one postoperatively.
4. Separation from parents or a trusted guardian is traumatic for infants older than 6 months, toddlers, and preschool children. Infants require cuddling and bonding. Toddlers are only just approaching the autonomy stage, and hospitalization forces them into passive behavior; thus their separation anxiety is greatest. Young children may fear strangers. The parent's presence is necessary for the toddler, and the parent should be encouraged to stay with the hospitalized child as much as possible.
5. The child should be permitted to bring a toy or other security object to the OR suite if a parent cannot be present. Many anesthesia providers encourage parents to accompany an infant or child to the OR and to stay through induction if they wish. The presence of a parent can significantly reduce anxiety and ease induction. Some facilities allow parents to accompany the child to the holding area but restrict entrance into the OR. Highly anxious parents who have difficulty coping with stress may cause an increase in the child's anxiety level.
6. Ambulatory surgery, if feasible, is an advantage because the child enters the facility 1 to 2 hours before the surgical procedure and returns home after recovery from anesthesia. This minimizes the trauma of separation.
7. A preoperative visit by a perioperative nurse should be planned to get to know the child, confirm appropriate consents, and provide emotional support to the family. Parents should be taught to provide postoperative care, especially before and after an ambulatory procedure. Verbal instructions may be supplemented with a videotape or storybook to reinforce understanding for both the child and the parents.
8. The perioperative nurse should bring the patient to the OR in a crib or on an appropriate-size cart. Carrying a child into the OR presents the risk for dropping or bumping the child. Each situation should be determined by the patient's need. Some facilities use toy wagons for child transport.

Pediatric Anesthesia

Pediatric anesthesia has become increasingly specialized as the many variables in the management of infants and children have become better understood. The anesthesia provider recognizes and respects the small margin for error and the uniqueness of the physiology and responses to drugs of pediatric patients. For example, the high metabolic rate of children causes rapid oxygen consumption. Changes occur rapidly in infants and children.

Preoperative Assessment by the Anesthesia Provider

A preoperative visit by the anesthesia provider to establish rapport and assess the patient is also a vital part of preparation of the pediatric patient. Preferably, this visit is made with the parents present so that the child considers the anesthesia provider a trustworthy and caring friend. During physical assessment, special attention is given to the heart, lungs, and upper airways. Loose teeth are noted. Possible difficulties are anticipated.

Preoperative care includes correction of dehydration, reduction of excessive fever, compensation for acidosis, and restoration of depleted blood volume. An American Society of Anesthesiologists (ASA) physical status classification is assigned to the pediatric patient. The patient's age, developmental stage, psychologic characteristics, and history are considered to determine the patient's probable response to the anesthesia experience.

Premedication

Psychologic preparation of the child older than 7 years can decrease the need for an anxiolytic (i.e., a sedative or minor tranquilizer to reduce anxiety). Crying greatly increases mucus in the respiratory tract. At the discretion of the anesthesia provider, premedication may be ordered to produce serenity. Some anesthesia providers prefer children to be well medicated; others favor minimal or no sedation. Infants younger than 1 year usually do not require premedication, but pacifiers with medication ports are commercially available for delivery of oral drugs.

Premedication, which is tailored to the individual, varies considerably by age, weight, and health status. Preanesthetic sedation should allow the patient to be taken to the OR lightly asleep or drowsy and should facilitate induction of anesthesia without waking the child. It should also provide some analgesia during the recovery period.

Timing of administration is extremely important. To be effective, drugs should be given at least 45 to 60 minutes before the surgical procedure. The circulating nurse should check with the anesthesia provider and the surgeon before sending for the patient. If ample time is not available for the appropriate effect of premedication, the anesthesia provider may prefer to omit the medication to avoid precipitation of psychologic trauma. Fast-acting drugs are available and may be useful for rapid sedation preoperatively. Narcotics, such as morphine and meperidine (Demerol), are rarely indicated for routine premedication in healthy pediatric patients.

No ideal premedicant exists, but the following list contains the drugs that are commonly used (see also the comparison of sedatives in Table 8.6):

- Sufentanil (Sufenta) given nasally (i.e., sprayed onto the nasal mucosa) or sublingually facilitates separation from parents by causing relaxation and drowsiness. The child becomes calm and cooperative.

- Fentanyl (Sublimaze) can be incorporated into a lozenge or a flavored hard candy mounted on a stick (i.e., an anesthetic lollipop). When the child licks the candy, the drug is absorbed into the bloodstream through the oral mucosa and produces sedation for 30 to 60 minutes. The correct dose should be double checked because this form is available in numerous strengths.
- Diazepam (Valium), 0.05 to 0.03 mg/kg administered intramuscularly (IM) or 0.2 to 0.3 mg/kg given orally (PO), causes relaxation for 3 to 4 hours. It can be administered rectally 0.2 to 0.5 mg/kg. This drug has few cardiovascular side effects.
- Midazolam (Versed), 0.01 to 0.15 mg/kg administered IM 15 minutes before induction, greatly reduces anxiety. Oral preparations also work well. This drug is also good for intravenous conscious sedation (IVCS) during endoscopy. Doses range between 0.25 and 0.6 mg/kg IV. Cardiovascular stability is good, and ventilation is not depressed.
- Atropine, 0.01 to 0.02 mg/kg, may be administered IM, IV, or subcutaneously (SQ) to inhibit secretions, especially in a child with a severe airway problem, or to counteract bradycardia. Cardiac effects last about 1 hour. Dosage is decreased to 0.004 mg/kg for infants less than 5 kg. It is not given in the presence of fever or glaucoma.
- Glycopyrrolate (Robinul), 0.004 to 0.01 mg/kg administered IM, lowers gastric acidity. It may be given as an alternative to atropine sulfate to reduce secretions. It is contraindicated in the presence of paralytic ileus, urinary tract obstruction, and glaucoma.

Anesthesia Equipment

Simple lightweight anesthesia equipment is used. Disposable equipment is popular. Facemasks designed for minimal dead space are available to closely fit a child's relatively flat face. Nonrebreathing circuits provide less resistance and valves for fresh flow of gas at higher flow rates relative to a child's metabolism and ventilation. For avoidance of hypothermia, anesthetic gases are warmed and humidified.

Induction

Induction is facilitated with a quiet atmosphere, a soft voice, and a reassuring touch. A parent may be present if the policies of the facility permit. Children should be told what to expect without precipitating fear. The induction experience can be described as getting on a merry-go-round. Noises will seem louder. To avoid confusion it is best for the child to listen to one person speak at this time. The circulating nurse should remain at the patient's side, maintain a gentle touch, and be alert to the patient's needs and condition.

The considerations for anesthesia induction include the following:

1. Restraints should be loose. Minimal pressure should be applied. If the patient is a newborn, infant, or toddler, restraint straps are omitted while the circulating nurse holds the patient during induction. A toddler or preschool-age child is less frightened when holding on to someone's hands. Restraints can be applied after the patient is asleep.
2. A few drops of food extract of the child's choosing (e.g., mint, banana, strawberry) can be placed in the facemask. This makes the anesthetic gas more acceptable and gives the patient a sense of control. The scent of anesthetic gas may be compared with the scent of special jet fuel used for airplanes or spaceships.
3. If the child is awake, crying, or struggling, apprehension during induction can be avoided with distraction and rapport. Establishing rapport with young children is not easy. If a parent is present, the child may be more cooperative. The child's cooperation may be solicited with counting out loud, singing the alphabet song, blowing up a balloon, taking a space trip, or discussing a favorite plaything or television character. The facemask can be held slightly over the face, permitting anesthetic gas to flow by gravity, and lowered gently as the child becomes drowsy. Some anesthesia providers permit the child to hold the mask. Care is taken to avoid having the parent's face too close to the mask when anesthesia gases are flowing. The parent could be affected and sense altered consciousness.

   A child who has been crying may have somewhat edematous tissue in the nose and larynx. Secretions are frequently increased. Swollen tissues in an obligate nose-breather can complicate breathing. Note that the parent, who may be present, is viewing the child's activities range from animated to lethargic (Fig. 8.3). This gives the appearance of helplessness or death. The parent may feel emotional and shed tears or feel faint. Reassurance should be given, and the parent should be escorted to the waiting area before intubation takes place.
4. Induction may be accompanied by regurgitation and aspiration of gastric contents in infants with pyloric stenosis, tracheoesophageal fistula, intestinal obstruction, or food in the stomach. The hazard is minimized with aspiration of gastric contents with a sterile catheter before induction and with the tube left in place for drainage during the surgical procedure. Rapid-sequence induction also may be used. This consists of a sedative or hypnotic agent, muscle relaxant, and intubation with cricoid pressure (Sellick's maneuver) applied to close the esophagus and avoid silent regurgitation of food from the stomach. All trauma patients should be considered to have a full stomach.

Types of Induction

Inhalation

If asleep from premedication on arrival in the OR, the child can be anesthetized quickly. If the child is awake, induction may be initiated with inhalant anesthetic. Pregnant caregivers should avoid any anesthetic gasses that might escape during mask administration before intubation.

Nitrous oxide may increase peripheral vascular resistance if it is used to maintain general anesthesia for cardiovascular procedures. It may also increase the risk for air embolus because it combines with smaller air bubbles that may enter the system during repair of congenital heart defects. Potent inhalants are absorbed more rapidly in the presence of nitrous oxide and may cause myocardial depression and decrease cardiac output in very young children. Atropine may minimize this effect.

Rectal Induction

Rectal induction is not frequently used. Given by enema, methohexital (Brevital), 10 to 25 mg/kg of 1% solution, produces sleep in 6 to 8 minutes and lasts 45 to 60 minutes. This is a painless method used in the presence of parents for preschoolers or toddlers. The parent may hold the child. It is a good method for short diagnostic procedures. The anesthesia provider remains with the patient.

Once the child is asleep the anesthesia state may be maintained with an inhalant. Gentle assisted ventilation may be needed. This method is tolerated best in children younger than 3 years.

• **Fig. 8.3** Parent sitting with child for administration of general anesthesia.

Intravenous Infusion

IV infusion is often preferred for patients older than 9 or 10 years. Induction with a small dose of barbiturate or ketamine is rapid. Studies have shown that IV induction causes less psychologic trauma than do inhalant methods. A mixture of lidocaine and prilocaine in a transdermal cream base is commercially available for application to the site to decrease pain associated with venipuncture.

Care is taken if the child has a central line because infection or thrombosis may result. If the central line is used for anesthetic administration, all residual drug is flushed from the port so that none remains in the tubing after the procedure.

Ketamine, 0.5 to 2 mg/kg IV, is useful in a combative, burned, or hypovolemic patient. If given PO or IM to a healthier child who weighs less than 10 kg, the usual dose is 2 to 10 mg/kg. The pharmacologic predictability of ketamine is a good reason for its use in pediatric sedation. Its onset takes place 1 to 2 minutes after IV administration and 5 minutes if given IM. Either way, the duration of the dose is approximately 45 minutes. Low doses provide sedation and analgesia. Higher doses cause general anesthesia. Ketamine provides a moderate level of general anesthesia and maintains blood pressure, breathing, and airway reflexes. Ketamine offers a safer choice of anesthesia if the patient has a known or potential risk for malignant hyperthermia.

Epidural Block

A caudal epidural block may be used in combination with general anesthetic for orthopedic, abdominal, and thoracic procedures.

Intubation and Airway Placement

Airway obstruction in infants and children usually occurs early during anesthesia administration, especially if the child has been crying. When anesthesia deepens, oral airway insertion is essential after assisted ventilation with oxygen. Assisted or controlled ventilation reduces the labor of breathing and therefore reduces metabolism. Many anesthesia providers prefer the use of a laryngeal mask airway.

Intubation

Placement of an endotracheal tube in the trachea of a newborn or infant differs from placement in a child or adolescent. Regardless of age, the patient's airway must remain patent. Sterile equipment and gentle manipulation to avoid soft tissue injury are essential for intubation and suctioning. Other considerations include the following:

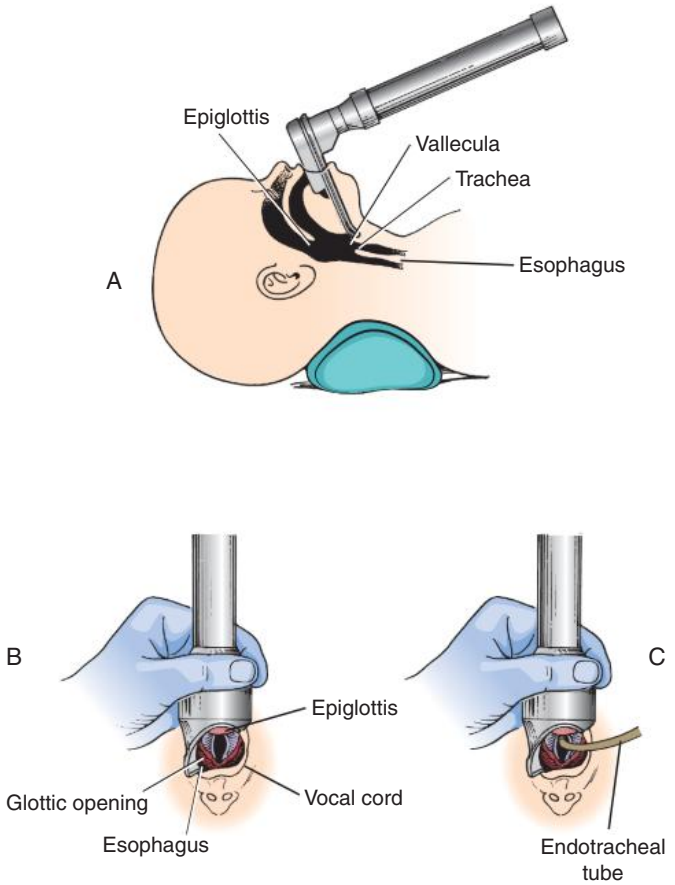
- Endotracheal intubation is used by some anesthesia providers for all procedures in infants younger than 1 year. It is necessary for intraabdominal, intrathoracic, and neurosurgical procedures;

TABLE 8.7 Recommended Endotracheal Tube Sizes

Age	Diameter (mm)
Preterm	2.5-3
Newborn	3
Newborn-6 months	3.5
6-12 months	3.5-4
12 months-2 years	4-4.5
3-4 years	4.5-5
5-6 years	5-5.5
7-8 years	5.5-6
9-10 years	6-6.5
11-12 years	6.5-7
13 years and older	7-7.5

for those in the head or neck areas; and for emergency procedures when contents of the stomach are uncertain. Intubation while the patient is awake may be used in neonates. A certain amount of jaw tightness (masseter muscle rigidity, trismus) is common in some pediatric patients after the administration of succinylcholine, but this should be observed closely because it also may be a premonitory sign of malignant hyperthermia.

- The size of the endotracheal tube is selected according to the width and length of the trachea (Table 8.7). Endotracheal tubes for children younger than 8 years are not cuffed. The uncuffed tube allows for a slight space around the exterior circumference and a wider internal diameter than a cuffed tube. Soft tissue at the narrowest level of the cricoid cartilage, located just below the vocal cords, forms a loose seal around the tube. The pediatric larynx sits more cephalad (higher) in the throat (C3 in a preterm infant and C4 in the average child compared with C5-6 in an adult).
- The nasotracheal tube may inadvertently dislodge adenoid tissue and carry it into the trachea.
- The head of a newborn or infant is elevated slightly and not hyperextended during placement of the endotracheal tube. A toddler also has a larger occiput and therefore needs little posterior extension of the head. A child with Down syndrome is predisposed to instability of the odontoid articulation at the first cervical vertebra (C1) and is at risk for dislocation if the head is placed in extreme hyperextension.
- A straight blade generally is used on the laryngoscope because the epiglottis must be raised to visualize the glottis during intubation (Fig. 8.4). An infant's epiglottis is long and stiff and projects posteriorly at an angle of 45 degrees above the glottis. The epiglottis of a toddler and a preschool child is short and easily traumatized.
- Intubation and suctioning are preceded and followed by oxygen administration. If the process of introducing the endotracheal tube takes longer than 30 seconds, the patient should be ventilated with 100% oxygen before additional attempts at intubation ensue.
- The length and diameter of the suction catheter should be considered when suctioning oropharyngeal secretions. An oversized catheter may perforate the oropharynx, trachea, bronchus, or esophagus.
- The newborn's head is maintained in a neutral position, midway between full extension and full flexion, while an endotracheal tube is in place. The tip of the tube should be positioned in the mid trachea. The average distance between the vocal cords and the carina, where the trachea separates into two branches, is only about 2 inches (4 to 5 cm) in a term neonate and much less in a preterm neonate. If the head shifts, the tube can shift, leading to inadequate oxygenation.



• **Fig. 8.4** Intubation of Infant, Toddler, or Preschool Child. **A,** Straight blade on laryngoscope is advanced to vallecula, space between base of tongue and epiglottis. **B,** Gentle elevation of tip of blade lifts epiglottis to visualize glottic opening between vocal cords. **C,** Endotracheal tube is advanced below the blade and into the trachea.

Anesthetic Agents and Maintenance

The following characteristics of anesthetic agents and maintenance of anesthesia are considered:

1. Topical agents are not often used because of the hazard of overdose. Local anesthetic cream (eutectic mixture of local anesthetics [EMLA]), may be used to start an IV access point with minimal risk for toxicity.
2. Inhalation anesthesia, especially with sevoflurane, is popular. Nitrous oxide–oxygen is frequently used in combination with IV agents. Halothane and succinylcholine are contraindicated with a family history of malignant hyperthermia because they trigger the condition. Nitrous oxide is used with caution in patients with congenital cardiac defects, particularly cyanotic

conditions. Isoflurane (Forane) is irritating and necessitates a slow and more difficult induction to prevent laryngospasm, but it offers the advantage of circulatory support. It is not useful in short procedures. Sevoflurane is less irritating to the airway and is comparable with halothane for induction. Emergence is smooth and rapid. Pain sensation may be immediate after arousal. Analgesia should be administered.

Alveolar concentrations of inhaled anesthetics rise much more rapidly in pediatric patients than in adults because of relatively greater blood flow and smaller functional residual capacity. Children therefore have higher anesthetic requirements than do adults. Increased anesthetic requirement and more rapid induction can cause hypotension and reduced cardiac output in infants and children.

3. Ketamine provides sedation for preschool children during invasive diagnostic procedures. It is a short-acting general anesthetic for short procedures such as burn debridement, tonsillectomy, or circumcision. Because it does not alter pharyngolaryngeal reflexes or skeletal tone, intubation is unnecessary. Cardiovascular and respiratory stimulation is minimal; ketamine may be useful in asthmatic and other poor-risk patients. It is contraindicated in the patient who has increased intracranial pressure. It is not advised for use with teenagers. Premedication with diazepam counteracts possible emergence delirium.
4. Local anesthesia is commonly used as a supplement to light general anesthesia. Long-acting agents, such as bupivacaine (Marcaine), prolong postoperative analgesia, thus reducing or eliminating the need for narcotics (Table 8.8). Epinephrine added to bupivacaine enhances its duration to a greater extent in children than in adults. Doses of epinephrine up to 10 mg/kg are considered safe.
5. Epidural anesthesia can be administered for sensory blockade intraoperatively. The epidural catheter may be left in place for prolonged postoperative analgesia. A continuous infusion of narcotics provides uninterrupted pain management, as administered to adults to attenuate postoperative stress response.
6. Narcotics are used in situations comparable to adult indications. Nitrous oxide–narcotic-relaxant provides stable anesthesia for the very ill patient. Fentanyl has minimal cardiovascular effect.

TABLE 8.8 Local Anesthesia for Pediatric Patients

Agent	Maximum Pediatric Dose
Lidocaine	
Without epinephrine	4.5-5 mg/kg
With epinephrine (epinephrine should not exceed 10 mcg/kg)	7-10 mg/kg
Bupivacaine	2.5-3 mg/kg
Tetracaine	3 mg/kg
Procaine	12 mg/kg
Chloroprocaine	10-12 mg/kg

Data from: Taketomo C, Hodding J, Kraus D: *Pediatric & Neonatal Dosage Handbook*, Lexi-Comp, Inc, 25th edition, 2019.

7. The critically ill neonate does not tolerate anesthesia well. Adequate ventilation and oxygenation are vital, but care is taken to avoid oxygen toxicity with resultant retrolental fibroplasia; neovascularization of the retina can produce blindness. Neonates and preterm infants less than 34 weeks' gestational age and 1500 g or less body weight are at risk. Adequate blood-gas tension is ensured only with intraoperative invasive measurement.
8. Neuromuscular blockers are used judiciously. Infants younger than 1 year exhibit a lesser degree of blockade from succinylcholine than do older children. Bradycardia and an increase in intraocular tension are more conspicuous in infants. Response decreases with age. The dosage varies. A peripheral nerve stimulator should be used to assess blockade to avoid overdosage. Blockers seldom are needed in infants because of their poorly developed abdominal musculature.
9. Consideration is given for postoperative analgesia. When an inhalation agent is reduced near the end of the surgical procedure, a narcotic may be given. Regional or local infiltration also provides relief of pain (e.g., after circumcision or cleft lip repair).

Emergence and Extubation

Airway problems are the most common concern on emergence from anesthesia and immediately postoperatively. At the conclusion of the surgical procedure, the oropharynx is suctioned. Some anesthesia providers also suction the stomach. All monitors are left in place until the patient is fully awake and extubated.

Reversal with a narcotic antagonist such as naloxone (Narcan) may be used to reverse narcosis, but the drug also has the effect of reversing analgesia. Pain sensation may result in restlessness. The usual dose is 0.01 to 0.1 mg/kg for infants and older children.

Extubation of an infant or child is preceded and followed by oxygen administration and performed either with the patient under deep anesthesia or on return of spontaneous respiration. This is done because laryngospasm is possible between these periods. Heart and breath sounds are monitored after extubation. If spasm occurs, oxygen is given with positive pressure. Airway obstruction, aspiration, and hypothermia are hazards of the recovery period.

Children, particularly in the 2 to 5-year age-group, may develop hoarseness and a croupy cough after removal of an endotracheal tube. Racemic epinephrine (Vaponefrin) provides relief; 0.5 mL of 2.25% diluted in 3 mL of sterile water can be delivered through a facemask and nebulizer. Constant observation after extubation is necessary.

The patient should not be taken from the OR with a body temperature less than 95° F (35° C). If this temperature is below this crucial level, the risk for acidosis, hypoglycemia, bradycardia, hypotension, and apnea increases. This metabolic depression and delayed return of activity set the stage for possible sudden cardiac arrest.

Dehydration and low humidity increase the viscosity of secretions. Pediatric patients need close observation for development of laryngeal edema, which is noted by croupy cough, sobbing inspiration, intercostal retraction, tachypnea, or tachycardia. Laryngeal edema greatly reduces the small diameter of the airway of an infant or toddler. Controlled humidity and oxygen are vital.

Intraoperative Pediatric Patient Care Considerations

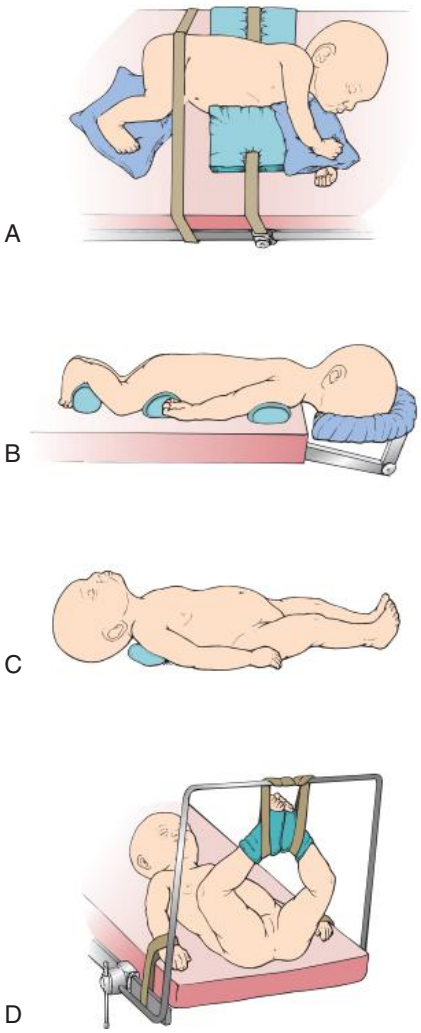
Basic principles of patient care and OR techniques used for adults apply to pediatric surgery; however, some additional

considerations are necessary in the plan of care. The room should be warmed to 78° F (25.5° C) to 85° F (29.4° C) based on age, before the pediatric patient is taken to the OR. Heat loss is a serious issue. A warmed blanket should be positioned on the OR bed as an undercover to prevent conduction of the child's body heat into the cooler mattress. A second warmed blanket should be placed over or around the child to prevent heat radiation into the room air. An appropriate-sized safety belt should be placed over the blanket so it is visible at all times.

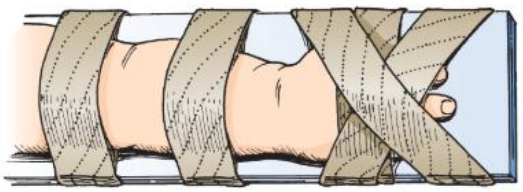
To differentiate this specialty from care of adult patients, a few points specific to pediatric surgery are mentioned as follows:

1. Hair is not removed with a depilatory or shaved, except for cranial procedures and as ordered by the surgeon for an adolescent. All hair removed should be saved and given to the parents. Some parents feel their child's hair is a keepsake.
2. Diagnostic studies may be done in the OR with the patient under local anesthesia before induction of general anesthesia for an open surgical procedure. An infant may be swaddled on a padded (papoose) board to restrain him or her from moving while x-rays are taken and to permit easy change of position. A pacifier helps comfort and keep the infant quiet. Pacifiers with built-in medication chambers to deliver sedation are commercially available.
3. The patient is protected from injury. An infant or child should never be left alone anywhere in the perioperative environment. Preparation for induction should be made before the child's arrival.
   a. Guard against a fall from a crib or stretcher. Side rails should remain up at all times. An over-bed cage or mesh crib cover on a crib helps confine a toddler without restraint. Children are restrained at all times while on a stretcher or in a specially designed pediatric cart.
   b. Do not place a crib where the patient can reach an electrical outlet or near any article that can be picked up and cause injury.
   c. After the infant is asleep, pad wrists and ankles with several layers of sheet wadding (Webril). Restrain with Kerlix or Kling roller gauze, and secure straps. Sheet wadding prevents possible abrasion of delicate skin by the restraint straps. Care is taken not to restrict circulation.
   d. Small objects are not left within reach of an infant or child.
4. Catheters as small as 6 Fr are available for use as needed in newborns and infants. A plain-tip or whistle-tip catheter is used for a stomach tube. An indwelling Foley catheter with a 3-mL balloon may be used for urinary drainage. Small calibrated drainage containers are connected to permit accurate determination of output.
5. Positioning principles are essentially the same as those described for adults. Fig. 8.5 depicts ideas for positioning small infants. The head of the table or foot section can be lowered to shorten the distance between the team and the patient's body.
   a. Correspondingly smaller pillows, gel pads, and beanbags are used to stabilize anesthetized infants and children. The size of the child or adolescent determines the appropriate supports to maintain the desired position.
   b. A small gel roll or positioning device at each side of the body takes the weight of drapes off the small body of an infant or keeps the patient in a lateral position.
6. Pediatric-sized drapes are preferred. A disposable drape sheet without a fenestration is sometimes used. The surgeon can cut an opening of the desired size to expose the site of intended incision. Keep in mind that the cut edges of nonwoven drape sheets may shed cellulose fibers into the surgical site that can cause inflammation and stimulate adhesion formation. The use of an adhesive plastic incise sheet over the cut edges before the tissue incision may help minimize fiber shed.

   Small towels and nonpiercing towel clips are used with a laparotomy sheet if self-adhering and disposable drapes are not available. A standard opening 3 × 5 inches (7.6 × 12.7 cm) in a pediatric laparotomy sheet is usually too large for a newborn or infant. Part of the fenestration may be covered with a towel. Consider the use of an eye fenestrated drape for tiny incisions.
7. Blood loss on sponges is measured by weighing them while they are still wet. Blood loss on the drapes is estimated, and blood loss through suction is measured. The surgeon and anesthesia provider determine whether blood replacement is necessary, volume for volume, as it is lost. The measurements are calculated in grams. The calculation is 1 g equals 1 mL of blood. Care is taken not to include the weight of the sponge container in the total gram weight. Discussion about weighing sponges is found in Chapter 31.



• **Fig. 8.5** Positioning of infant. (From Fortunato N, McCullough SM: *Perioperative nursing series: plastic and reconstructive surgery,* St. Louis, 1998, Mosby.)



• **Fig. 8.6** Upper extremity restraint to splint elbow and hand of infant or toddler. Hand is pronated on armboard.

8. Adhesive tape is abrasive to tender skin and should be avoided when possible. A chemical wound cover such as liquid adhesives or collodion is adequate over a small incision with a subcuticular closure and is especially desirable under diapers unless dressings are needed to absorb drainage. Care is taken that clothing or the blanket does not touch this substance until it is dry. Skin-closure strips may be used instead of a chemical wound cover.
9. Dressings on the face or neck should be protected from vomitus and food particles and from an infant's or toddler's hands. Elbows should be splinted when the patient potentially may disturb the incision, dressings, or a tube (Fig. 8.6). This is particularly important after eye surgery or cleft lip or palate surgery or when a tracheostomy tube is inserted.
10. A stockinette pulled over dressings on an extremity protects them from becoming soiled and helps keep them in place. This can be changed easily as needed, leaving the dressings in place.

Instrumentation

Gentleness and precision in handling small structures and fragile tissues are essential. Basic or standard instrument sets, sutures, needles, and other items used for surgical procedures on adults are duplicated in miniature for infants and children in each surgical specialty.

The perioperative nurse and surgical technologist should be informed about the patient and then use good judgment in preparing supplies for pediatric surgery. The following principles apply:

- Size and weight are more critical factors than age in the selection of instruments, sutures, needles, and equipment.
- Small instruments are used on the delicate tissues of a newborn, infant, or small child.
- Hemostats should have fine points. A mosquito hemostat clamps a superficial vessel but not a major artery.
- Noncrushing vascular clamps permit occlusion of major blood vessels. They also can be placed across the intestine of a newborn or infant rather than a large heavy intestinal clamp.
- Lightweight instruments do not inhibit respiration. Instruments not in use on tissues are never laid on the patient, especially not on the chest. An instrument's weight could restrict respiration or circulation or cause bruises. Return instruments to the Mayo stand or instrument table immediately after use.
- Umbilical tape or vessel loops are used frequently to retract blood vessels and small structures, thereby giving the surgeon greater visibility in a small surgical site and eliminating the weight of retractors.
- Needle holders have fine-pointed jaws to hold small, delicate needles.
- Surgical procedures on an adolescent necessitate adult-size instruments.
- The scrub person closely watches the tissue being dissected and selects the instruments to hand to the surgeon accordingly.

Common Surgical Procedures

General Surgery

Minimally Invasive Surgery

Gastroscopy, colonoscopy, and laparoscopy are performed for diagnosis of complaints of abdominal pain or symptoms of intestinal obstruction or inflammation. Hybrid ORs with advanced technology with three-dimensional imaging, high-definition screens, navigational systems, and single-port systems are being utilized in pediatric surgery.

The indications for pediatric endoscopic procedures are comparable to those for adults. There are no size or weight restrictions concerning a pediatric patient's suitability to have an endoscopic procedure. Contraindications to pediatric laparoscopy may include, but are not limited to, the following conditions:

- Dense abdominal adhesions
- Hepatosplenomegaly
- Hemodynamic instability
- Coagulopathy or hemorrhagic condition
- Large tumor resection
- Congenital abdominal or diaphragmatic hernia

Preparation of the pediatric patient for laparoscopy should include (1) emptying the bladder by catheterization with a Foley and (2) inserting a nasogastric tube. Small 0° and 30° telescopes are useful. Body size may indicate the use of specialized equipment for unconventional use, such as arthroscopic scopes because of shorter shafts and sheaths.

Keep in mind that the tissues of neonates and tiny infants may be unable to withstand the intraabdominal pressures or the use of steep Trendelenberg's position to displace the abdominal organs cephalad. The infant's chest is pliant and CO_2 pressure may significantly impair diaphragmatic movement and place strain on cardiac motion. The vena cava can be compressed, causing a decrease in preload and cardiac output. Procedures lasting more than 2 hours can cause a decrease in circulating blood volume causing metabolic acidosis. The anesthesia provider may need to use a tiny cuffed endotracheal tube to counteract the need for increased inspiratory pressures. This differs for conventional surgery, in which a noncuffed endotracheal tube is preferred under the age of 8 years.

Insufflated CO_2 for pneumoperitoneum causes a decreased lung capacity up to 30% to 50%.[2] The lung capacity decreases by an additional 20% if the neonate is placed in Trendelenburg's position. The peritoneal membrane is highly absorbent of carbon dioxide.[2] The thorax is more absorbent of the gas, and the risk for neurotoxicity is high during thoracoscopic procedures.

The potential for anomalous organ position should be considered with placement of trocars and sheaths. The liver and spleen are proportionately large and difficult to maneuver around, especially in neonates under 3 kg. The open laparoscopic method with a blunt trocar is preferred over the use of a Veress needle for creation of the working space. A risk of the procedure in neonates is creating an access portal near the umbilicus, as it may remain patent resulting in a gas embolus. CO_2 pressures should be kept low, at around 8 to 10 mm Hg, as tolerated until insufflation is complete. Although an open method is preferred for the primary trocar, sharp insertion of the secondary trocars may be performed with direct vision.

Potential for injury to nontarget organs is great. The bowel and adjacent organs are in close proximity and could inadvertently be injured by graspers or electrosurgical instruments. Small injuries can go unnoticed and result in subsequent postoperative bleeding or peritonitis. Renal blood flow can be impaired by increased intraabdominal pressure, causing a decrease in glomerular filtration and urine production. Many neonates and infants temporarily become oliguric or anuric during laparoscopy, and fluid maintenance should not be based on output calculations. Forcing excess fluids at this time could cause fluid overload.

Hypothermia is a serious concern because the CO_2 is cold. The use of heated CO_2 may help in maintaining body temperature. The gas and the light from the laparoscope could be drying to tissues. Gentle irrigation should be used during the procedure. All solutions used in irrigation should be warmed to body temperature and carefully measured for intake and output to prevent fluid overload.

Robotics

Robotics are useful for small spaces and are being used in more endoscopic procedures for pediatrics. The robot is very large compared to the size of the neonate or small child's body. Most instrumentation is made for 8-mm ports, which are too large for the pediatric patient. This increases the difficulty of team maneuverability in the sterile field. Positioning for robotic surgery may be dangerous for circulation and oxygenation for the child. Robotic companies are designing pediatric instrumentation and systems to accommodate pediatric surgical techniques.

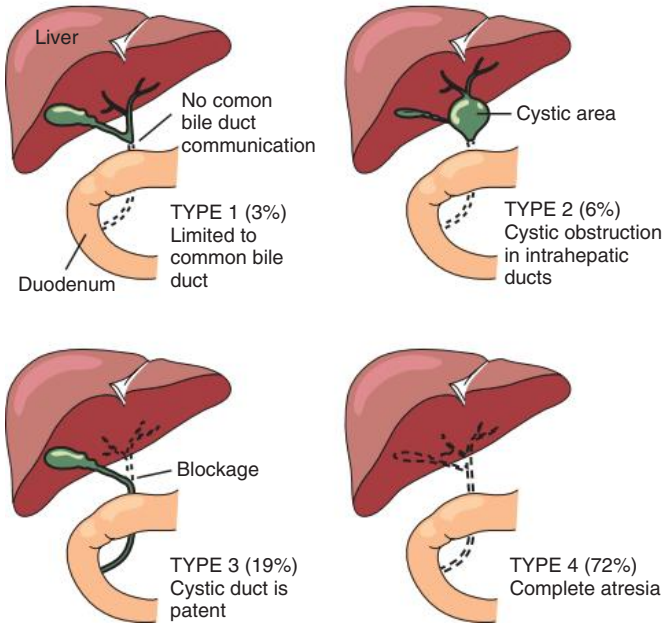
Emergent Procedures

Alimentary tract obstruction in a newborn or young infant is the most frequent cause for an emergency surgical procedure. The common sites of obstruction are in the esophagus, duodenum, ileum, colon, and anus. Atresia, an imperforation or closure of a normal opening, and stenosis, a constriction or narrowing, are the common causes of obstruction. Abnormal fistulae can develop between passages, such as in the tracheoesophageal area. The obstructive lesion is usually resected, and the viable segments of the visceral passages are anastomosed. A temporary or permanent gastrostomy, ileostomy, or colostomy may be necessary.

Intestinal obstruction can develop in infants and children months to years after the newborn period from a predisposing or associated congenital anomaly or acquired disease process. Inflammatory diseases, such as necrotizing enterocolitis, ulcerative colitis, Meckel's diverticulum, or Crohn's disease, and other intestinal conditions, such as Hirschsprung's disease or familial polyposis (Gardner's syndrome), require intestinal resection and anastomosis. An endorectal pull-through (also known as Duhamel's procedure) may be the procedure of choice to preserve the rectum.

Biliary Atresia

A form of intrauterine cholangitis that results in progressive fibrotic obliteration of bile ducts, biliary atresia may cause jaundice and **acholic** stool in the newborn. If untreated, this condition can cause cirrhosis and death within the first year of life. Excision of extrahepatic ducts or hilar dissection with a Kasai (hepaticoportoenterostomy) procedure, such as portal hepaticojejunostomy, is performed before the infant is 2 months old to relieve jaundice by improving bile drainage. If liver function becomes progressively impaired, liver transplantation may ultimately be necessary for survival (Fig. 8.7).



• **Fig. 8.7** Biliary atresia.

Esophageal Atresia

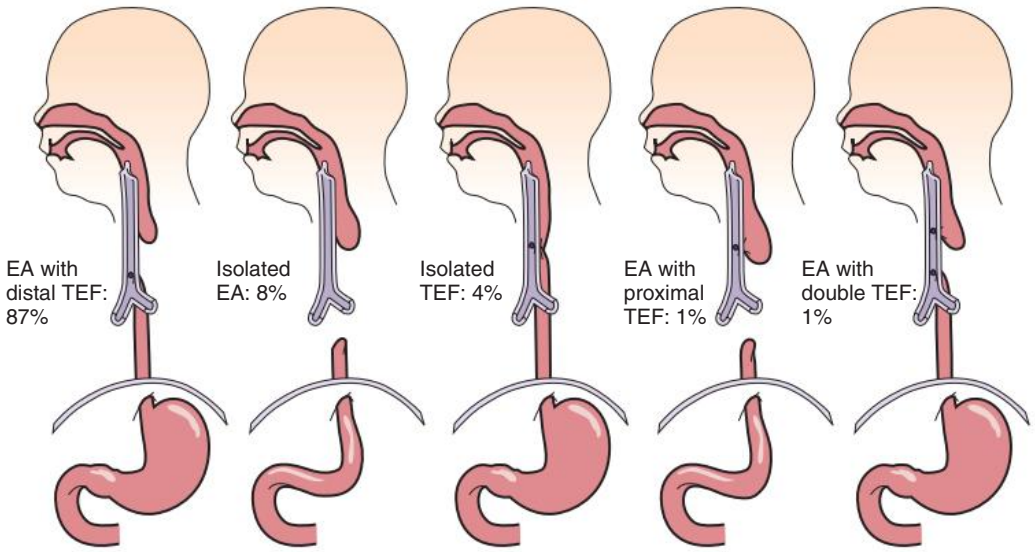
Esophageal atresia, with or without tracheoesophageal fistula, is an acute congenital anomaly characterized by esophageal obstruction, accumulation of secretions, gastric reflux, and respiratory complications (Fig. 8.8). The incidence is approximately 1 in 2500 live births and the presence of polyhydramnios. The goal of repair is to obtain an end-to-end esophageal anastomosis and closure of any tracheal fistula. The timing and technique to accomplish this goal depend on the specific type of anomaly, degree of prematurity, birthweight, and extent of other associated anomalies.

Repair may be either primary or staged. Gastrostomy (either open or endoscopic) is performed initially to establish a conduit for feeding the newborn weighing less than 1200 g. Percutaneous placement of the gastrostomy tube (percutaneous endoscopic gastrostomy [PEG] tube) is commonly performed (Fig. 8.9).

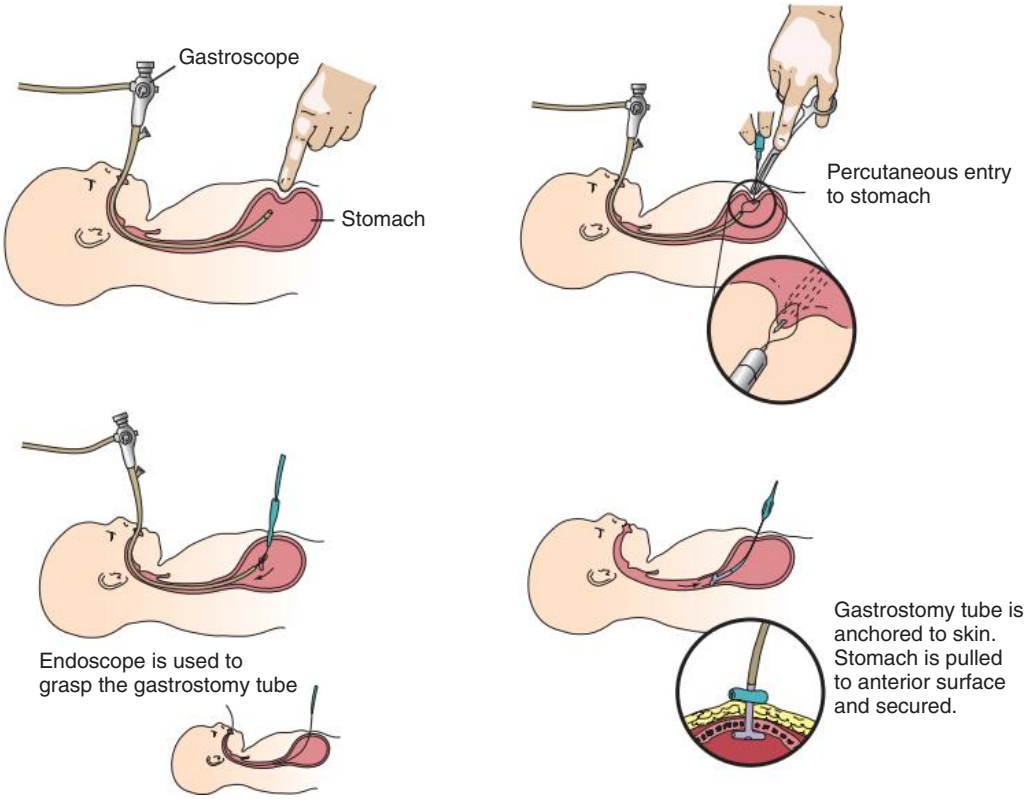
Open repair includes division of the tracheoesophageal fistula, if present, and anastomosis of the esophageal pouches. Submucosal myotomies and lengthening of the upper pouch permit primary anastomosis to establish alimentary tract continuity. This may be delayed to allow the esophagus to grow as the infant grows so that the gap between the pouches shortens. A transthoracic or retrosternal interposition colon graft may be necessary for esophageal replacement if the gap between the proximal and distal segments is too large for a primary esophageal anastomosis. Usually an extrapleural approach is used for these procedures.

Imperforate Anus

Anorectal malformation generally occurs during the 4th to 12th week of fetal development. The incidence of anal malformations is 1 in 4000 live births. More males have the condition than females. Imperforate anus (IA) is classified as high or low in relation to the levator muscles. Males have more high-level IA incidence and manifest fistulas between the colon and bladder. Females may have more low-level IA incidence with vestibular-vaginal fistulas but also can have a fusion of the anogenital tract referred to as a **cloaca**, a single opening for the urethra, rectum, and vagina.



• **Fig. 8.8** Esophageal atresia

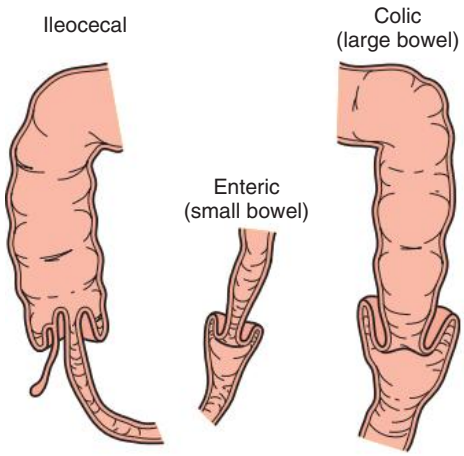


• **Fig. 8.9** Percutaneous endoscopic gastrostomy tube placement.

If the anus remains closed (i.e., imperforate) during fetal development, the intestinal tract is opened surgically soon after birth. A posterior sagittal anorectoplasty or an abdominoperineal pull-through procedure may be done for primary management with a temporary colostomy. Some children experience fecal incontinence or chronic constipation as they grow into their teens after repair procedures for high IA in infancy. Various secondary procedures are performed, most frequently an endorectal pull-through procedure or gracilis muscle transplant for reconstruction of the rectal sphincter.

Intussusception

Intussusception occurs when a portion of bowel slides into another segment and causes obstruction (Fig. 8.10). The most common site is the ileocolic junction. The motion is like a telescope. The ileum moves into the cecum. The ileum can twist causing **volvulus** (a twisted obstruction). The bowel becomes inflamed, hemorrhagic, and necrotic. Most cases are diagnosed between 5 months and 1 year, and the incidence ranges from 1 to 4 in 1000 live births. This is the most common surgical emergency for children younger than 2 years and occurs primarily in the spring



• **Fig. 8.10** Intussusception.

and fall months. The condition may be accompanied by Meckel's diverticulum.

Theories about the cause include lingering viral infection that causes inflammation of the lymph glands (Peyer's patch) in the lumen of the bowel that develop hypertrophied adhesions. These adhesions cause the bowel to stick together during peristaltic motion stimulated by digestion. Other theories indicate that when a baby is weaned from the bottle or breast and new foods are introduced into the diet, the digestive tract has not yet adjusted to the change. Intussusception occurs more frequently in males than in females.

The symptoms range from intense pain to nausea and vomiting. A sausage-shaped curve is sometimes apparent across the abdomen over the location of the intussusception. The baby may have bloody, jelly-like stool.

Treatment can range from hydrostatic reduction with a barium enema to open laparotomy through a right lower quadrant incision. Some surgeons use oxygen as a gas enema to insufflate the colon and small bowel (at the ileum) for intussusception less than 12 hours in duration and with no signs of obstruction or bleeding. The flow rate is maintained around 2 L/min without exceeding 80 mm Hg in pressure until fluoroscopy shows small bowel insufflation and its return to a natural anatomic position. Parents are advised to observe for signs of recurrence during convalescence. If open laparotomy is required, a transverse incision is made in the right lower quadrant and the overriding bowel is "milked" into the correct anatomic position. A cecopexy is done. If Meckel's diverticulum is present, it is resected. A patent **urachus** may be closed, and an appendectomy is also performed.

Pyloromyotomy

Pyloric stenosis is a congenital obstructive lesion in the pylorus of the stomach. The opening becomes hypertrophic and prevents food from entering the intestine. It occurs in 3 in 1000 live births. Symptoms include progressive vomiting after every meal. The onset of symptoms usually occurs between the third and eighth weeks of life and is more common in males. The stenosis is relieved with modified pyloromyotomy, also known as a Fredet-Ramstedt procedure. After the serosa is cut through, the muscle layers of the pylorus are divided. Pyloromyotomy can be performed endoscopically. Feeding in small amounts can resume 8 to 10 hours postoperatively.

Herniorrhaphy

Herniorrhaphy (i.e., hernia repair) is the most frequently performed elective surgical procedure in infants and children by general surgeons. Of the four types of hernias seen in pediatric patients, indirect inguinal hernia is the most common; it occurs much more frequently in male patients than in female patients and appears during the first 10 years of life. Inguinal hernia is found in 1 in 3% of all live births. Female patients who have an inguinal hernia also may have a prolapsed ovary in the hernia sac.

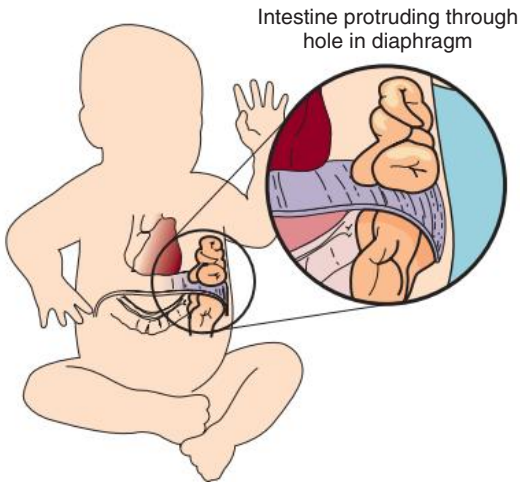
A risk of an untreated hernia is migration of bowel loops into the hernia sac. If bowel enters the sac, it can become twisted and incarcerated (i.e., entrapped). The first line of treatment is to reduce the bowel back into the abdomen. If the loop reincarcerates, surgery is performed as an urgent procedure. Strangulated bowel can become ischemic and necrotic, causing peritonitis and sepsis. The child will be in extreme pain.

Male pediatric patients with an inguinal hernia may also have a hydrocele. A hydrocele is more common on the right side and is a collection of fluid between the layers of the tunica vaginalis that extends into the scrotum. Diagnosis can be made by transillumination of the scrotum with a flashlight and confirmed by ultrasound. Some hydroceles resolve without surgical intervention by age 2 years. Aspiration of the fluid should not be attempted. Hydroceles that accompany hernias can be surgically repaired at the same time as the herniorrhaphy procedure. Laparoscopy can be used to repair the hernia and permits the surgeon to inspect the **contralateral** inguinal ring for potential hernia. Postoperatively the child can resume normal activity as tolerated without restrictions.

Although frequently seen, most umbilical hernias do not always need surgical intervention. Femoral hernias need surgical correction but are rarely acute problems in childhood.

A hiatal hernia is a surgical emergency in the newborn if abdominal contents are in the chest and cause acute respiratory distress (Fig. 8.11). Diaphragmatic hernias in infants and children are caused by congenital weakness in the fascia, abdominal wall, or diaphragm. They are more common in males and manifest by respiratory distress and cyanosis within a few minutes to hours after birth.

Diaphragmatic hernias are more common in the left chest, and x-rays show the intestines in the chest. If the defect is large, the liver or spleen may be shifted cephalad. Pulmonary hypertension



• **Fig. 8.11** Diaphragmatic hernia.

caused by poor lung development is usually present. The patient should be immediately intubated and a nasogastric tube inserted to decompress the bowel. ECMO can be used. The surgical approach is abdominal, and the repair is made with mesh. Unfortunately, prenatal diagnosis before 25 weeks offers little hope because the mortality rate is close to 60% despite the best care.

Advances with intrauterine fetal surgery have allowed surgeons to correct birth defects that would normally lead to physical disabilities or death. The first intrauterine fetal surgery took place in 1981 at the University of California at San Francisco to correct a urinary obstruction. More facilities are offering this option. Criteria for the procedure include (1) no risk to the life of the mother or her future reproductive capacity, (2) tocolytic treatment to forestall labor postoperatively, and (3) the premise that no other treatment is an option. If the hernia involves the liver and partial resection, the risk to the umbilical circulation could cause fetal demise.

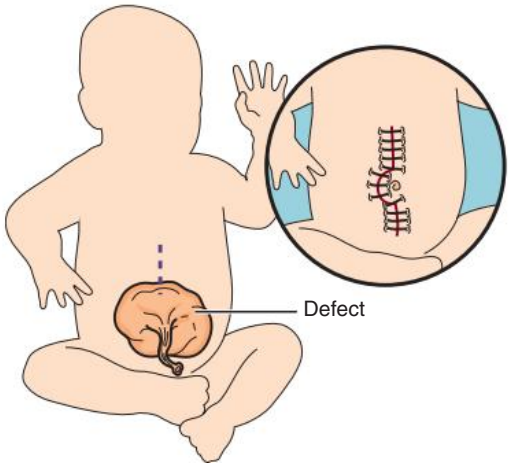
Two types of congenital diaphragmatic hernias are possible based on the location of the defect. The Bochdalek hernia is the most common. It is located in the posterolateral aspect of the diaphragm. The Morgagni hernia is a retrosternal defect.

Other correctable surgical procedures include urinary tract obstruction, myelomeningocele (spina bifida), sacrococcygeal teratoma, and twin-to-twin transfusion syndrome. More information about intrauterine fetal surgery can be found in Chapter 34 of the text.

Omphalocele and Gastroschisis

Failure of abdominal viscera to become encapsulated within the peritoneal cavity during fetal development results in herniation through a 4 to 10-cm defect in the abdominal wall at the right paraumbilical area (Fig. 8.12). The intestines, liver, and spleen can be within the sac. The sac containing the protruding organs consists of chorion, Wharton's jelly, and peritoneum. The normal size of the intraabdominal cavity is reduced because the organs have been displaced from within. Surgical repair is done in stages to allow the abdominal cavity to accommodate the placement of the organs.

Diagnosis is usually made with ultrasound before the 20th week of pregnancy. If routine prenatal blood work shows an elevated alpha-fetoprotein (AFP) level, a transvaginal ultrasound may reveal the condition as early as 12 weeks' gestation. When the condition is discovered the physician usually performs echocardiography and genetic studies to rule out heart or inherited problems, including genitourinary defects. Plans are made for preterm surgical delivery between 37 and 38 weeks' gestation.



• **Fig. 8.12** Omphalocele.

The contents of the sac are surgically reduced back into the peritoneal cavity. The method of closure depends on the extent of the defect. Skin may be closed primarily if the defect is small. More commonly, primary closure of the abdominal wall is facilitated by tissue expanders in the abdominal wall and reduction of organs from the sac. Closure is performed without undue tension or compartment syndrome can develop. Synthetic mesh or sheeting may be used.

For large defects, closure of the abdominal wall usually is staged over a period of weeks or months, with implantation of a silicone silo or tissue expansion prosthesis to reduce intestines at the first stage, followed by removal of the device and abdominal wall closure at the second stage. Fluid management and temperature regulation are important because the exposed viscera can dry out and become cool, thus lowering the infant's body temperature. The bowel was exposed to amniotic fluid in utero, which caused tissue damage and loss of peristalsis. Other defects may be present, such as intestinal atresia. Nutritional status is supported parenterally, and an ostomy may be necessary for elimination. Necrotizing enterocolitis requires bowel resection.

Appendectomy

Appendicitis, an acute inflammation of the appendix, is the most common cause for an abdominal surgical procedure in the child aged 5 to 10 years. Appendectomy may be performed with laparoscopy or open laparotomy. Appendectomy was one of the earliest procedures performed endoscopically on pediatric patients.

Gangrene or rupture may occur before diagnosis or surgical intervention. A questionable diagnosis may be confirmed or ruled out with laparoscopy. Endoscopic approaches are associated with fewer postoperative complications, such as paralytic ileus and wound infection, except in the case of a ruptured appendix.

Splenectomy

Removal of the spleen may be indicated to correct hypersplenic disease, either congenital or acquired. Emergency splenectomy is necessary after rupture of the spleen, usually from blunt trauma. An attempt is made to salvage as much of the organ as possible to minimize future susceptibility to infection.

Bezoars

Intestinal obstruction can be caused by ingested matter that forms a foreign body and accumulates in the stomach, possibly even extending into the small bowel. The foreign body consists of hair (tricho-), vegetable matter (phyto-), or milk curd (lacto-) and is commonly associated with strange appetite compulsions (trichophagia) and emotional disturbances. Removal can be done endoscopically with hydrodissection or with open laparotomy. Shockwave therapy is sometimes successful in fragmenting the bezoar mass for endoscopic removal.

Genitourinary Surgery

Pediatric urology basically concerns the diagnosis and treatment of infections and congenital anomalies within the genitourinary tract. Some type of anomaly of the genitourinary system may be found in 10% to 15% of newborns. Secondary infections are frequently associated with congenital anomalies; chronic diseases

are frequently associated with infections. Pediatric and adolescent gynecology is discussed in Chapter 34. The following surgical procedures include those most commonly performed by pediatric urologists.

Cystoscopy

Diagnostic evaluation and therapeutic removal of obstructions within the structures of the genitourinary tract may be performed through an infant-size or child-size cystoscope. Cystoscopes from 9.5 Fr through 16 Fr are used for infants and children. A 3-Fr ureteral catheter can be introduced through the smallest cystoscope. Hypothermia can occur when the sterile water used to expand the bladder is cooler than body temperature.

Nephrectomy, Nephrostomy, or Pyeloureteroplasty

Hydronephrosis, congenital or acquired, may necessitate surgical intervention. Nephrectomy is indicated only if severe disease is unilateral, with a contralateral kidney capable of life-sustaining function. More conservative nephrostomy or pyeloureteroplasty is indicated for bilateral or moderate to mild kidney disease.

Wilms' Tumor

Wilms' tumor is a malignant solid renal tumor that develops rapidly in a child usually younger than 5 years. Nephrectomy is necessary to resect the tumor. If the adrenal gland is intimately connected to the tumor in the upper pole of the kidney, the gland is resected en bloc with the renal mass. Vascular extension of the tumor into the suprahepatic vena cava may necessitate a cardiopulmonary bypass to ligate all tumor vessels. **Ipsilateral** periaortic lymph node dissection often is performed to stage the extension of cancerous cells.

Neurogenic Bladder

Defective bladder function may be a result of a central nervous system lesion such as a myelomeningocele or spinal cord trauma. For preservation of renal function and achievement of urinary continence in the presence of a neurogenic bladder, an enterocystoplasty may be performed. This procedure retains an intact urinary tract. An artificial urinary sphincter can be implanted to achieve dryness in the child who has sufficient dexterity to operate the pump.

Exstrophy of the Bladder

In exstrophy of the bladder, a congenital anomaly, the bladder herniates through the lower abdominal wall in the suprapubic region. Repair requires reconstruction of the lower abdominal wall and external genitalia, which usually can be accomplished in one surgical procedure on a female infant but requires two or more staged procedures on a male infant. A gastrocystoplasty may be the procedure of choice. If urinary continence cannot be established, urinary diversion through ureteral reimplantation may become necessary.

Ureteral Reimplantation

Repositioning the ureters (i.e., ureteral reimplantation) may be performed to correct either congenital or acquired total urinary incontinence or vesicoureteral reflux.

Incontinence causes parents to seek help for an infant or child. Incontinence is usually not caused by a single factor. The urologist plans the procedure on the basis of an accurate assessment of anatomic and physiologic causes. Creation of a tubularized trigonal muscle, when reconstructed into a new bladder neck, acts as a sphincter to maintain continence. With ureters in the normal position, this muscular tube in the bladder wall cannot be constructed. Therefore the ureters are reimplanted superiorly into the bladder through a created tunnel. Care is taken that the ureters are not hooked or angled but follow a smooth curve into the bladder.

Vesicoureteral reflux is the most common reason for reimplantation of ureters in pediatric patients.

Chronic reflux, regurgitation of urine from the bladder into the ureters, can lead to pyelonephritis and hydronephrosis. Ureteral reimplantation may be necessary to prevent kidney damage. The objective of the surgical procedure is to position a segment of the ureters at a higher level within the bladder wall so the level of urine is below the orifices and intravesical pressure prevents reflux.

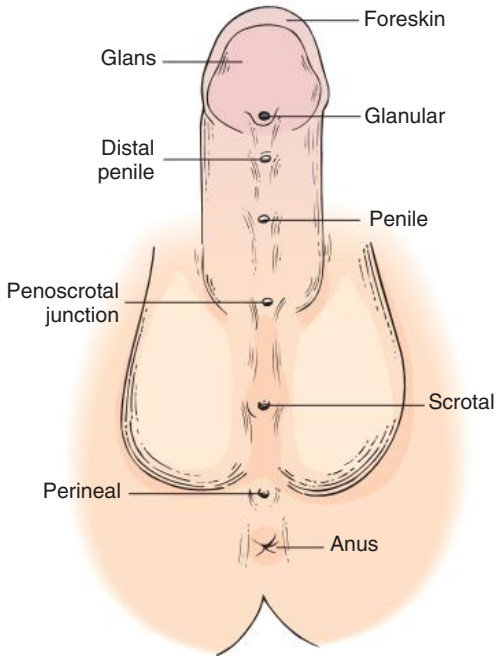
When ureters cannot be reimplanted in the bladder, a urinary diversion procedure may be necessary. Ureters are usually anastomosed to a nonrefluxing colon conduit.

Urethral Repair

The external opening (meatus) of the urethra may be displaced at birth. Hypospadias is an anomaly in the male in which the urethra terminates on the underside of the penis or on the perineum (Fig. 8.13); in the female with hypospadias the urethra opens into the vagina. With epispadias in the male the urethra terminates on the dorsum of the penis; in the female it terminates above the clitoris. Hypospadias has a familial association and occurs in approximately 1 in 250 newborn males.

Multistage procedures are usually necessary to correct these anomalies. The goal is to center the meatus at the tip of the glans penis of the male. This may be accomplished in a one-stage procedure with a transverse island flap derived from prepuce or with a vertical-incision/horizontal-closure technique for distal coronal or subglandular hypospadias.

Some surgeons use androgen treatment briefly preoperatively to cause enlargement of the penis to facilitate handling during the procedure. The androgens are discontinued after the procedure and have no known lasting adverse effects. Tissue grafts from the



• **Fig. 8.13** Meatal opening in hypospadias.

inner mouth mucosa can be used to span structural gaps. Oral mucosa grafts well in the moist environment of the urethra.

Females with meatal anomalies may need multistage procedures to approximate normal anatomic position. In addition to general anesthesia, a caudal or epidural is commonly used to manage postoperative pain. A Foley catheter is used for several days to a week. This procedure is usually performed between ages 6 and 12 months.

Orchiopexy

One or both testicles that failed to descend down the inguinal canal during fetal development can be brought into the scrotum and stabilized with a traction suture until healing takes place before the age of 2 years. Upon abdominal exploration the testes can be located along a pathway between the inguinal ring and the hilum of the kidney. Most undescended testes are on the right side; however, 25% of cases can be bilateral. The most important consideration is to reposition the testicles before the Leydig cells degenerate. The risk for seminoma in undescended testes is higher in these patients than other males in the population. Although malignancy is uncommon, it is the highest form of cancer in the 15 to 35-year age range. **Cryptorchidism** (undescended testicles) may be present in males with hypospadias.

In the two-stage Torek operation the testicle and supporting structures are dissected free from the inguinal region. An adequate length of spermatic vessels is released to permit the testicle to reach the scrotal sac. After it is pulled down through the scrotum, the testicle is sutured to fascia of the thigh. At the second-stage procedure, 2 to 3 months later, the testicle is freed from the fascia and embedded into the scrotum.

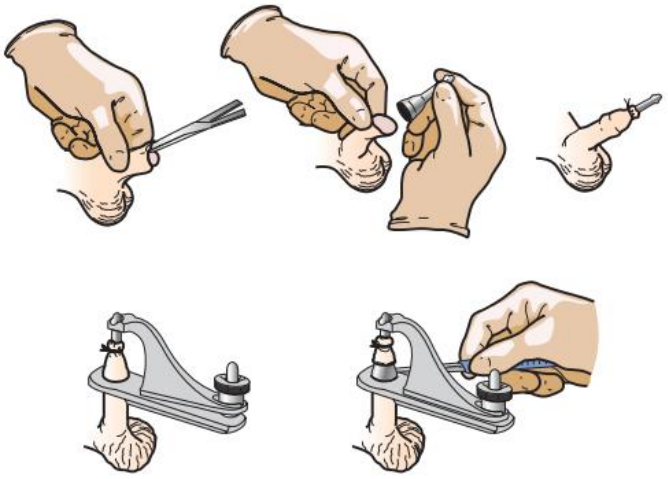
If one or both testicles are absent, silicone prostheses may be inserted into the scrotum for cosmetic appearance. Psychologically for the child and parents, absence (agenesis) of testicles is cosmetically repaired at age 5 or 6 years, before the boy begins school.

Circumcision

Excision of the foreskin of the penis (circumcision) may be done to prevent phimosis, in which the foreskin becomes tightly wrapped around the tip of the glans penis, or to remove redundant foreskin. Complications can ensue if the phimotic foreskin strangulates around the erect penis.

Circumcision is the most commonly performed pediatric surgical procedure but is not necessary in all male babies. Some physicians perform the procedure on newborns without anesthetic. Local anesthesia without epinephrine additive can be safely used to avoid pain and discomfort during the procedure (Fig. 8.14).

Circumcision, as an elective procedure, is contraindicated if an abnormality of the glans penis or urethral meatus is present. Urethral repair can require the use of foreskin tissue as graft tissue.



• **Fig. 8.14** Circumcision.

Orthopedic and Spinal Surgery

Pediatric orthopedic surgery is principally elective and reconstructive for correction of deformities of the musculoskeletal system. These deformities may be congenital, idiopathic, pathologic, or traumatic. Traumatic injuries do not always manifest on conventional x-ray. Magnetic resonance imaging is used to disclose injuries that could be missed. The extent of the anomalies and functional disorders often involves prolonged immobilization and hospitalization. Many patients need a series of corrective procedures.

Some of the conditions most commonly seen in the OR include those discussed in the following sections.

Fractures

Fractures that occur in infants and children generally are treated as they are in adults. Fixation devices are not well tolerated by children and often prevent uniting of the fracture. Closed reduction of long-bone fractures is preferable.

Tendon Repair

Tendons may be lengthened, shortened, or transferred to correct congenital deformities of the hand or foot. Lacerated tendons are repaired to restore function. A tourniquet is used to control bleeding. The tourniquet cuff size should be appropriate for the size of the infant or child. Padding under the cuff is applied smoothly. Sheet wadding may be used under an infant cuff to protect delicate skin. The cuff should be tight but should not restrict circulation before inflation. The time of inflation is closely watched to prevent ischemia. The surgeon may ask the circulating nurse to release the pressure every 30 minutes on an infant or up to every 1 to 2 hours for an older child, depending on age. Tendon procedures are often lengthy.

Congenital Dislocated Hip

Displacement (dysplasia) of the femoral head from its normal position in the acetabulum can be present at birth, either unilaterally or bilaterally. If dysplasia is diagnosed early in infancy, closed reduction with immobilization usually corrects the dislocation without residual deformity (Fig. 8.15). If dysplasia is not diagnosed until after the child has begun to walk, open reduction of the hip with an osteotomy to stabilize the joint may be necessary.

• **Fig. 8.15** Hip abduction splint for congenital dislocation of the hip.

Leg Length Discrepancies

The epiphyseal cartilaginous growth lines progressively close as the child matures. Bones lengthen from the activity of the epiphyses. The absolute physiologic criterion for completion of childhood is when this cartilage becomes a part of bone. A discrepancy in activity of an epiphyseal line may retard or overstimulate growth of a bone in one extremity and not in its contralateral counterpart. When this occurs in one femur, legs become unequal in length.

The orthopedic surgeon may correct leg length discrepancies, usually in excess of 1 inch (2.5 cm), with epiphyseal arrest (i.e., stopping growth of the bone). This is done in the contralateral leg to let the shorter extremity catch up. The longer leg may be shortened with a closed intramedullary procedure. With use of fluoroscopy, a reamer is inserted into the medullary canal of the femur through a small incision high on the hip. After the reamer widens the canal, a rotating saw is manipulated to cut a section from the bone. The bone ends are aligned and fixed with a flexible intramedullary rod.

Slipping of the upper femoral epiphysis causes displacement of the femoral head, which can occur as a result of traumatic injury or as a chronic disability usually seen in obese adolescents. Fusion of the epiphysis to the femoral neck may be necessary to prevent slipping and shortening of the leg.

Many limb deformities in children are a complex combination of angulation and shortening as a result of trauma, infection, metabolic bone disease, congenital deformity, and developmental problems. The Ilizarov external fixator technique provides an alternative treatment option. Thin strong wires are transfixed through bones and attached to rings under tension. The rings, which encircle a leg or arm, are held firmly in place with threaded rods. Bolts on the rods are turned several times a day to pull cut ends of bone apart. Corticotomy, performed through a small skin incision after wires are inserted, preserves periosteal and endosteal blood supply to bone. This promotes rapid healing to regenerate new bone that fills in the gap.

Talipes Deformities

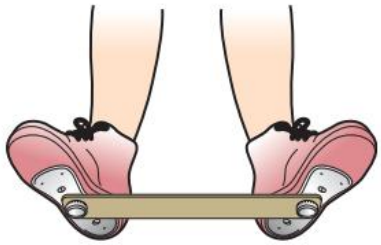
Combinations of various types of deformities of the foot, especially those of congenital origin, are referred to as *talipes;* the addition of the medical term is used to describe whether the forefoot is inverted (varus) or everted (valgus) and whether the calcaneal tendon is shortened or lengthened.

Talipes Varus

Talipes varus, known as clubfoot, is the most common of the talipes deformities; it may be unilateral or bilateral. The forefoot is inverted and rotated, accompanied by shortening of the calcaneal tendon and contracture of the plantar fascia. Conservative treatment with casting or a brace during infancy usually corrects a mild postural deformity before the infant bears weight on the foot (Fig. 8.16). A wedge cast with turnbuckles may be applied to an older child to allow gradual manipulation. If conservative treatment is unsuccessful, an open surgical procedure may be necessary.

Talipes Equinovarus

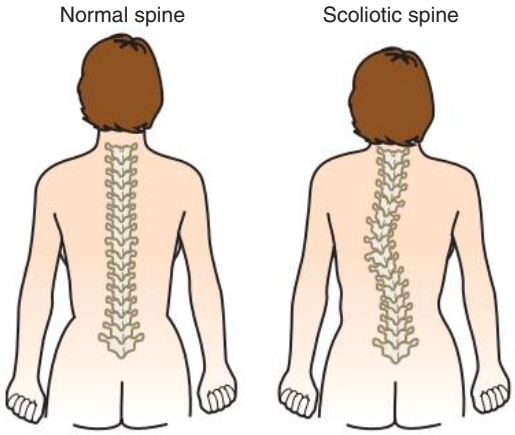
Talipes equinovarus, an idiopathic true clubfoot deformity, almost always necessitates surgical intervention for correction. In varying degrees, talipes equinovarus includes an incomplete dislocation (subluxation) of the talocalcaneonavicular joint with deformed talus and calcaneus bones, a shortened calcaneal tendon, and soft tissue contractures. As a result the forefoot curls toward the heel (adduction, supination), the midfoot points downward (equinus), and the hindfoot turns inward (varus). The orthopedic surgeon uses a sequential-release approach to obtain maximum correction of all contractures and realigns bones in the ankle joint. Pins are inserted, and the extremity is put in a cast to maintain alignment of the foot and ankle.



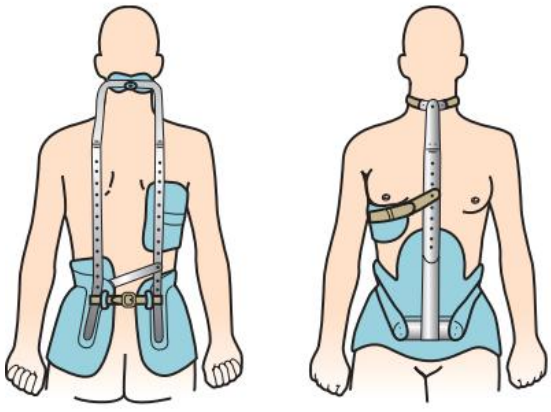
• **Fig. 8.16** Denis Browne splint for clubfoot deformity.

Scoliosis

Scoliosis is a lateral curvature and rotation of the spine, most frequently seen in rapidly growing school-age (older than 10 years) or adolescent females (Fig. 8.17). Treatment depends on the degree and flexibility of the curvature, chronologic and skeletal age of the child, and preference of the surgeon. The child may be fitted with a Milwaukee brace (Fig. 8.18), immobilized



• **Fig. 8.17** Scoliosis.



• **Fig. 8.18** Milwaukee brace for scoliosis.

in a cast, or stretched with traction. As an alternative to these techniques, an electrical device may be applied with an underarm brace to stimulate muscle contraction on the convex side of the curvature.

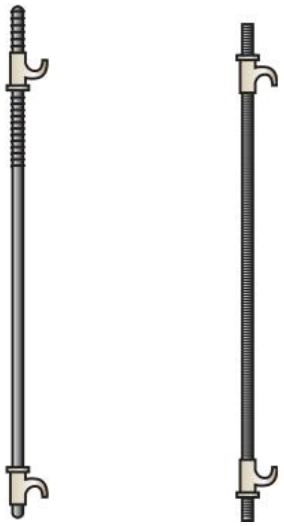
If untreated at an early stage, scoliosis produces secondary changes in vertebral bodies and in the rib cage. Spinal fusion is ultimately performed if the curvature has become severe (40% or more) or must be stabilized after corrections. Government-mandated screening programs in schools have reduced the need for surgical correction in many children. Two surgical techniques using technology that grows with the child are being used for early-onset scoliosis, along with other minimally invasive techniques.[3] Surgical correction for scoliosis is described in Chapter 38.

The following procedures are examples of treatments used for the correction of scoliosis:

1. A wedge body jacket or Minerva jacket may be applied. Turnbuckles may be incorporated. Turnbuckles are adjustable metal rods placed along the edges of the wedge of the cast. Gradual opening of the turnbuckles by the surgeon as tolerated by the patient corrects the lateral curvature of the spine.
2. A Sayre sling, an appliance used for head traction, is sometimes used when applying a body jacket to correct slight scoliosis. Traction is obtained by means of pulleys and a rope suspended from the ceiling or an arm of the fracture table.
3. Halo traction is used to stretch the spine in some patients in whom the spine is too rigid to be straightened in a cast. A metal band is applied to the skull by means of four pins inserted into the cortex of the skull. A Steinmann pin is inserted into the distal end of each femur. A traction bow is put on each pin. Weights, usually equal, are put on the halo and Steinmann pins and gradually increased as tolerated. When x-rays show maximum correction, a spinal fusion is done. Traction may be continued until healing has taken place to the degree that there will be no loss of correction; a plaster jacket is then applied.
4. A Risser jacket is applied a few days before posterior spinal fusion to gain as much correction as possible. The orthopedic table is used. Traction is applied with a chin strap, similar to a Sayre sling, and countertraction is applied with a pelvic girdle. The spine is straightened as much as possible, and the body and head are encased in plaster.

   Posterior spinal fusion may be performed as a two-stage procedure: vertebral body wedge resection at the first stage and insertion of Cotrel-Dubousset or Harrington rods (Fig. 8.19) with fusion at the second stage. Bone fragments removed during the first stage may be saved for the second-stage fusion or sent to the bone bank. Rods and hooks are stainless steel; appropriate instruments are needed to insert them. Two rods are inserted, one on either side of the curvature. These rods are secured to the spine and force it into a more nearly normal position. Implanted on the outside of the vertebral column, the rods apply a longitudinal force on the spine. The spine is then fused.

   The procedure may be done through a window in the Risser jacket, but usually the cast is bivalved and the patient lies in the anterior section. If the procedure is done through a window, an electric cast cutter should be at hand to bivalve the cast if the patient has any respiratory difficulties. After the procedure, the bivalved posterior part is put in place and the jacket is fastened together with several rounds of plaster or with webbing straps with buckles. The patient is in the Risser jacket for a year. Progress is checked with x-rays.



• **Fig. 8.19** Harrington rods.

5. Segmental spinal fixation with Luque rods may be the procedure of choice to stabilize the spine after fusion. Two L-shaped rods are placed next to the spinous processes and held by wires threaded under the lamina of each vertebra to be fused. Transverse traction internally on each vertebra stabilizes the spine without the need for a postoperative cast.
6. Anterior spinal fusion through a transthoracic approach is performed as a one-stage procedure to correct severe curvatures in patients who have malformed vertebral bodies. With Dwyer instruments, titanium staples are fitted over vertebral bodies on the convex side of the curve. Each staple is held in place by two titanium screws. A multistrand titanium cable, threaded through the heads of the screws, is tightened to compress the vertebrae and straighten the curve. Staples and screws are secured the full extent of the curvature. A plaster body jacket may be applied after the procedure to immobilize the back until the fusion is healed. The patient is then ambulatory.

Ophthalmologic Surgery

Congenital Obstruction of the Nasolacrimal Duct

An obstruction, usually at the lower end of the nasolacrimal duct that enters the inferior meatus of the nose, often results in dilation and infection of the lacrimal sac. Treatment consists of passing a malleable probe from the lid punctum through the nasolacrimal passages to push out the obstructing plug of tissue.

Oculoplastic Procedures on the Eyelids

Congenital malformations such as ptosis (drooping of the upper or lower eyelid) are corrected with extraocular procedures. Ptosis repair is indicated when the levator is inadequate. In the levator resection procedure, which shortens the muscle and gives a more physiologic result, the levator muscle may be approached through the skin (Berke method) or the conjunctiva (Iliff method). A fascial sling procedure to support the lid consists of attaching the upper lid margin to the frontalis muscle. Materials used include autogenous fascia from the thigh, homograft fascia, and synthetic nonabsorbable suture material. The Fasanella-Servat operation is a simpler procedure for obtaining only a small amount of lid elevation.

Extraocular Muscle Procedures

Surgical procedures on extraocular muscles to correct strabismus or squint are the third most commonly performed pediatric procedures on patients between ages 6 months and 6 years. The trend is to correct the congenital type during infancy and the acquired type in preschool years. Patterns of using two eyes together are more flexible and adaptable in a young child.

These procedures on extraocular muscles are done to correct muscle imbalance and promote coordination either by strengthening a weak muscle or by weakening an overactive one. The mechanical strength of a weak muscle can be increased by the following factors:

- *Tucking:* A tuck is sutured in the muscle to shorten it, thereby increasing its effective power.
- *Advancement:* The attachment point of the muscle is freed and reattached closer to the cornea, thereby increasing its leverage.
- *Resection:* Part of the muscle is removed to shorten it, and cut ends are sutured together.

An overactive muscle can be weakened by the following factors:

- *Tenotomy:* The point of attachment of the muscle is severed, and the muscle is dropped back, held by ligaments only.
- *Recession:* The muscle is detached from the eyeball and reattached farther back to decrease its action.
- *Myotomy:* The fibers of a section of the muscle are divided to diminish muscle action.
- *Myectomy:* A section of the muscle belly is excised.
- *The Faden procedure:* The muscle belly is sutured to the posterior sclera, thereby restricting muscle action considerably, producing a super-weakening effect.

Congenital Cataract Extraction

Under the operating microscope, with use of irrigation-aspiration and cutting instruments, the cataract and often the posterior capsule and a portion of the anterior vitreous are removed at one time. This procedure obtains a clear optical zone so that a contact lens can be fitted on the infant's eye within a few days postoperatively. The goal is to avoid intractable amblyopia (lazy eye) by correcting the defect during the first few weeks of life. An intraocular lens may be implanted. More commonly, epikeratophakia is performed to reshape the cornea.

Keratoplasty may be performed on children with Fuchs' dystrophy. The corneal endothelial cells degenerate, causing reduction in vision and corneal edema. The cornea is removed and replaced with a donor corneal graft.[4]

Goniotomy

Although congenital glaucoma is rare, early surgical intervention is urgent to prevent blindness. Goniotomy is a microsurgical procedure that involves dividing a congenital layer of abnormal tissue that covers the drainage angle of the anterior chamber. It is performed with use of a special operative contact lens placed on the eye that permits visualization of the angle. An incision is made through an opening in the contact lens.

Otorhinolaryngologic Surgery

Foreign Body Removal

Although often instructed not to put objects in their mouths, children continue to do so. They often swallow small objects or insert them into the nose or ears. Foreign objects placed in the nose can be removed using a pediatric nasal speculum and bayonet forceps. Care is taken not to advance the object further into the cavity. Many small swallowed items can be allowed to pass naturally through the gastrointestinal tract. The child is carefully observed for signs of pain, abdominal distention, constipation, or lack of appetite that could signal bowel obstruction. Prompt evaluation at a medical facility is necessary.

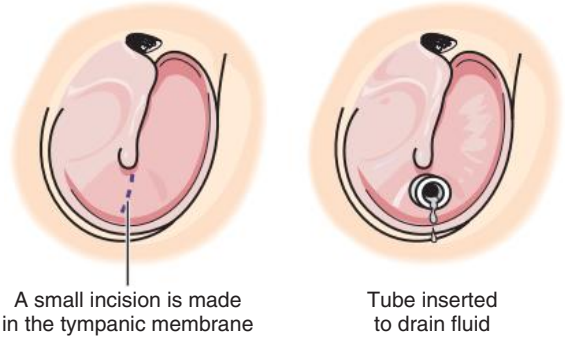
Aspiration of tiny parts of toys is a common occurrence. It is possible to cough or sneeze when holding an item in the mouth and cause it to be inhaled into the bronchus of the lung. Emergent rigid bronchoscopy under general anesthesia is necessary for removal. The object usually enters the right main bronchus because it is straighter than the left and is a direct line from the trachea.

Larger objects, such as coins, can become lodged in the esophagus or trachea. An x-ray or fluoroscope can confirm the size and location of the item. One technique for removal utilizes a small 12 to 14-Fr Foley catheter inserted in the passage past the occluding item. The retention balloon is inflated distally and slowly drawn toward the mouth. The balloon can elevate the foreign object to a point at which it can be grasped with forceps. Other instrumentation, such as stone basket snares from urology can be useful.

Ingestion of coin-sized batteries or multiple magnets can cause serious damage if not removed promptly. Batteries can degrade and discharge their contents, causing necrosis or poisoning. Magnets can cause bowel obstruction by attracting each other internally. Loops of bowel can twist in response to the magnetism, causing ischemia and necrosis. Multiple magnets can stack internally and appear as one piece on x-ray, then later separate and disperse. Deaths have been reported in the literature. Use of stainless steel instruments can complicate removal because they may increase the magnetic attraction. Titanium, plastic, or nonferrous instruments are useful because they do not have magnetic properties. Removal by endoscopy can be difficult. Exploratory laparotomy may be necessary, especially if multiple magnets have been swallowed.[4] A single magnet may pass from the body naturally, and patients are advised to avoid wearing apparel with metallic buttons, zippers, studs, or buckles that might cause the magnet to stop moving toward the rectum. Serial x-rays are commonly performed to monitor progress.

Myringotomy

Secretory otitis media is the most common chronic condition of childhood. Fluid accumulates in the middle ear from eustachian tube obstruction. This condition is corrected with myringotomy, an incision in the tympanic membrane (eardrum) for drainage (Fig. 8.20). Through aspiration of fluid and pus, pressure is released, pain is relieved, and hearing is restored and preserved.



• **Fig. 8.20** Myringotomy with perieustachian tube.

Myringotomy is done to prevent perforation of the eardrum and possible erosion of middle ear ossicles. When exudate is especially viscid, the patient has "glue ear," or mucoid otitis media.

Tympanostomy is commonly performed bilaterally in association with myringotomy. A self-cleaning, plastic pressure-equalizing tube is placed through an incision in the tympanic membrane, bypassing the eustachian tube, to facilitate aeration of the middle ear space and prevent reformation of serous otitis media. The tube usually extrudes spontaneously. Premature extrusion before normal eustachian tube function resumes may necessitate replacement of the tube.

Middle Ear Tympanoplasty

Congenital fused ossicles in the middle ear often are associated with stenosis or absence of an external auditory canal. Depending on the deformity, tympanoplasty may be performed with a temporalis fascia graft. If mobilization or ossiculoplasty is impossible, a total or partial ossicular prosthesis may be implanted to replace one or more ossicles. Congenital or acquired conductive deafness may be helped with tympanoplastic surgical techniques. Single-channel cochlear implants, approved for children, may be helpful for the profoundly deaf child.

Correction of Choanal Atresia

Newborns are obligate nose-breathers and may die at birth if choanal atresia (congenital closure of nasal passages) is undiagnosed. They are unable to breathe and feed properly without an adequate nasal airway. Bone or fibrous tissue blocking the posterior choanae usually is excised via a transseptal approach to create an opening into the nasopharynx. A CO_2 laser may be used to develop appropriate apertures.

Adenoidectomy

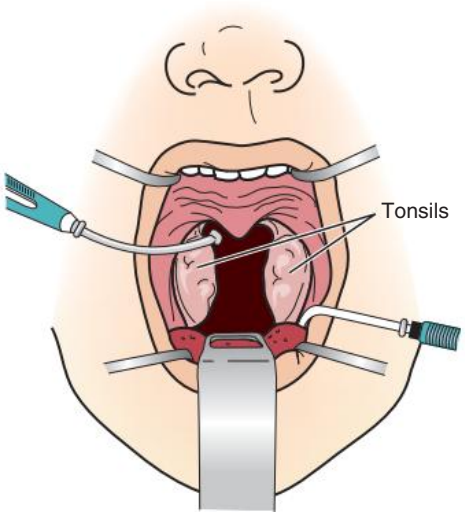
Abnormally enlarged lymphoid tissue or infected adenoids can obstruct breathing. A child usually is at least 2 years old before adenoid tissue in the nasopharynx is removed, but he or she can undergo an adenoidectomy at an earlier age. Removal of adenoids can positively influence the outcome of otitis media with effusion in childhood. Adenoidectomy is usually performed in conjunction with tonsillectomy.

Tonsillectomy

Tonsillectomy, the excision of hypertrophied or chronically infected tonsils, is not generally advised before the child is 3 years of age (Fig. 8.21). General anesthesia is used for patients up to about 14 years of age. Tonsillectomy and adenoidectomy frequently are performed together; the procedure appears on the surgical schedule as T&A. Sterile technique is carried out throughout the procedure because the patient's vascular system is encountered. Precautions during the surgical procedure include control of bleeding and prevention of aspiration of blood or tissue.

Esophageal Dilation

Children, usually of preschool age, may ingest caustic agents that cause chemical burns of the mouth, lips, and pharynx and corrosive esophagitis. Long-term gradual esophageal dilation with balloon catheters or bougies (pronounced *boogee*) may be necessary to restore adequate oral intake of food after the acute phase of traumatic injury. When all attempts at dilation fail, the esophagus is replaced. The most successful source of esophageal replacement is the colon.



• **Fig. 8.21** Tonsillectomy.

Laryngeal Papillomas

Recurrent respiratory papillomatosis is localized in the larynx of children. Laryngeal papillomas are benign wartlike lesions caused by the human papillomavirus (HPV). HPV can be transmitted during passage through an infected mother's birth canal. Hoarseness is an early symptom; airway obstruction is a later, life-threatening sign. Ablation with the CO_2 laser, manipulated through the operating microscope, preserves underlying laryngeal muscles and ligaments while vaporizing papillomas located on vocal cords.

Laser ablation is not a cure; recurrence often necessitates repeated procedures to maintain a patent airway. HPV is a common cause of throat cancer later in life.

Tracheal or Laryngeal Stenosis

Some accidental injuries result in a narrowing (i.e., stenosis) of the trachea or larynx. Of greater concern are the injuries that result from therapy for respiratory problems, especially in newborns. Prolonged endotracheal intubation can lead to injury from tubes that are too large for the lumen, are too long, or move too much. These injuries may necessitate balloon dilation or endoscopic resection of the stenotic area. Most infants then need an intraluminal stent to maintain patency of the airway.

In the presence of severe circumferential intraluminal scarring with involvement of the cartilages, surgical reconstruction becomes necessary. Laryngotracheoplasty widens the stenosed cartilaginous framework of the airway in the midline anteriorly and posteriorly and reconstructs the mucosal lining. Free or composite rib cartilage grafts are taken with mucosal tissue of the perichondrium for lining the airway. A stent assembly with a tracheostomy tube supports the reconstructed airway during healing. It can then be removed and the tracheostomy closed.

Tracheotomy

Tracheotomy, incision into the trachea and insertion of a tracheostomy tube, is advisable in cases of severe inflammatory glottic diseases, when endotracheal intubation is needed for longer than 72 hours, and when respiratory support is necessary for more than 24 to 48 hours to treat respiratory problems. Prolonged endotracheal intubation can lead to tracheal malacia, or softening, which in turn destroys the tracheal integrity.

• **Fig. 8.22** Cleft lip and palate.

Appropriate sizes and types of tracheostomy tubes for infants and children should be available. Tubes that are too large, too rigid, or too long or that have an improper curve can produce ulceration and scarring at pressure points. Strictures that develop at the site of the tracheotomy may necessitate resection to relieve airway obstruction after decannulation. Infants have a shorter neck and are prone to distal displacement of the tracheostomy tube from the intratracheal insertion point. Head motion causes the tube to shift superiorly if it is not secured in position by ties.

Plastic and Reconstructive Surgery

With the exception of burns and other traumatic tissue injuries, most plastic and reconstructive surgery performed on infants and children is to correct congenital anomalies.[5] The most common of these surgeries include those discussed in the following sections.

Cleft Lip

Lack of fusion of the soft tissues of the upper lip creates a cleft or fissure. The degree of cleft lips varies from simple notching of the lip to extension into the floor of the nose (Fig. 8.22). The cleft may be unilateral or bilateral. The number of procedures necessary for correction depends on the severity of the deformity. Some plastic surgeons do a primary cheiloplasty, closure of the cleft lip, within the first few days after birth to facilitate feeding and minimize psychologic trauma of parents. Surgeons who prefer to wait until the infant is older follow the **"Rule of Tens"**: 10 weeks of age, 10 g of hemoglobin, 10 lbs of body weight.

To relieve tension on the incision postoperatively a Logan bow (a small, curved metal frame) may be applied over the area of the incision and held in place with narrow adhesive strips to splint the lip. Skin closure strips may be used. Arm or elbow restraints are used to prevent the infant from removing the bow or strips and injuring the repaired lip. These restraints are applied in the OR.

Cleft Palate

Failure of tissues of the palate to fuse creates a fissure through the roof of the mouth. Palatal clefts may be a defect only in the soft palate or may extend through both hard and soft palates into the nose and include the alveolar ridge of the maxilla. Cleft palate is often associated with cleft lip; however, the two deformities are closed separately. Palatoplasty, closure of the soft palate, is done before speech begins, to avoid speech defects. A mouth gag is used during the surgical procedure to permit access to the palate without obstructing the airway. General anesthesia is administered via an endotracheal tube. This may be supplemented with infiltration of a local anesthetic agent. When epinephrine is used by the surgeon to minimize bleeding, the anesthesia provider is informed. Epinephrine can increase the patient's heart rate as it vasoconstricts the surgical site.

In patients with bilateral and, frequently, unilateral clefts an additional surgical procedure is performed to elevate the tip of the nose and correct asymmetry before the child is 4 years of age.

Hemangioma

Hemangiomas are the most common of all human congenital anomalies. A hemangioma is a benign tumor (angioma) made up of blood vessels that may pigment or appear as a growth on the skin. All hemangiomas have abnormal patterns of hemodynamics, which is the effect of blood flow through tissues. Variations in vessel size distinguish the different types of these tumors. Argon or tunable dye laser or surgical excision in combination with a skin graft or pedicle flap repair is the treatment of choice for intradermal capillary hemangiomas (port-wine stain). Cryosurgery, surgical excision, or steroid therapy may be used for some other cavernous-type tumors.

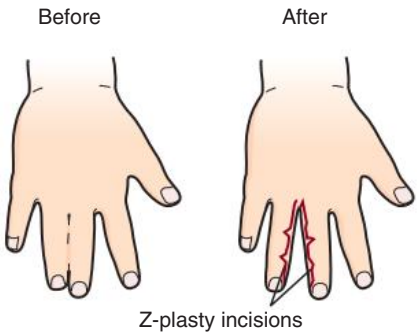
Otoplasty

Abnormally small or absent external ears can be reconstructed in several surgical stages. An autogenous rib cartilage graft with the perichondrium intact or a silicone or porous polyethylene prosthesis is used for the supporting framework to produce an anatomic contour. Usually necessitated by microtia, a congenital anomaly, reconstruction of the external ear can follow traumatic injury with loss of all or part of the pinna. Free flaps of temporoparietal fascia are used to secure a prosthesis or may be used to cover a carved cartilage armature procured from the patient's rib or other site for secondary reconstruction.

Otoplasty procedures to correct protruding or excessively large ears are performed more frequently than are procedures for microtia. These procedures often are done on preschool-age children, usually boys, to prevent psychological harm from teasing.

Syndactyly

Syndactyly is a congenital anomaly characterized by fusion of two or more fingers or toes. Webbing between fingers is the most common congenital hand deformity (Fig. 8.23). Tissue that is holding digits together is cut to separate the fingers if phalangeal bones are present. Separation of webbed digits almost always necessitates skin grafts to achieve good functional results.



• **Fig. 8.23** Syndactyly.

Polydactyly

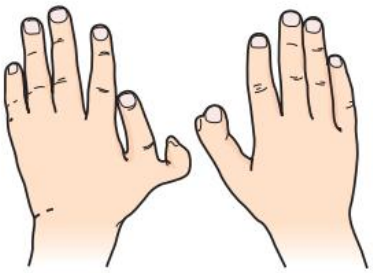
Polydactyly is a congenital anomaly characterized by the presence of more than the normal number of fingers or toes. A supernumerary digit may be alongside a thumb or little finger on one or both hands (Fig. 8.24). Extra digits on the feet are less common. Skin and tissue resemble a rudimentary digit. Some supernumerary digits contain bone, ligament, and tendon. Excision is recommended at an early age. If the excised digit contains rudimentary bone, multistage procedures may be necessary to enhance function of the remaining digits of the affected extremity.

Neurologic Surgery

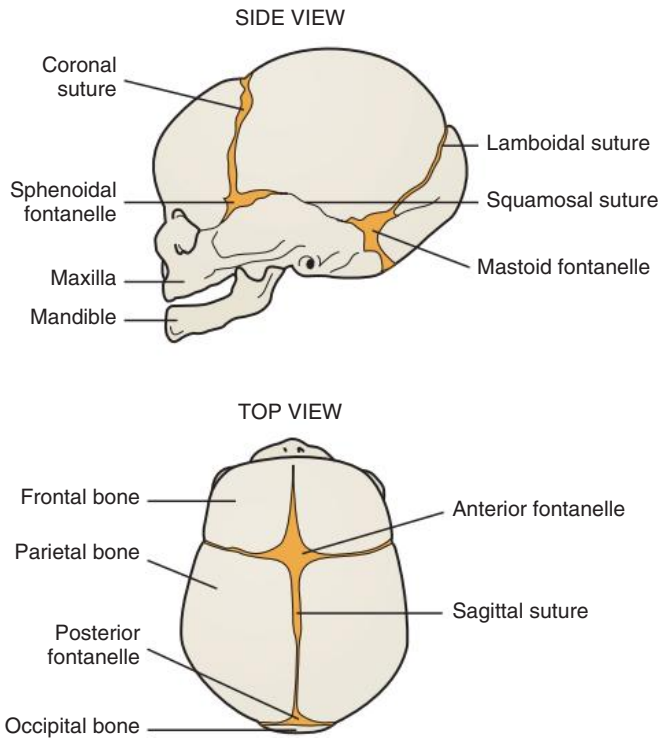
Children of all ages sustain head injuries with hematomas that must be evacuated. Although brain tumors occur in children, the more commonly performed pediatric neurosurgical procedures are related to correction of congenital anomalies.

Craniosynostosis

If one or more of the suture lines in the skull, normally open in infancy (Fig. 8.25), fuses prematurely (craniosynostosis), the skull cannot expand during normal brain growth.[6]



• **Fig. 8.24** Polydactyly.



• **Fig. 8.25** Craniosynostosis.

A newborn with multiple-suture involvement may need surgical intervention because of increased intracranial pressure. Even fusion of a single suture puts a newborn at risk for altered cranial capacity and brain damage. The surgeon performs a craniectomy to remove the fused bone and to reopen the suture line. A strip of polyethylene or Silastic film may be inserted to cover bone edges on each side.

In an older infant or child, more extensive freeing of other bones may be necessary to achieve decompression of frontal lobes and orbital contents. The standard procedure takes 8 hours or more to perform.

Craniofacial microsomia with severe facial asymmetry and the dysostosis of Apert's syndrome and Crouzon's disease also are associated with multiple skull and facial deformities. Congenital malformations of the skull are described in Chapter 41.

Craniofacial surgery, performed by a multidisciplinary team, involves repositioning and reshaping of skull and facial bones and a variety of soft tissue reconstructive techniques.[5] Microplating systems may be used for rigid fixation of bones. The skull may provide a donor site without creating a deformity if bone grafts are necessary. Demineralized cadaver bone powder may be used to stimulate bone growth.

Endoscopic techniques have been developed that enable the surgeon to separate the dura from the skull and snip away stenosed suture lines to free up the skull segments. The whole procedure takes less than 1 hour. The child then wears a skull-molding helmet for several months. Blood loss has been minimized, and the maximum hospital stay is 3 days. The endoscopic procedure is preferred for infants younger than 3 months; however, infants younger than 6 months can still be cared for with this method. The most commonly stenosed suture lines are the sagittal, coronal, metopic, and lambdoid. Older children are treated with the more extensive form of surgery because they have more stenotic areas.

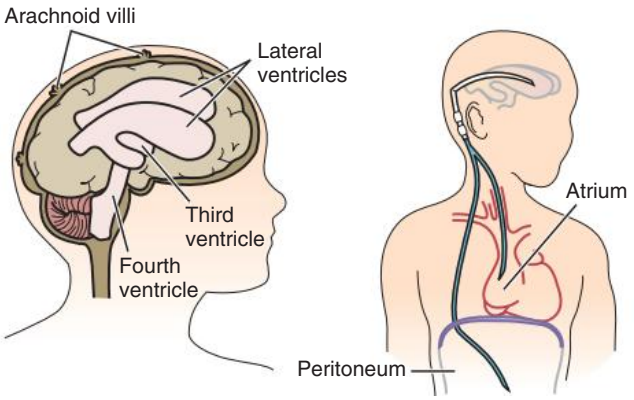
Encephalocele

Encephalocele is the herniation of brain and neural tissue through a defect in the skull. This is present at birth as a sac of tissue on the head. Usually these lesions can be removed 6 to 12 weeks after birth, unless the condition is complicated by hydrocephalus.

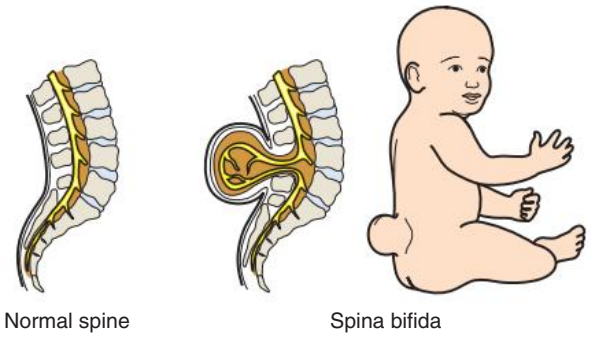
Hydrocephalus

Usually a congenital condition, hydrocephalus occurs when the passages between the ventricles are blocked and are dilated by accumulated cerebrospinal fluid. Failure of the absorptive mechanisms also can produce impairment in the normal circulation of cerebrospinal fluid and cause excess fluid to accumulate in the ventricles. The intracranial pressure created causes enlargement of the infant's head if the condition develops before fusion of cranial bones and often causes brain damage.

Hydrocephalus may be diagnosed in utero with ultrasound scan. Cephalocentesis can be performed, and a ventriculoamniotic shunt may be inserted to drain the ventricles. After birth, surgical treatment involves establishment of a mechanism for transporting excess fluid from the ventricles to maintain an intracranial pressure close to normal. This may be done with implantation of a shunt, which carries fluid from the lateral ventricle to the peritoneal cavity (ventriculoperitoneal shunt) or to the right atrium of the heart (ventriculoatrial shunt; Fig. 8.26). Ventriculoatrial shunts are more commonly associated with infection, pleural effusion, and cardiac dysrhythmia. Other types of shunts are used, but less commonly, to bypass localized obstructions.



• **Fig. 8.26** Hydrocephalus.



• **Fig. 8.27** Spina bifida.

One end of the shunt catheter is put into the ventricle; the other end may connect to a one-way valve, which in turn is connected to the catheter that drains fluid distally from the head. An endoscopic technique may be used for catheter placement in the ventricle. Shunt malformation is usually caused by obstruction by the choroid plexus or debris. This complication can be reduced by positioning the shunt catheter tip opposite the foramen of Monro visually via a miniature fiberoptic pediatric neuroendoscope.

Catheters are made of silicone. An antithrombotic coating may be incorporated into the distal end. Some valves are regulated to open for drainage when predetermined pressure in the ventricle is reached. Other valves are designed as flushing devices to keep the distal catheter patent; the skin over the device is manually depressed to flush the system. For each patient the surgeon chooses the shunt mechanism that is safest for the particular type of hydrocephalus being treated. Follow-up minor revisions are sometimes necessary, generally because of growth of the child.

As an alternative to a shunt procedure a ventriculostomy can relieve intracranial pressure. A rigid neuroendoscope is introduced into the third ventricle. The contact fiber of a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, inserted through the scope, blanches and perforates the floor of the third ventricle at several points to establish circulation of cerebrospinal fluid into the subarachnoid space.

Myelomeningocele

A saclike protrusion may bulge through a defect in a portion of the vertebral column that failed to fuse in fetal development. If the nerves of the spinal cord remain within the vertebral column and only the meninges protrude into the sac, the congenital anomaly is a meningocele. However, if the sac also contains a portion of the spinal cord, it is a myelomeningocele, with associated permanent nerve damage. The degree of impairment depends on the level and extent of the defect.

Clubfeet (talipes deformities), dislocated hips, hydrocephalus, neurogenic bladder, paralysis, and other congenital disorders often accompany a myelomeningocele.

Each patient is evaluated and treated individually according to his or her needs. In general it is best to delay the surgical procedure to repair a myelomeningocele until danger of development of hydrocephalus has passed or cerebrospinal fluid has been shunted. If the sac is covered with a thin membrane, meningitis is an imminent danger. The defect is repaired soon after birth, usually within the first 48 hours, to close cutaneous, muscular, and dural defects.

Spina Bifida

Spina bifida, incomplete closure of the paired vertebral arches in the midline of the vertebral column, may occur without herniation of the meninges (Fig. 8.27). A spina bifida may be covered by intact skin and can occur at different levels of the spine (Fig. 8.28), causing various types of disability. Laminectomy may be indicated to repair the underlying defect.

Spastic Cerebral Palsy

Selective posterior rhizotomy can improve muscle tone and function of school-age children with spastic cerebral palsy. The procedure involves division of lumbar and sacral posterior nerve roots associated with an abnormal motor response as identified by nerve stimulation.

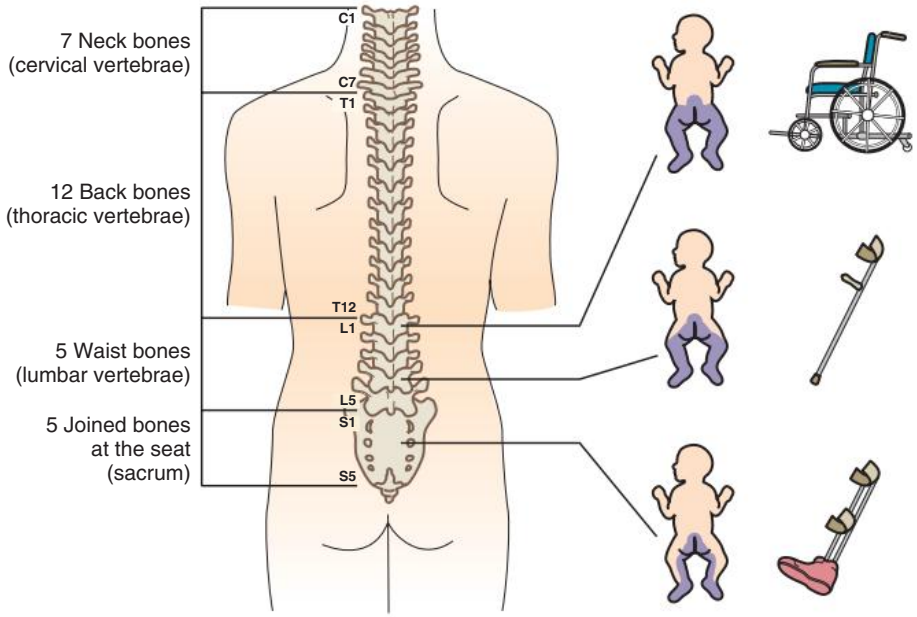
Thoracic Surgery

Aspiration of a foreign body can seriously compromise a child's respiratory status. Bronchoscopy with the child under general anesthesia may be necessary to remove the object. Bronchoscopy is also performed to diagnose tracheobronchial compression by an innominate artery, a vascular ring, or some other pathologic condition causing obstruction, stridor, or apnea. Thoracoscopy provides visualization of the chest wall and visceral pleura for diagnosis of diffuse or localized pulmonary disease. An intrathoracic biopsy can be obtained via a thoracoscope.

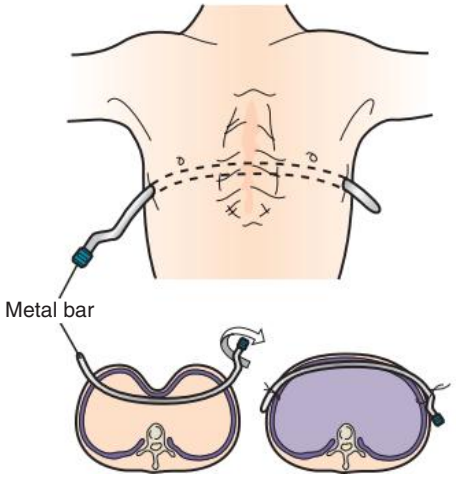
Pectus Excavatum

Pectus excavatum, a congenital malformation of the chest wall, is characterized by a pronounced funnel-shaped concave depression over the lower end of the sternum beginning at the angle of Lewis and extending to the xyphoid. Cardiopulmonary impairment can result from extreme pectus excavatum during the pubertal growth period. Children with moderate to severe forms have displacement of the heart and lung tissue, which results in exercise intolerance and chest pain. Pectus is more common in males than females.

Minimally invasive procedures have been developed that require a curved metal bar to be slid under the ribs to elevate the sunken part (Fig. 8.29). No ribs or cartilage are removed. Thoracoscopic vision is used to guide the metal bar through two incisions made in the bilateral chest at the level of T4-5 interspace. The bar is secured to the ribs on each side to maintain the elevation of the deformity. Each bar is individually tailored to the recipient. The patient remains in the hospital for 2 to 3 days to be monitored for complications and frequently has a thoracic epidural for pain management. Movement is restricted during



• **Fig. 8.28** Levels of spina bifida.



• **Fig. 8.29** Pectus excavatum.

convalescence. The child must remain supine with a small pillow under the head. Side lying or twisting can cause a shift in the bar. The child can return to school within 2 weeks.

The Nuss procedure, developed in 1987 by Dr. Donald Nuss, is less complicated in younger children because the cartilage is softer and less calcified. Teens and young adults can have the procedure performed successfully, but their osseous tissue is less flexible. The bar is removed after 2 to 3 years as an outpatient procedure.

The deformity can be corrected during an open procedure with resection of lower intercostal cartilages and substernal ligaments to free up the sternum in a procedure referred to as the Ravitch repair. The sternum is elevated, and the cartilages are fitted to the sides of the sternum. Some pediatric surgeons believe that endoscopic approaches minimize chest wall scarring that could minimize physical motion.

Care is taken to try to avoid extreme positioning of the arm in abduction by suspending the arm rather than exceeding a 90-degree angle of shoulder-arm positioning. Occasionally a pediatric patient has transient postoperative brachial plexus injury caused by extremes of arm positioning during the procedure for the insertion of the bar and the camera.

Risks of the Nuss procedure include bleeding, cardiac perforation, pericardial effusion, pneumothorax, and dysrhythmias. Chest asymmetry in older children may necessitate surgical adjustment and the insertion of double chest bars and side stabilizers.

Pectus Carinatum

Pectus carinatum is a protrusion of the breastbone. The cartilage buckles and causes pain. The condition progresses during periods of growth. The chest is rigid and stationary in a full inspiration position. Respiratory effort is compromised and uses the diaphragm and accessory muscles instead of the normal processes. Pulmonary function is diminished, and emphysema can develop. The condition may be genetically mediated and increases in severity with age.

Pectus carinatum is seen in combination with some connective tissue disorders such as Marfan's syndrome or Ehlers-Danlos syndrome. Some cases have scoliosis and mitral valve prolapse. Other vascular disease is sometimes present.

In mild cases the patient wears a brace across the chest for 12 to 18 months. In moderate to severe cases a transverse incision is made across the chest for an open correction. Bilateral wedges are removed from the ribs, and excess cartilage over the sternum is removed to correct the condition. The perichondrium is left in place to grow over the excised area. The patient needs to remain hospitalized for several days. Outcomes are usually excellent.

Cardiovascular Surgery

Congenital cardiovascular defects are the result of abnormal embryologic development of the heart or major vessels. During fetal life, blood bypasses the lungs through the foramen ovale and the ductus arteriosus to the placenta. From the placenta the blood bypasses the liver through the ductus venosus. The right ventricle pumps 66% of the circulation, and the left ventricle pumps 34%. At birth the pulmonary ventilation is established during the first breath and the increasing atmospheric pressure causes increased

left atrial force that in turn causes the foramen ovale to close. The right atrial pressure drops, causing the blood flow to reverse. The ductus arteriosus usually closes after 15 hours. Some neonates have a delay of 1 to 3 weeks for complete closure of the ductus.

Most cardiovascular defects are diagnosed in infancy, often when symptoms of congestive heart failure develop within the first few days or months after birth.[7] Corrective or palliative procedures are necessary to sustain or prolong the life of these infants. Many of these cardiovascular procedures are enhanced by or are made possible with the use of hypothermia and cardiopulmonary bypass. However, significant brain damage may be associated with a cardiovascular bypass in infants. Bypass perfusion time should not exceed 40 minutes between periods of temporary normal circulatory perfusion.

The use of robotics has revolutionized the field of pediatric cardiac surgery because the dexterity of the surgeon is enhanced in a small, confined space. Implantable materials such as grafts and valves have reduced the rate of reoperation.[8] Congenital cardiovascular defects in infants or children that are amenable to conventional or endoscopic surgical intervention include, but are not limited to, the following conditions.

Anomalous Venous Return

Failure of any one pulmonary vein or a combination of these veins to return blood to the left atrium precludes the full complement of oxygenated blood from entering the systemic circulation. The anomalous pulmonary vein or veins are transferred and anastomosed to the left atrium.

Coarctation of the Aorta

A coarctation is a narrowing or stricture in a vessel. This is one of the more common congenital cardiovascular defects; it usually occurs in the aortic arch. It may cause hypertension in the upper extremities above the obstruction and hypotension in the lower extremities from slowed circulation below the coarctation. For correction of the defect the coarctation is resected and the aorta may be anastomosed end-to-end. An aortic patch graft may be necessary when the length of the coarctation prevents anastomosis. A subclavian flap angioplasty capable of growth in length and width, referred to as the Waldhausen procedure, is the surgical procedure of choice in infants.

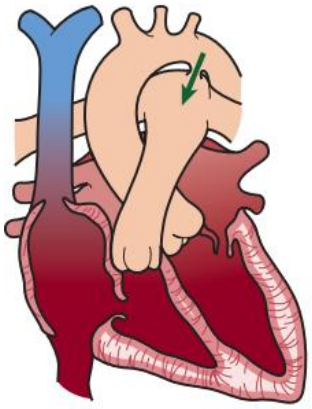
Patent Ductus Arteriosus

During fetal life the ductus arteriosus carries blood from the pulmonary artery to the aorta to bypass the lungs. Normally this vessel closes in the first 24 hours after birth to prevent recirculation of arterial blood through the body. If closure does not occur, blood flow may be reversed by aortic pressure, which causes respiratory distress (Fig. 8.30).

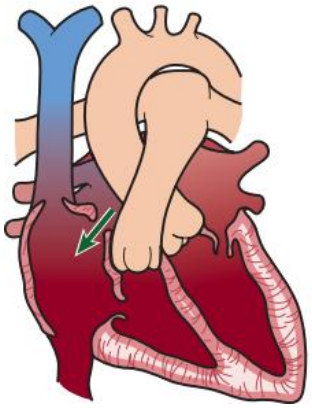
Signs of patent ductus arteriosus (PDA) include widening pulse pressure and a characteristic murmur. The incidence of PDA is 10% of all congenital cardiac defects; PDA is usually diagnosed by 1 month of age. Surgical intervention is indicated, in lieu of prolonged ventilatory support, to prevent development of chronic pulmonary changes. The PDA can be clamped and ligated with ligating clips or suture in an open procedure or occluded with a coil using a transcatheter approach or endoscopically with a thoracoscope.

Septal Defects

An open-heart procedure with cardiopulmonary bypass is necessary to close abnormal openings in the walls (septa) separating the chambers within the heart.



• **Fig. 8.30** Patent ductus arteriosus.



• **Fig. 8.31** Atrial septal defect.

Atrial Septal Defect

An opening in the septum between the right and left atria may be sufficiently large to allow oxygenated blood to shunt from left to right and return to the lungs (Fig. 8.31). An atrial septal defect (ASD) can increase pulmonary blood flow, with resultant pulmonary hypertension, if the defect is not closed. The incidence of ASD is 8% to 14% of all congenital heart defects; the defect can remain asymptomatic until adulthood. Signs include acyanosis, thin body stature, and decreased tolerance to exercise. ASD is more common in females than in males (4:1). If the defect cannot be closed with sutures, a patch graft is inserted.

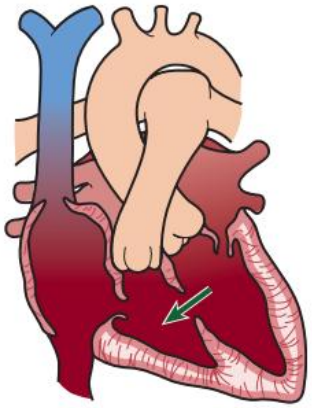
Ventricular Septal Defect

A ventricular septal defect (VSD) is usually located in the membranous portion of the septum between the right and left ventricles (Fig. 8.32). It is the most common of the congenital heart anomalies (25% to 30% of all congenital cardiac defects). Signs include alternation between cyanosis and acyanosis.

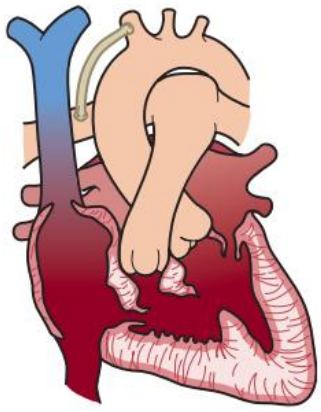
Patients with small defects are relatively asymptomatic, and repair may be unnecessary. One third of the small defects spontaneously close by age 2 years. Large defects with left-to-right shunting of oxygenated blood back to the lungs, which increases pulmonary hypertension, become symptomatic by age 2 months. A patch graft may be necessary to close the defect.

Atrioventricular Canal Defect

An atrioventricular canal defect is present if the atrioventricular canal of connective tissue that normally divides the heart into four chambers has failed to develop. Deficiencies are present in the



• **Fig. 8.32** Ventricular septal defect.



• **Fig. 8.34** Blalock-Taussig repair.

lower portion of the interatrial septum, upper portion of the interventricular septum, and tricuspid and mitral valves. The result is a large central canal that permits blood flow between any of the four chambers of the heart.

A corrective procedure referred to as the Rastelli procedure involves repair of mitral and tricuspid valves and patch grafts to close septal defects. Creation of a competent mitral valve is of utmost importance to relieve pulmonary hypertension.

Tetralogy of Fallot

Tetralogy of Fallot is a combination of four defects (Fig. 8.33):

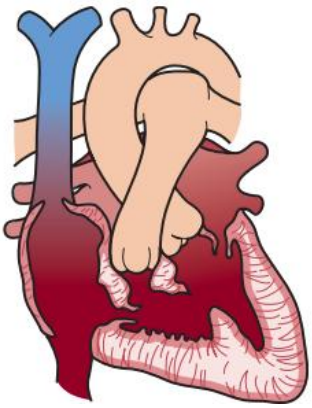
1. VSD (large)
2. Stenosis or atresia of the pulmonary valve or outflow tract into the pulmonary artery
3. Hypertrophy of the right ventricle
4. Dextroposition (displacement) of the aorta to the right so that it receives blood from both ventricles

Often referred to as "blue babies," infants with tetralogy of Fallot are cyanotic because insufficient oxygen circulates to body tissues. The incidence is 8% of all congenital cardiac defects; the defect is commonly associated with Down syndrome. Total correction of the multiple anomalies is difficult. Assessment of the technical ease of correction is generally the dominant consideration. If cyanosis is severe, one of the following palliative shunt procedures may be performed during infancy to increase pulmonary blood flow:

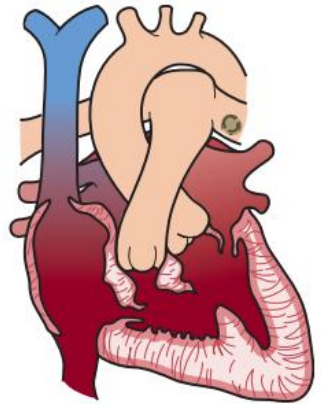
- *Blalock-Taussig procedure:* The right subclavian artery is anastomosed, end-to-side, with the corresponding pulmonary artery (Fig. 8.34). Mixed arteriovenous blood from the aorta flows through the shunt to the pulmonary artery and into the lungs for oxygenation. A modification of this includes the use of a conduit graft, such as Gore-Tex.
- *Potts-Smith-Gibson procedure:* The descending aorta is anastomosed, side-to-side, with the left pulmonary artery (Fig. 8.35). The shunt enlarges as the child grows, but it is more difficult to reconstruct than a Blalock-Taussig shunt at a later time, when a corrective procedure is performed.
- *Glenn procedure:* The superior vena cava is anastomosed with the right pulmonary artery. Modern versions are bidirectional and allow flow to the right and left pulmonary arteries.
- *Waterston procedure:* The ascending aorta is anastomosed with the right pulmonary artery (Fig. 8.36). The anastomosis is placed on the posterior aspect of the aorta to provide perfusion to both pulmonary arteries.

With cardiopulmonary bypass and hypothermia, the VSD is closed with a patch graft that also corrects the abnormal communication between the right ventricle and the aorta. Then the obstruction to pulmonary blood flow is relieved. This may include enlarging the pulmonary valve or widening the outflow tract. Resection of obstructing cardiac muscle may be necessary with insertion of a prosthetic outflow patch.

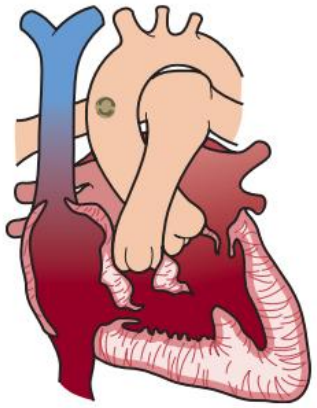
An aortic allograft that contains the aortic valve with the septal leaflet of the mitral valve and the ascending aorta attached may be inserted.[9] The septal leaflet of the mitral valve is used as a portion of the right ventricular outflow patch. All or part of the aortic valve and ascending aorta is used as a new conduit with the pulmonary artery or as a patch graft.



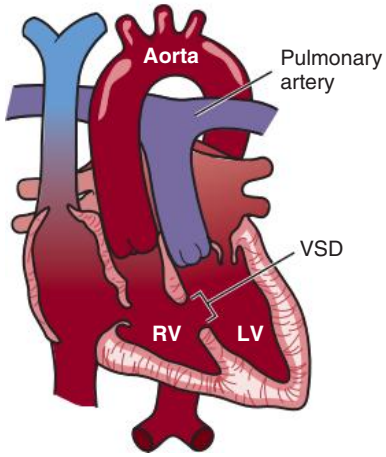
• **Fig. 8.33** Tetralogy of Fallot.



• **Fig. 8.35** Potts-Smith-Gibson repair.



• **Fig. 8.36** Waterston procedure.



• **Fig. 8.37** Transposition of the great vessels.

Transposition of the Great Vessels

In a transposition the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle (Fig. 8.37). This creates essentially two separate circulatory systems, one systemic and the other pulmonary, but they are not interconnected as in normal anatomy. Life depends on the presence or creation of associated defects to permit exchange of blood between the two systems.

The incidence of complete transposition of the great vessels is 10% of all cardiovascular defects. Males are affected more than females (2:1). A palliative procedure, such as one of the following, is performed in the newborn to improve oxygenation and sustain life until the infant grows enough to tolerate a corrective procedure:

- *Rashkind procedure, or balloon septostomy:* In the cardiac catheterization laboratory, with fluoroscopy, a balloon catheter (deflated) is advanced into the right atrium, through the foramen ovale, and into the left atrium. The balloon is inflated and pulled backward out of the left atrium across the atrial septum to enlarge the foramen ovale, thus creating an ASD.
- *Park procedure:* In the cardiac catheterization laboratory, with fluoroscopy, a catheter with a knife tip is passed through the right atrium to enlarge the opening of the foramen ovale.
- *Blalock-Hanlon procedure:* Atrial septectomy is done to create an ASD. A segment of the right atrium is excised.
- *Pulmonary artery banding:* The pulmonary artery is constricted in the presence of a large VSD to prevent irreversible pulmonary vascular obstructive changes from developing.

A corrective procedure, such as one of the following, is usually performed when the child is between 18 and 36 months of age:

- *Mustard procedure, atrial switch:* An intraatrial baffle made of pericardial tissue is sutured between the pulmonary veins and the mitral valve and between the mitral and tricuspid valves. The baffle directs systemic venous return into the left ventricle and lungs and allows pulmonary venous return to enter the right ventricle and aorta.
- *Senning procedure, atrial switch:* Flaps of the intraatrial septum and right atrial wall form new venous channels to divert pulmonary venous blood flow. Any atrial or septal defects are closed.
- *Jantene procedure, atrial switch:* The aorta and pulmonary artery are anatomically switched (i.e., transposed). This procedure is useful in infants with a VSD or a large PDA in addition to transposition of the great arteries.

Tricuspid Atresia

The absence (atresia) of a tricuspid valve between the right atrium and ventricle prevents normal blood flow through the chambers of the heart. Blood flows through an ASD, into an enlarged left ventricle, and through a small rudimentary right ventricle to the pulmonary artery. Anastomosis of the superior vena cava with the right pulmonary artery or an aorticopulmonic artery shunt may be created as a palliative procedure to increase pulmonary blood flow in infancy. When the child is 3 or 4 years old, the corrective reconstructive Fontan procedure is performed. This procedure involves direct anastomosis of the pulmonary artery to the right atrium to create a connection between the pulmonary and systemic venous circulation.

Truncus Arteriosus

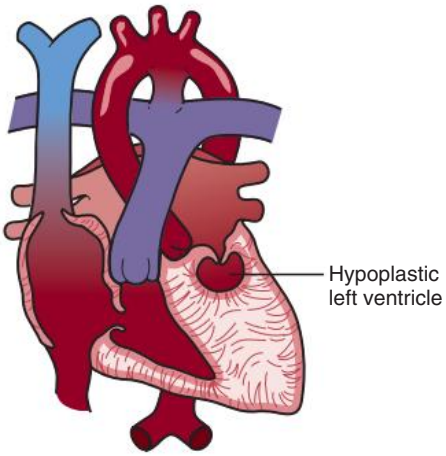
In truncus arteriosus a single great artery carries blood directly from the heart (with a large associated VSD) to the coronary, pulmonary, and systemic circulatory systems. A single tricuspid valve is present with two to six cusps. Initial palliative banding of the pulmonary arteries, as close to their origins off the truncus as possible, decreases pulmonary blood flow in an infant in congestive heart failure. At a later stage a corrective procedure can be performed to close the VSD and insert a conduit with an ascending aortic graft and aortic valve. Correction in infancy necessitates replacement of the conduit as the child grows. Incidence of this defect is 1% of all congenital cardiovascular defects.

Valvular Stenosis

Congenital aortic or pulmonary valve stenosis necessitates valvotomy, which is also referred to as the Brock procedure. An incision is made into the valve to open the narrowed or constrictive area obstructing blood flow.

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome is the most common cause of cardiac death in the first week of life. The left ventricle is severely underdeveloped (Fig. 8.38). The severity of the situation can vary according to the multitude of defects that can be present. The systemic perfusion of the aorta is entirely through a patent ductus arteriosus. The right ventricle is overloaded, and the patient is extremely dusky. The patient is in complete heart failure within 28 hours of life. The only real immediate treatment is cardiac



• **Fig. 8.38** Hypoplastic left heart syndrome.

transplant. Hearts available for neonatal transplant are few in number.

Postoperative Pediatric Patient Care

The patient is taken to a postanesthesia care unit (PACU) for observation. Larger facilities have a PACU specifically designed to accommodate phase I and II pediatric patients. Parents are typically permitted in the pediatric PACU. The patient usually finds comfort in parental presence. The pediatric patient is never to be left unattended.

The PACU nurse receives the postanesthesia report from the anesthesia provider and a postprocedure report from the perioperative nurse. Vital signs are taken and include temperature, pulse, respirations, and blood pressure. The objective signs found in the head-to-toe assessment are compared with preoperative baseline values. Cardiac monitoring and pulse oximetry are done. Physical assessment is performed and compared with other data obtained about the patient. Fluid intake and output are evaluated. The surgical site is inspected. Specific physician orders pertaining to treatments and laboratory work are carried out.

The patient's recovery is evaluated at 5 to 15-minute intervals as the patient emerges from anesthesia to a more alert state. Each evaluation is documented in the patient's record per facility policy. The patient is discharged from the PACU when specific physiologic parameters are reached according to departmental policy. The anesthesia provider is responsible for the patient in the PACU and is responsible for release criteria.

The parents are instructed in postoperative home care and are informed about signs and symptoms that should be reported to the physician. The instructions should be given verbally and in writing with the appropriate emergency phone consult numbers included. Directions for prescription medications such as antibiotics or analgesics should be explained to the parents by the PACU nurse. Pediatric patients who are of an age of reason and understanding should be addressed directly and given the opportunity to ask questions.

Within 24 to 48 hours after discharge a postoperative phone call should be made as a follow-up to care. Pertinent information should be exchanged about the care of the patient and progress in recovery. The caller should be qualified to answer questions about the procedure and the recovery phase. Patient and family satisfaction should be evaluated. Some facilities ask the parent to call in during the evening hours to give an update to the PACU nurse.

Perioperative Geriatrics

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Discuss the theories of aging.
- Describe how comorbidity influences the care of geriatric patients.
- List the effects of aging on four body systems.
- Identify the effects of surgery on the geriatric patient.

KEY TERMS AND DEFINITIONS

Aged Social and legislative policies define aged as 65 years. Physiologic evaluation terms incorporate aged as 75 years.

Caregiver Any person who provides physical, emotional, and help with activities of daily living for another individual.

Comorbidity Two or more medical conditions in addition to current diagnosis.

Frailty syndrome Age-related decline in skeletal muscle that may predict the risk for postoperative complications.

Gerontology The study of aging and the older adult in all phases of life: sociologic, biologic, psychologic, and physiologic.

Life cycle The span of time and events from birth to death.

Longevity The condition of living a prolonged life span.

Sarcopenia Loss of skeletal muscle mass, quality, and function caused by inactivity or altered metabolism that can be a predictor of postoperative complications.

Senescence The process of growing old.

Senile The state or process of aging. Derived from the Latin word *senex,* meaning "old man" or "old age." Aging takes place at all biologic levels.

Perspectives on Aging

The process of aging is an orderly transformation of the body and mind that begins with birth and concludes with death. **Gerontology** is the study of elderly people. People older than 65 years are often considered old or elderly. In actuality, persons with advanced age may maintain functional capabilities throughout their lifetime until adaptation to biologic, psychologic, or social influences is no longer sufficient to sustain the independent activities of daily living (ADLs). The main influences on the aging process are genetics, environment, and lifestyle.

Data about the changes that occur as the result of natural processes and environmental exposure are inconclusive because the only data available are those derived from comparisons among existing generations. The experiences and exposures of these generations have been vastly different and widely influenced by the period of the life span and **senescence**.[1] No normal measurements are available on which to base the parameters of the aging process.

Life expectancy has increased steadily with major advancements in the study of disease processes, prevention, and treatment. According to the U.S. Social Security Life Expectancy Calculator 2019, males born in 1950 might expect to live to age 85.4 years and females might expect to live to age 87.5 years. With the increasing age of the "baby boomer" population (those born between the years of 1946 and 1964), over 74 million people will be over the age of 65 by 2030. These ages do not account for lifestyle or comorbidity. The increase in life expectancy and the decrease in mortality mean that the largest patient population will be geriatric patients—the fastest-growing segment of the population. More information can be found at www.agingstats.gov.

As the life expectancy of the geriatric population increases, so does the incidence of comorbidity. **Comorbidity** is the existence of two or more disease processes in a single individual (e.g., coronary artery disease in a patient who has osteoporosis and also may be hypertensive and diabetic). It is the most common negative influence on the health status and functional ability of geriatric patients. A chronic condition affects recovery after surgical intervention, and many geriatric patients have multiple chronic or debilitating health problems. Comorbidity is also a major consideration in the attainment of expected outcomes; all medical diagnoses should be considered in the development of the plan of care.

Another consideration is the **frailty syndrome**, which is a natural process that accompanies aging. The frailty syndrome is a collection

of physiologic changes that affects organ systems and older adult patient's reserves.[2] In combination with comorbidity, frailty can predispose patients to unfavorable outcomes in the perioperative environment. **Sarcopenia** is a loss of muscular strength and function that significantly increases after 70 years of age. Body mass index (BMI) shifts because of weight loss, but it can shift in obese patients, who maintain a high BMI with decreased muscle mass.

Aging is viewed from many perspectives, some positive and some negative. The positive aspects involve respect for maturity and the wealth of knowledge gleaned from experiences. The negative aspects involve the debilitation, pervading weaknesses, and dependence that can occur during the closure of life. Philosophers tend to focus on the positive inner peace derived from the wisdom acquired over many years. The view of aging adopted by individuals is based in part on the view of aging created by their cultural background. Geographic, financial, educational, religious beliefs, and subjective influences shape the prototype of the older adult's place in society.

Cultural Considerations

Positive views of aging are found in many cultures that can trace their heritage back for many generations. Repetitious storytelling and historical accounts support the cultural growth of an individual from youth to old age. Many cultures appreciate, honor, and respect their older members for their experience and maturity. Growing old with dignity is not feared or deemed repulsive. A positive view of aging may be observed in an individual who is a first-generation immigrant to a new land, because he or she may not have assimilated the value systems of the new environment. The individual may have retained many time-honored beliefs of the country of origin; the values are held dear and are deeply ingrained.

Negative views of aging may be generated by cultures that are primarily youth-oriented. Most members of these societies are second-generation and third-generation descendants of immigrants. They have developed value systems that do not reflect their country of origin. In a close community, values are supported within the belief structure of the group as a whole.

A culture is a set of structured social behaviors and personal beliefs that enable an individual to respond to social situations and relationships within a close community. The foundation of human relationships in a culture is more than ethnicity or race. Specific cultural practices such as dietary habits, lifestyle, and hygiene should be of concern to the perioperative nurse. For example, a patient's physical condition may be a direct result of a traditional activity, such as fasting during holy days. A geriatric patient who has been fasting may appear dehydrated, malnourished, or confused.

The perioperative nurse also should be aware of gender identity. Some patients may have significant others of the same sex and hide the information because it is "taboo" or prohibited within the culture or portrayed as a younger person's lifestyle. Same-sex relationships may have been legally sanctioned like a marriage. Spousal relationships are treated equally.

The psychologic assessment may reflect a high risk for an alteration in self-image because although patients may feel comfortable in their culture, they may have had a negative interaction with societal influences. For example, the media glorify young bodies and degrade the natural aging process, with advertisers using models that reflect the desirable aspects of youth and beauty. Cultural climate has a direct effect on the geriatric patient. The expected outcomes of the geriatric patient undergoing a surgical intervention are influenced by cultural views of aging and those of society as a whole.

Theories of Aging

Biologic, psychologic, and ethnocultural factors influence the manner in which an individual ages. The extrinsic influences surrounding the physical and psychosocial components depend on the interaction of persons with the environment and their view of health and wellness. Many older people tend to optimistically overstate their actual health status and minimize or dismiss symptoms as age-related. The intrinsic influences on the aging process are also interdependent, but to a less controllable degree. Certain inherited traits, such as pathologic conditions, are continued through the generations.

Each **aged** individual is unique. Perioperative nurses should understand the distinct aspects of each geriatric patient before developing a plan of care. Generic care plans do not address the specific problems, needs, and health considerations of the individual. Understanding the theories of the aging process enables the perioperative nurse to provide care throughout the surgical experience that optimizes the attainment of identified expected outcomes. The following theories explain aging and the **life cycle** as they are defined by science and research.

Wear-and-Tear Theory

The wear-and-tear theory suggests that the body loses its ability to keep pace with life processes. The sustenance of life suffers because the body begins to deteriorate in a natural wearing-down process. The body continually tries to maintain homeostasis but degenerates over time because of cellular loss and destruction caused by interactions with the environment. During this process the body becomes increasingly vulnerable to injury and disease. If a disease state occurs, the body is less able to maintain normal homeostasis and even less able to tolerate the assault of illness. Eventually the body is unable to support life and ceases to function. Examples of wear and tear include, but are not limited to, the following scenarios:

- Prolonged exposure to the sun and other external sources can cause breakdown of the skin. Thinning of the skin makes bedridden or inactive people vulnerable to pressure sores.
- Turbulent blood flow in the areas of bifurcation of blood vessels may cause rupture if the vessels are weakened by arteriosclerosis.
- Abuse of chemical substances and alcohol can damage liver and brain cells. Nicotine is responsible for many effects of smoking. Although these effects are self-induced rather than the result of natural wear and tear, they do affect health status.
- Wearing of muscles and joints can lead to risk for falls. Fracturing a hip, head injuries, or broken bones can lead to immobility.

Genetic Mutation Theory

DNA has been a target for age-related changes because it preserves the ongoing genetic message for cell replication and organism maintenance. DNA is a template, or coding mechanism, for the preservation of the life processes of cellular structures. Various agents damage DNA codes through physical, chemical, or biologic interactions. An alteration in the structure of DNA can cause an organism to change. This alteration can occur within the cell itself or be caused by a force in the environment. Mutated DNA cannot perform the processes necessary for normal cell activities. A cell containing wrongly coded DNA continues to replicate itself in the wrong patterns. It does not return to normal.

In the aging process, DNA may mutate for a variety of reasons and continues to produce the wrong types of cells during replication. For example, skin cells may be deficient in collagen or in the elastic properties associated with supple tissue. As a result, the skin replication process may yield drier, less elastic skin. This is

characteristic of the skin of an older person. In certain circumstances the mutated DNA could cause tumor production or other pathologic conditions, such as skin cancers.

Major organ systems affected by these changes are the central nervous system, the musculoskeletal system, and the cardiovascular system. Other systems affected include the gastrointestinal, genitourinary, endocrine, and integumentary systems. Essentially, all body systems change during the aging process as part of the frailty syndrome.

Viral Theory

Researchers have approached the concept that viruses may invade human cells and remain inactive until the body loses its ability to suppress them. This theory is closely linked to the genetic mutation theory because the virus can hide undetected in the DNA for many years. The replication process of the virus is comparable to the replication of DNA. Some viruses are able to use genetic materials as a disguise to fool the body's immune system. The body does not recognize the virus as an invader or foreign substance.

The mechanism of viral activation is unknown but is very injurious to the body. Major targets include the endocrine, nervous, and immune systems. The incubation period may be several decades. Because the viral theory has no proof, a treatment or cure is unknown.

Environmental Theory

Exposure to natural and synthetic elements in the environment may accelerate the aging process. Although climate is often blamed for an increased rate of aging, studies indicate that the natural flow of the aging process is comparable among different geographic regions. Tropical climates are cited most often as areas of premature aging. Studies of tropical populations show that aging is not accelerated by the temperature, although mortality in these areas is affected by poor nutrition, parasites, and tropical diseases. Both tropical and desert groups tested did not show any mean blood pressure elevations diagnostic of hypertension, arteriosclerosis, or coronary artery disease between the ages of 20 and 83 years. The most astounding finding was the absence of angina pectoris and sudden heart attack deaths, which may be partly a result of a physically strenuous lifestyle and a diet that is low in animal fat.

Extremes of climate do not seem to accelerate the aging process. Studies involving Eskimo populations have shown that despite the difficult conditions of their lifestyles, blood pressure and cholesterol measurements do not vary significantly between the ages of 20 and 54 years. Mortality is affected by the harshness of the cold climate and the risk for physical injury or death associated with hunting and lifestyle practices. The Centers for Disease Control and Prevention (CDC) provide tables of life expectancy based on census data collected. Individuals in certain areas showed **longevity,** especially in colder climates.

Altitude has not been shown to accelerate the aging process. Results of studies performed among Peruvian Indians have shown stable blood pressures in a range lower than that of people living at sea level. The incidence of ischemic heart disease is very low at higher altitudes. In several documented communities of mountain-dwelling people, many residents were older than 100 years.

Ionizing radiation has been targeted as a cause of environmentally accelerated aging, but studies have not shown this to be true. Relevant evidence has shown that exposure to ionizing radiation does accelerate disease processes and pathologic conditions such as skin cancer, blood dyscrasias, and reproductive anomalies. Populations living in areas where nuclear tests frequently occurred have not shown signs of rapid aging compared with control groups in nuclear-free areas. The most significant finding was an increase in leukemia and skin tumors.

Pollution causes many physiologic changes in the body. Chemicals in air, food, and water supplies have been shown to increase the incidence of health decline and disability. Exposure to pollutants throughout the life span dramatically shortens an individual's life expectancy through pathologic processes such as chronic lead poisoning and lung cancer (www.niehs.nih.gov).

Physical Factor Theory

Free radicals are being investigated as a potential cause of premature aging. Free radicals represent imbalances between the production and the elimination of unstable chemical compounds in the body. More research is needed to prove or disprove this theory.

Low-calorie diets do not alter the aging process in humans. In populations studied for dietary habits no increase in the life span is evident between control groups and groups that have a low calorie intake. The most remarkable factor is the lack of increase in body weight after 30 years of age. A low-calorie diet may range between 1500 and 2500 kcal per day depending on body size and sex. Notably, low-calorie diets are usually deficient in animal protein. Aged individuals who have low-calorie diets generally have lower blood pressure and lower serum cholesterol levels, with no significant change throughout the aging process. Subcutaneous fat deposits do not increase with age.

High-calorie diets that exceed 3200 kcal per day for men and 2200 kcal per day for women have the opposite effect on aging. An increase in caloric intake is accompanied by an increase in body mass that causes the individual to decrease body mobility. This is particularly evident in Euro-American populations, who often show a steady increase in weight up to the age of 60 years. Women in particular experience a thickening in fat deposits as they mature. Blood pressure and serum cholesterol levels steadily increase. The most significant elevations begin at age 50 years, with the development of coronary artery heart disease and atherosclerosis.

Animal fat content and excess calories are not the only considerations in the dietary aspect of aging and health. Vegetarians do not always follow a low-calorie pattern. They also can have a diet rich in fats, particularly if they consume saturated fats in the form of coconut oil. Salt is another consideration in the aging of the cardiovascular system. Diets high in sodium tend to increase circulating blood volume, thereby increasing systolic blood pressure. Studies have shown that an increase in systolic blood pressure significantly increases the risk for heart disease and stroke.

Exercise plays an important role in the health of the aging individual. Most populations studied have an exercise regimen linked to their ADLs. People in cultures characterized by many intrinsic diseases, parasites, malnutrition, poor hygiene, and harsh living conditions have remarkable physical fitness because of the amount of exercise they must perform to sustain life. People in societies in which the inhabitants are overfed and underexercised do not enjoy good health in the same manner as the moderately fed and highly exercised residents of less advantaged societies.

As the body ages the endocrine system declines and the hormones responsible for the regulation of many interrelated body systems decrease in volume. Beta cells of the pancreas, thyroid, ovaries (in females), and testes (in males) exhibit less activity, which affects many other organ systems. For example:

- A decrease in estrogen production can increase the risk for osteoporosis and heart disease in women.
- A decrease in thyroid activity decreases the basal metabolic rate and increases weight gain.

- A decrease in the efficiency of insulin production decreases the efficiency of glucose metabolism.
- A decrease in testosterone production may decrease the libido in men.

Myths about Aging

Many misconceptions and myths surround the process of aging. Myths are stories created to explain the practices or beliefs of unknown origin regarding a person, place, or event. The creation of a myth about aging may be based on an isolated incident or a single observation and may not apply to all older adults.

Some myths have a small basis in fact, but most are unfounded and have a harmful effect on social policy and interpersonal relationships. Myths about the aging process may result in negative stereotypes, and a belief in negative stereotypes results in discrimination and improper treatment of the aging individual. Abnormal signs, symptoms, or behaviors exhibited by a geriatric patient usually indicate the presence of a pathologic process and should not be discounted as normal expectations of the aging process. Some of the negative myths about aging are as follows:

- *Myth:* Older adults are **senile**. *Truth:* If mental processes decline, a contributing factor, such as stroke, carotid insufficiency, or Alzheimer's disease, is usually the cause.
- *Myth:* Older adults do not engage in sexual behavior. *Truth:* Sexual desire remains throughout the life span. Sexual activity may decline because of decreased physical mobility, circulatory impairment, or the unavailability of a partner. Self-gratification may be the only outlet.
- *Myth:* Older adults always decline in health after a surgical procedure. *Truth:* The identification of problems, needs, and health considerations during the assessment phase of the nursing process decreases the probability of unmet expected outcomes.
- *Myth:* Older adults should not drive. They cause more accidents. *Truth:* Teenage drivers between the ages of 16 and 19 years have the highest rates for car accidents. They are also the group with the highest death-related accidents according to the CDC. Older individuals must keep a current driver's license through renewal, pass the eye examination, and retake a road test if safety is a question. After the age of 70, an application for renewal must be completed every 3 years (www.cdc.gov/motorvehiclesafety).

Myths and stereotypes should not be allowed to influence the assessment of geriatric patients. Every aspect of the physical, psychosocial, and ethnocultural data should be assessed as unique to each individual and not as a generic group expectation. Reaching the age of 65 years does not instantly transform individuals into being old and debilitated.

As people grow older they may experience more developmental aging before they experience physical aging. Some people become frail as they age, but this is not true of everyone. Age alone does not make individuals less productive members of society. Limitations and disabilities may be decreased because of scientific advances and a better understanding of the aging process and health-promotion activities.

Perioperative Assessment of the Geriatric Patient

The patient's ability to adapt to aging should be assessed by the perioperative nurse as part of the nursing process. With the exception of nursing diagnoses directly associated with the anticipated surgical procedure, specific nursing diagnoses should be associated with the patient's adaptation to the aging process. If positive adaptation has not been met, the risk is high for an augmentation of existing health conditions, such as a cardiovascular incident (e.g., stroke, myocardial infarction, hypertensive crisis). Comorbidity is a leading cause of death among older adults. More than 73% of all geriatric patients have more than one medical diagnosis capable of causing death; therefore recognition of potential problems in the attainment of expected outcomes is as important as identification of actual problems.[3]

Geriatric patients may present to the perioperative environment for urgent or emergent surgery because of the clinical signs and symptoms associated with a life-threatening illness. Common urgent problems include intestinal obstruction, ruptured diverticula, and orthopedic fractures. Vascular incidents such as ruptured aneurysm or bleeding from the gastrointestinal tract necessitate immediate surgery. Sudden arterial occlusion that is unresponsive to chemical treatment is also considered emergent.

The postoperative phase of care is important to the well-being of the geriatric patient. Maintaining or improving the preoperative level of wellness should be considered a primary expected outcome. A preoperative functional assessment is the foundation of the plan of care. Baseline parameters vary to a high degree among individuals, and all patients do not age at the same rate. Some patients are very young at 70 years of age, and some are very old. The difference should be assessed, and optimal outcomes should be identified for each geriatric patient. Influences on the level of functioning include physical ability, psychosocial support and resources, and environmental interactions.

Functional Assessment

Functional assessment can serve multiple purposes. In the preoperative phase the plan of care includes the patient's unique differences, family involvement, resources, and level of independence. Many of these data are obtained with observation, interview, and lifestyle questionnaires. The information may be obtained from the patient, family, or significant others.

Many aspects of the patient's unique nature are easily discerned during the preoperative interview. Adequate time should be allowed for the interview (at least 30 minutes) so the patient has time to reflect and respond. Reaction time slows with age. The nurse should listen for subtle modifications or inconsistencies in the patient's information regarding health status. Sensory deficits should be considered, and the environment should be modified as needed during the interview. The nurse should establish rapport and have respect for the patient's dignity.

During the intraoperative phase, the functional assessment may allow for anticipation of needed supplies or additional help to accommodate the patient's needs. The patient's physical capabilities allow some independence in self-care. Patients tend to regress when they are not permitted to do things for themselves. A self-care deficit takes place when a patient feels the loss of independence while restrained on an operating room (OR) bed. The freedom to assist with the transfer as able from the transport stretcher to the OR bed gives patients a sense of participation in their own care. Maintaining a high level of self-esteem and value enables patients to prevent emotional regression or loss of control.

Activities of Daily Living

During the course of a normal day an individual performs self-maintenance tasks and interacts with the environment. The ability

to perform these ADLs is influenced by health status, emotions, mental clarity, and mobility. Limitations in performing these activities may be permanent or temporary, and many of the temporary limitations can be eliminated with medical or surgical treatment.

The perioperative nurse should assess the activity level of the geriatric patient. Advance preparations may need to be considered before the patient can undergo a surgical procedure. Because of identified physical limitations, special positioning or additional padding may be needed in combination with some form of communication assistance at the time the surgical procedure is performed. The functional baseline is the patient's capacity to perform self-care (e.g., feeding, bathing, toileting). Any deviation from the baseline assessment in the postoperative phase should be recorded and reported to the patient's physician.

Functional Activities

The activity patterns of geriatric patients reflect many aspects of their daily lives. Their ability to feed, bathe, and toilet themselves is one way to measure physical and psychologic wellness. Basic daily activities such as grooming and dressing may be indicators of the level of the patient's involvement with his or her own care.

The range of self-care activities depends on various factors, such as whether the patient is active and mobile enough to shop for food and prepare meals or is living in assisted housing where these services are provided. The ability to provide self-care should be assessed preoperatively to evaluate the outcome in the postoperative phase (i.e., resumption of activity level).

Functional Capacity

A basic assessment of physical strength and endurance indicates whether the patient will be able to move from the transport stretcher to the OR bed. A patient who is weak or disabled by arthritis will need assistance or a total lift device. A patient who is visually impaired also may need assistance.

Communication through speech and hearing is vital to establishing the cognitive baseline. A hearing deficit or aphasia could be mistaken for a cognitive impairment. The patient who uses a hearing-assist device should be permitted to wear it to the OR and, if possible, throughout the surgical procedure. It should be in place during emergence from anesthesia so the patient can hear requests to deep breathe or move extremities.

The patient's sensory ability should be assessed. Tactile sensation dulls with age, and a patient's inability to feel external stimuli may lead to an inadvertent injury. Any sensory deficit, including a visual or hearing impairment, should be documented in the plan of care. The administration of a general anesthetic alters the tactile assessment parameter during the intraoperative phase of care.

As the patient emerges from anesthesia the postanesthesia recovery nurses use the baseline assessment to measure the progress of the patient in the postoperative phase. Because of the interdependent aspects of the central nervous system with other vital physiologic systems, the evaluation of expected outcomes should include a sensory assessment.

Cognitive ability also should be assessed. The patient may be required to comprehend a command that is vital to the perioperative experience. A cognitive deficit may be of organic origin or result from a language barrier. Regardless of the reason, an inability to understand can cause anxiety for the patient and the **caregiver**. Alertness, short-term memory, capabilities to concentrate and problem solve, and motivation toward self-care are areas of cognition that influence the ability of the geriatric patient to adapt to illness and recovery. A patient who is cognitively impaired experiences disorientation and responds inappropriately to the environment. The impairment may be temporary but often is prolonged after anesthesia. Cognitive impairment also may be a permanent or chronic condition.

The patient's psychologic state should be assessed preoperatively; a change in mood or temperament may indicate an unexpected outcome caused by an injury or a physical problem resulting from the surgical procedure. Dementia, delirium, and emotional depression are common in older adults. Sudden withdrawal or a change in affect should be investigated promptly.

External Interactions

The manner in which an individual experiences illness depends on external forces and the number of barriers that may interfere with the attainment of outcomes. The nursing diagnoses may include self-care deficit or impaired mobility. These diagnoses factor significantly in the postoperative phase and should be considered and placed in the plan of care. The reaction of patients to either one of these nursing diagnoses depends on their interactions with the external environment, the availability of resources, and the presence of barriers.

Resources

The level of independence exercised by the geriatric patient may depend on the resources available. The type of housing may depend on self-care ability and financial security. In developing the plan of care the perioperative nurse should consider how the patient will meet postoperative needs at home. Will help be available or will arrangements for a visiting nurse or a family caregiver be needed? The patient's possible need for transportation to and from the surgeon's office for postoperative checkups should be considered. With age comes the need for assistance, especially after a surgical procedure. Many resources are available for home health care, transportation, nutrition, legal advice, learning, and discount programs. A variety of information can be found on the Internet, government agencies for the aging, local libraries, and health care facilities. Additional information is available on the following websites:

- www.ssa.gov
- www.americangeriatrics.org
- www.eldercare.acl.gov/Public/Index.aspx
- www.AARP.org
- www.noca.org (National Council on Aging)

Barriers

The type of housing may be a problem for the postoperative geriatric patient. If the patient lives alone in a multilevel dwelling, using the stairs may pose a significant problem. The location of the bathroom or kitchen may complicate the self-care process. Financial constraints may limit the number of home health care visits by an independent agency. The inability to drive may prevent the individual from getting necessary medication and food. The unavailability of family members may necessitate planning for institutionalization, which may be temporary but may become permanent.

The perioperative nurse should be aware of possible signs of elder abuse. According to the National Institute on Aging, some signs to look for include the following:

- Physical: bed sores, burns, bruises, malnutrition, trouble sleeping

- Emotional: agitation, depression, afraid
- Neglect: unbathed, body odor, dirty clothes
- Financial: the patient may be forced to sign over all assets to another person, a lawyer may have the patient sign papers before a mental evaluation is completed.

Psychosocial Assessment

Gathering data about geriatric patients should begin with the assessment of how the individuals view other aged people and their own progression through the aging process. The assessment of a patient's self-concept may be an important indicator of a decline in the status of psychologic health. A patient's views of health and normative activity are influenced by culture and affect the attainment of outcomes.

If patients believe that older people are helpless, they may see the role of the aging process as one of helplessness. Although capable of many independent activities, individuals may adapt to an illness by becoming helpless. Even needing help temporarily may cause an older patient to believe that the condition is permanent. The perioperative nurse should be aware that the geriatric patient might experience a temporary period of helplessness. By establishing a functional baseline and stressing the temporary nature of postoperative recovery, the nurse can help patients return to their routine.

The geriatric patient may feel rejected, unsupported, and worthless. Between 10% and 65% of geriatric patients experience depression and an alteration in self-image. Depression is not part of the aging process. The physical decline may be rapid when psychologic well-being is threatened. The perioperative nurse should be aware that the geriatric patient who is depressed and lonely needs additional emotional support throughout the surgical experience.

Perioperative nurses should be aware of their own subjective views of aging and cultural attitudes and should not allow personal feelings to influence the assessment process. When assessing the geriatric patient the nurse should consider the culture of origin, the cultural influence of the patient's current residence, and the patient's subjective perception of wellness and illness.

Self-perception has a great influence on how well the geriatric patient adapts to aging. The nursing diagnoses should reflect the patient's adaptation because adaptation affects the attainment of the expected outcomes. The perioperative plan of care should reflect the need for ongoing evaluation by postoperative caregivers.

Adaptation to the Aging Process

An individual should make many adjustments during the aging process. The adaptation to aging is unique for each individual and is influenced by physical condition, psychologic strengths and weaknesses, family and significant others, social support systems, financial resources, and functional ability. The geriatric patient develops a belief system about life expectations primarily on the basis of subjective feelings.

If the patient's condition is in decline, the outlook is usually negative based on how the patient feels at a particular time. If the patient is feeling well and able-bodied, the outlook is usually positive, which helps delay the patient's fear of declining health outside the expected parameters of aging.

The prevention of decline not related to normative aging is an important factor in avoiding health deficits. The patient who can postpone health problems caused by factors that include avoidable health considerations—accidents, poor nutrition, inactivity, depression, and the effects of loneliness, smoking, substance abuse, and obesity—enjoys a higher quality of life in the later years.

Self-Perception of Health

The patient's view of his or her health plays an important role in the actual health status. If the patient perceives health as important, preventive health maintenance should be a priority. Patients who feel well perform ADLs to the best of their ability. Minor interruptions in health status do not cause a major problem in the long-term prognosis of the patient's return to baseline parameters.

Physical Assessment

The physical assessment of the geriatric patient begins with general appearance. The perioperative nurse should first observe the patient from head to toe. The basic picture or image the patient creates can provide information about the health status. The patient should be assessed for posture, mobility, gait, rising or sitting, dexterity, body height and weight, abdominal girth, body odors, psychologic affect, communication, and comprehension of surroundings. The perioperative nurse should perform an assessment of the total patient by each body system. A summary of the physiologic changes associated with the normal aging process is provided in Table 9.1.

Any medications the patient takes on a routine or periodic basis should be listed on the chart, with the last dosages itemized. The patient should be encouraged to discuss all medications, including vitamins and topical ointments. Recreational drugs (e.g., street drugs, narcotics) should not be excluded from consideration just because the patient is older. Glomerular function and metabolism can cause drugs to remain in the patient's system for prolonged times, thereby increasing the circulating serum concentration when the next dose is taken.

Many medications can alter the results of blood work and the findings of the physical assessment. Patients with multiple physicians may have prescriptions for drugs that interact with each other. Drugs such as aspirin can alter blood tests for clotting times. Pain medications can alter sensorium.

Smoking and alcohol use are important assessments because they can affect many body systems. All assessment data should be recorded in the chart. The perioperative nurse should read the physician's medical history and physical examination report and review laboratory reports to discern the medical diagnoses. Any additional abnormal findings should be reported to the surgeon and the anesthesia provider.

Integumentary System

Establishing a preoperative baseline for the condition of the skin facilitates evaluation of the expected outcome (i.e., no injury to the skin as a result of surgical intervention). Assessment of the integumentary system includes the skin, fingernails and toenails, and all hair patterns of the body, face, and scalp. The nurse should ask the patient whether any skin changes have taken place within the past several months.

The skin is inspected for color, temperature, sensation, texture, turgor, thickness, and amount of subcutaneous tissue. The geriatric patient has a decreased number of sweat glands and an increased sensitivity to external temperature. The patient may have skin dryness, itching, and flaking.

The surface of the body should be inspected for sores, ulcers, and moles that have exhibited change over time. Broken or

TABLE 9.1 Physiologic Changes Associated with Normal Aging Processes in the Geriatric Patient

Age-Related Factors	Assessment Factors
Integumentary System	
Decreased subcutaneous fat, decreased turgor (elasticity)	Thin dry skin, wrinkles
Diminished sweat glands, dulled tactile sensation	Poor thermoregulation, heat and cold sensitivity
Thickened connective tissue	Keratosis (patchy overgrowths of dermis), warts, skin tags (especially on face and neck)
Increased fat deposits over abdomen and hips	Poor excretion of fat-soluble drugs
Diminished capillary blood flow, reduced vascularity, capillary fragility	Pressure sores, delayed wound healing, purpura or lentigo (liver spots), bruises
Dry mucous membranes, decreased salivation and secretions	Dry mouth and vagina
Musculoskeletal System	
Diminished protein synthesis in muscle cells, decreased muscle mass and tone	Muscle weakness, reduced strength, muscle wasting
Erosion of cartilage, thickened synovial fluid, fibrosed synovial membranes	Joint pain, swelling, stiffness, diminished range of motion
Diminished mobility, flexibility, and balance	Poor gait, poor posture, risk for falling
Increased porosity and demineralization of bone, thinning of intervertebral discs, decreased height	Ankylosing spondylosis, kyphosis, osteoporosis
Respiratory System	
Atrophied respiratory muscles, kyphosis or other postural changes, ribcage rigidity	Chest wall limitations
Reduced vital capacity	Dyspnea
Risk for pneumonia	Ineffective cough
Cardiovascular System	
Decreased cardiac output and stroke volume	Chronic fatigue and dyspnea, orthostatic hypotension
Myocardial irritability and stiffness, decreased size of sinoatrial and atrioventricular nodes	Slow heart rate and circulation, dysrhythmias and murmurs
Increased vascular resistance, rigidity in arteries	Hypertension
Thickening and dilation of veins	Venous insufficiency, varicosities
Decline in renal blood flow	Edema in tissues
Gastrointestinal System	
Decreased esophageal peristalsis, slowed emptying of stomach	Indigestion, frequent antacid use
Diminished saliva production, which slows breakdown of carbohydrates; reduced gastric secretion of hydrochloric acid, which impairs absorption of vitamins and minerals; hepatic insufficiency, which affects absorption of fats	Malnutrition
Loss of perineal and anal sphincter tone	Diarrhea, fecal incontinence
Decreased intestinal peristalsis, loss of abdominal muscle turgor, reduced mucosal secretions in intestines	Constipation, frequent laxative use
Endocrine System	
Reduced hormonal activity, decreased physical activity	Slowed basal metabolic rate, subnormal temperature
Slowed release of insulin from pancreas	Impaired glucose metabolism
Reduced thyroid hormone production	Dry skin, temperature intolerance, poor appetite, lethargy, memory lapse
Disturbed fluid and electrolyte balance	Hydration status
Genitourinary System	
Decreased renal blood flow, reduced number of glomeruli, reduced glomerular filtration rate, decreased excretory ability	Diminished renal function, risk of acid-base imbalance and drug toxicity
Loss of elasticity and muscle tone in ureters, bladder, and urethra	Urinary frequency, urgency, and nocturia
Decreased bladder muscle and sphincter tone, estrogen deficiency in female	Stress incontinence
Enlarged prostate in male	Urinary retention
Reduced testosterone levels, hypertrophied prostate, sclerosis of penile arteries and veins	Male: slow erection and ejaculation
Reduced estrogen levels; atrophied vulva, clitoris, and vagina	Female: sagging breasts, painful intercourse

Continued

TABLE 9.1 Physiologic Changes Associated with Normal Aging Processes in the Geriatric Patient—cont'd

Age-Related Factors	Assessment Factors
Nervous System	
Decreased number of brain cells, reduced cerebral blood flow, reduced oxygen supply to brain	Cognitive deficits: delirium, temporary state of confusion, forgetfulness, disorientation, irritability, and insomnia; dementia, a permanent state of cognitive impairment
Decreased neurons Diminished neurotransmitters, decreased neurons	Paresthesia, akinesia, diminished pain perception Tremors, head nodding, and other repetitive movements
Degeneration of myelin sheath, which lessens motor neuron conduction Reduced sound transmission as eardrum thickens, decreased hair cells and neurons, reduced blood supply to cochlea	Slowed reflexes and reaction time Auditory impairment
Weakened lens muscles; hardening of lens; flattening of cornea; reduced blood supply, which leads to macular deterioration; increased rigidity of iris; reduced pupil size	Visual impairment: decreased acuity, poor perception of light and color, poor peripheral vision

injured skin areas may indicate a pathologic condition such as skin cancer or diabetes. Skin rashes may indicate an allergy. Skin color can indicate liver disease or problems with other body systems (e.g., cardiovascular, respiratory). Bruises or abrasions may indicate a recent fall or possible elder abuse.[4]

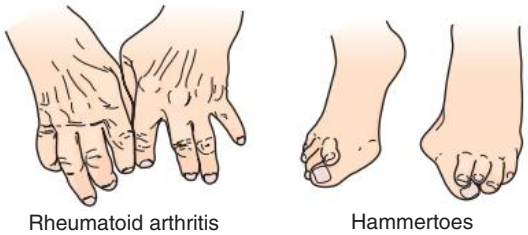
Careful assessment of the body surface can reveal pertinent data about the patient's health status, but differentiating normal from abnormal skin conditions may be difficult. Skin is often wrinkled as a result of changes in connective tissue. Pigmentation and skin tags can be normal lesions in the aging process.

The nails and nailbeds of the fingers and toes should be observed for their presence or absence, texture, growth pattern, cleanliness, infection, and color. Clubbing and cyanosis of the fingertips and nailbeds may indicate cardiovascular disease. Extreme overgrowth and deformity of the toenails may indicate decreased circulation to the feet and legs. An accumulation of soil and debris under the nails may indicate an inability to wash properly. Twisted and gnarled digits may be painful to the touch, which should be considered when planning positions for the surgical procedure (Fig. 9.1). The perioperative nurse should be aware that even the weight of the surgical drapes might create enough pressure to cause discomfort on the toenails.

Hair patterns on the scalp may show areas of thinning or loss. The nurse should note the condition of the hair, such as cleanliness, hair dye, and grooming. The condition of the hair may indicate the patient's level of interest or ability in performing self-care. A lack of care may be caused by inability or disinterest caused by depression. A patient with dementia may be unaware that the hair is dirty or uncombed.

Body hair patterns may be sparsely distributed in geriatric patients, with areas of thinning or absence. For this reason, hair removal from the surgical site is not routinely indicated.

The extremities should be observed for patterns of hair growth or its absence. The lower legs may not have much hair because of circulatory changes. The color of the legs should be observed at this time; duskiness and mottling may indicate a problem with arterial blood flow, whereas ruddiness may indicate a venous blood flow problem and possible deep vein thrombosis risk. The shape, size, and equality of the lower legs should be checked for edema or ulceration. The condition of the extremities may have implications for positioning during the surgical procedure and may indicate the need for further systemic testing.



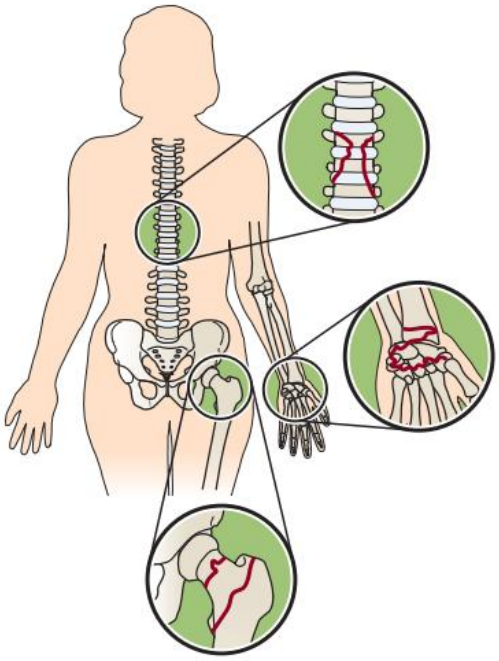
• **Fig. 9.1** Deformities of the hands and feet.

Musculoskeletal System

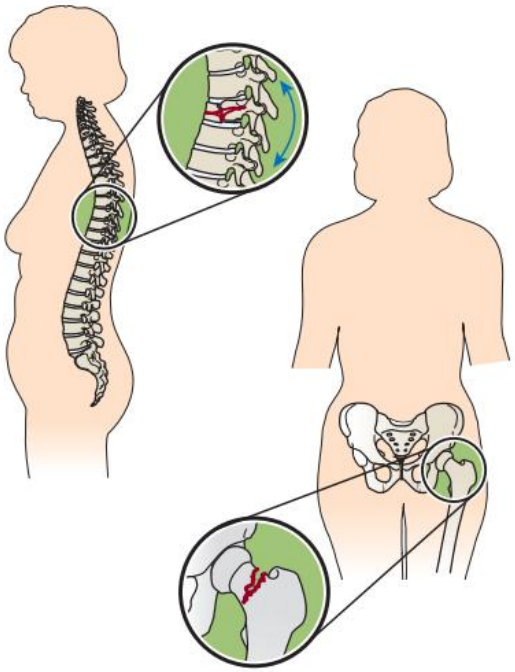
Assessment of the musculoskeletal system includes muscles, bones, posture, and gait. Muscle mass is usually decreased because muscle fibers atrophy, decrease in strength, and are fewer in number as noted in sarcopenia. Fibrous tissue replaces the lost mass. With less exercise and motion, muscle strength is compromised. Tendons become hardened, and range of motion decreases. Muscle cramps are common.

The patient may report a decrease in height. This is caused by demineralization of the bones, kyphosis, and narrowing of disk spaces in the vertebral column. The long bones do not decrease in length but become thin and brittle (osteoporosis), especially in older women; 78% of all patients older than 70 years have some degree of osteoporosis that is complicated by osteoarthritis (Fig. 9.2). Estrogen supplements after menopause may decrease the occurrence of brittle bones. However, fractures in the hips, vertebrae, wrists, and ends of long bones are common in older adults (Fig. 9.3).[5]

Assistance with moving or total lifting may be necessary to help the geriatric patient move from the transport stretcher to the OR bed for the surgical procedure. The plan of care should include lifting help or devices and adequate positioning supplies. Care must be taken not to injure bony structures that may be weakened by osteoporosis. Care is taken when log rolling by placing the hands at the shoulder and hips, rather than grasping the



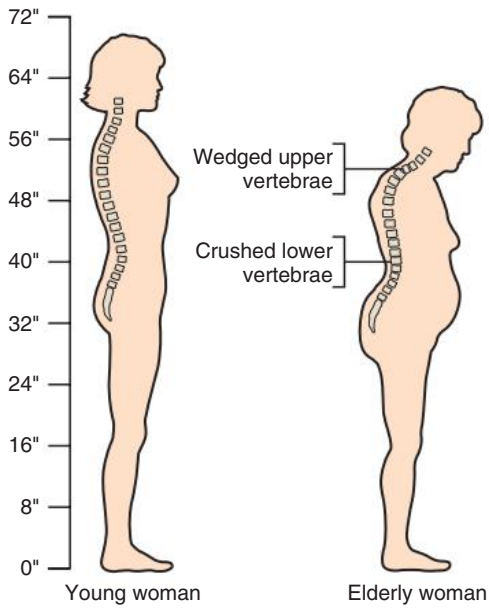
• **Fig. 9.2** Areas of the body commonly affected by osteoarthritis.



• **Fig. 9.3** Spontaneous fractures in the geriatric patient.

ribcage. Ribs are easily fractured and vertebrae can break when twisted.

Ankylosing spondylosis, a chronic inflammatory disease characterized by the fixation or fusion of a vertebral joint, often causes age-related postures. The body of the geriatric patient assumes an altered shape with an increased forward thoracic curvature (kyphosis) and a flattening of the lumbar curvature, particularly common in patients with osteoporosis (Fig. 9.4). The patient may not be able to lie flat on the OR

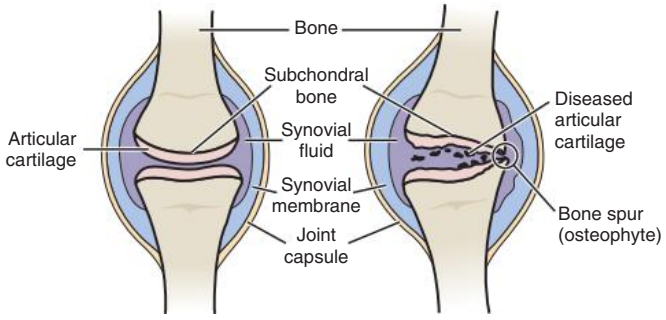


• **Fig. 9.4** The effects of osteoporosis.

bed. Supine positioning may be painful unless the upper back and neck are supported. Fractures or subluxation of the cervical spine are possible if the ankylosed neck is allowed to fall back with the weight of the head. Twisting and forceful flexion can cause permanent damage to the vertebral column or contribute to rupture of the vertebral arteries.

Anteroposterior angles of the chest may be increased because of respiratory disease. Respiratory effort and chest excursion should be considered in planning positioning. In the preoperative assessment the flexibility of the patient's spine and the presence of any deformity or associated disease should be noted. Flexion at the hip may be painful when the legs are maintained in a straight position. Placement of a safety belt over the thighs may exert counterpressure on the thighs and cause the legs to forcefully straighten against the flattened lumbar curvature. Modified positioning may include a small pillow under the knees to allow the natural flexion angle of the hips. Care in the placement of a safety belt or other restraint should include circulatory checks throughout the surgical procedure. The blankets should not exert pressure on the toenails, which can be painful.

The hands and feet may have painful deformities that should be considered when moving the patient to the OR bed and during positioning. Joints may be affected by arthritis, thickened synovium, and crystalloid formation in the synovial fluid. Patients may have osteoarthritis (Fig. 9.5) caused by cartilage



• **Fig. 9.5** Osteoarthritis.

degeneration, or they may have rheumatoid arthritis (Fig. 9.6) caused by the attack of the autoimmune system on joint lining. Either type of arthritis can cause pain on motion and positioning difficulties.

The patient may have a long history of taking herbal preparations,[6] nonsteroidal antiinflammatory medications, corticosteroids, salicylates, and analgesics. The preoperative assessment should include an evaluation for the side effects associated with long-term use of these medications. In reality, several herbs used by older people to improve memory and circulation are forms of anticoagulants. Gastrointestinal bleeding, prolonged clotting times, renal insufficiency, liver changes, loss of appetite, and alteration in mental status are common side effects that could adversely affect the desired outcomes of the surgical procedure.

The patient's center of gravity is altered by multiple changes in body shape. Postural imbalance caused by impaired mobility is often the cause of falls that result in fractures. Some geriatric patients limit attempts at ambulation because they fear the possibility of falling. The risk for falls is further increased by complicating conditions such as sedation, electrolyte imbalance, impaired vision, and altered proprioception (muscular stimulation). Orthostatic hypotension contributes to the potential for falling when the geriatric patient rises from a sitting position and experiences a sudden drop in blood pressure. A fall may be symptomatic of a health problem or a systemic illness.

Cardiopulmonary System

Assessment of the lungs, heart, and circulation provides a good source of information about the general health of the patient. The cardiovascular and respiratory systems are closely interrelated. For assessment of the lungs the nurse should ask the patient to describe how breathing is affected by exertion. The nurse can assess difficulty or inefficiency in breathing by observing the patient's physical activity, respiratory effort, chest shape, and lip color for circumoral cyanosis. The nurse should palpate the trachea to determine whether it is in midline. A deviation to the right or left may indicate the presence of a tumor. Tracheal position is an important consideration in the maintenance of an airway during a surgical procedure.

By listening to lung sounds with a stethoscope over the intercostal spaces, the nurse can refine the assessment to include specific sounds found in identified areas of each lobe. Percussion of the posterior chest wall tends to produce resonance, except in very thin older adults in whom tone is hyperresonant. The normal sound is hollow and moderately loud, with a low pitch and long duration; the sound flattens over the rib bones. If the patient slumps forward and rounds the shoulders, the intercostal spaces widen for better percussion.

Establishment of a preoperative respiratory system baseline is important. Intraoperative breathing difficulties may be avoided by adapting a position to accommodate the needs of the patient. Postoperative problems may be diagnosed and treated more efficiently if the patient's original respiratory condition has been assessed. Lung disease may affect the ability to clear secretions from the bronchial tree with coughing. Pneumonia is a common postoperative complication in geriatric patients. Coughing and deep-breathing exercises should be taught preoperatively.

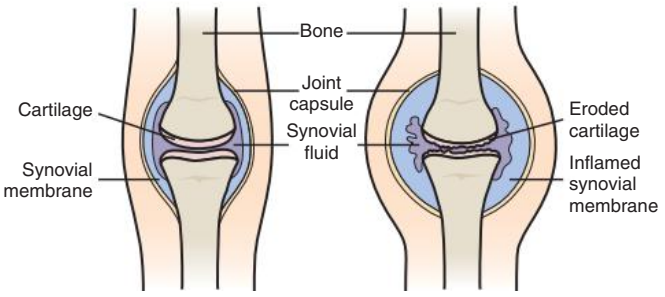
The heart and systemic circulation are assessed as separate units and together as a system. The patient should be asked whether dizziness, fainting, palpitations, or other abnormal subjective symptoms are experienced. The perioperative nurse should listen to heart sounds with a stethoscope.

Dysrhythmias unrelated to heart disease are not uncommon in the geriatric patient, and many have systolic murmurs caused by aortic stenosis. The sinoatrial and atrioventricular nodes decrease in size with age, and signal interruption may occur. Clicks, murmurs, and abnormal sounds should be recorded in the assessment data. The apical pulse should be counted and compared with the peripheral pulses of the radial, popliteal, posterior tibial, and dorsalis pedis arteries. A difference between the apical and the peripheral pulse may indicate an obstruction in a major artery. The jugular veins should be observed for distention. Veins in the lower extremities should be inspected for varicosities. Leg pain caused by circulatory impairment is common in older adults.

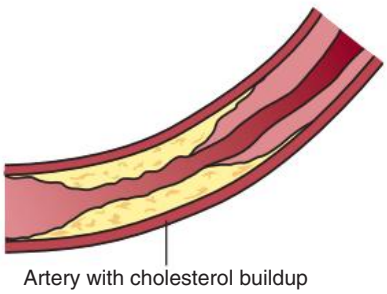
The carotid arteries should be auscultated with a stethoscope. Bruits and systolic murmurs, which are abnormal sounds, may indicate an evolving blockage (Fig. 9.7). Dizziness or cognitive impairment may be caused by carotid insufficiency. Care must be taken not to exert pressure over the carotid area because manipulation of a plaque could cause an embolus to break loose and travel to the brain. Sudden changes in mental status during a surgical procedure performed with a local anesthetic could be the result of an arterial occlusion caused by a plaque embolus.

The geriatric patient usually has decreased or slowed circulation to all areas of the body. This should be considered with administration of local anesthetics, because absorption of the medication takes longer and the effects are delayed. The surgical site should be tested for the effects of the anesthetic before the incision is made. Vasoconstrictive additives, such as epinephrine, may have an exaggerated effect. Postoperative dressings should not be applied too tightly because healing is affected by circulatory efficiency.

Blood pressure should be assessed with the patient in the sitting and lying positions and measured in both arms. Elevated systolic and diastolic blood pressures caused by arteriosclerosis are a common finding in 40% of the geriatric patient population.



• **Fig. 9.6** Rheumatoid arthritis.



• **Fig. 9.7** Atherosclerosis and plaque of the carotid artery.

Assessment of laboratory blood values is important. Anemia is common among older adults and is often overlooked as a potential cause of cerebral ischemia. Both men (21%) and women (34%) have slight normal decreases in hemoglobin and hematocrit levels because the blood-forming mechanisms lose efficiency with age. In men the decrease in androgen production may cause a noticeable decrease in hemoglobin.

Extreme decreases in hemoglobin and hematocrit values are significant in the diagnosis of pathologic conditions in major organ systems, especially the gastrointestinal or genitourinary system. Anemic conditions also can be caused by a nutritional deficit. In the absence of any other confirmed pathologic condition, hemoglobin or hematocrit levels less than the lower limit of altitude-adjusted normal values (at sea level: hemoglobin 12 g/dL, hematocrit 35%) may signal anemia caused by malnutrition.

The white blood cells do not decrease in number, but they do decrease in effectiveness. Inflammatory responses may be decreased or absent in the geriatric patient. This natural body response to injury may leave the patient more vulnerable to infection. The febrile response to infection may be diminished and therefore may not be a good indicator of a disease process. Older adults often have a subnormal baseline temperature.

Gastrointestinal System

Assessment of the gastrointestinal system should begin with observation for the visual signs of nutritional status, such as body weight, muscle wasting, bloating, and generalized weakness. Postoperative healing is profoundly affected by the ability of the cells to repair themselves. Both adequate nutrition and the ability to handle the necessary nutrients in the gastrointestinal system are essential for tissue restoration.

Many socioeconomic, psychologic, and physiologic factors influence the nutritional status of the geriatric patient. Living on a fixed income may limit the amount of nutritious food a patient can purchase. An adequate diet should include at least 1 g of protein per kilogram of desirable body weight, with an emphasis on a decreased number of calories. The average daily caloric intake of an older woman should range between 1280 and 1900 calories; for an older man the average daily caloric intake should range between 1530 and 2300 calories.

The perioperative nurse should keep in mind that actual caloric needs are unique for each patient and may vary in the presence of diabetes or other disease processes. A rapid weight gain or loss may indicate a serious pathologic condition and not an increase in body fat. Dietary control should focus on the quality, not the quantity, of food. Weight should be considered a vital sign in older adults and should be recorded in both pounds and kilograms because many medications are prescribed according to body weight in kilograms.

Psychologically, the patient may feel that food does not taste right and may refuse to eat. Many psychologic reasons for malnutrition are rooted in a physiologic cause. The geriatric patient's appetite may be decreased because of fewer taste receptors in the mouth. Nutrition in the older adult can be affected by physiologic anorexia associated with aging. Alterations in taste and smell can affect the desire to eat. Men are affected more often than women. Nutritional status should be assessed when planning to keep the patient on nothing by mouth status in anticipation of a planned surgical procedure. The patient's teeth may be in disrepair. Some patients are totally edentulous (toothless). The inability to taste, chew, and swallow discourages eating. Saliva production decreases and makes swallowing more difficult. Loose or missing teeth must be assessed because of the danger of aspirating a tooth during the surgical procedure. Patients with dentures, bridges, or partials may need to remove them just before general anesthesia. If dental appliances are removed in the OR, they must be placed in a labeled cup and placed with the patient's belongings. The anesthesia provider may want dentures left in the patient's mouth to have a better fit of a facemask for oxygen. Many patients are embarrassed and do not want to be seen without their teeth. In 2016 the Older Americans Act added funding for oral health because research shows periodontal disease can lead to disease in several body systems, such as the cardiac, pulmonary, and musculoskeletal systems.

During the preoperative assessment the perioperative nurse may find that a decreased ability to taste salty and sweet foods may cause the patient to increase the amount of salt and sugar in the diet. Increased salt intake may predispose the patient to congestive heart failure and fluid retention. Added sugar in the diet may cause an increase in unwanted body fat in proportion to muscle mass and difficult management of blood glucose.

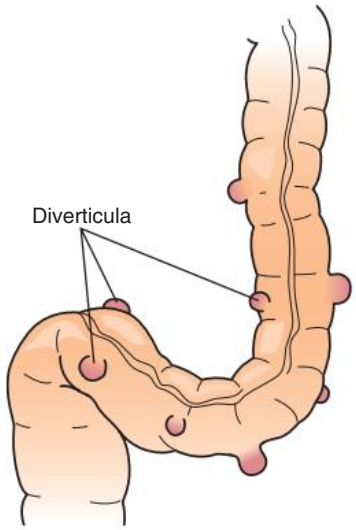
The geriatric patient undergoing general anesthesia may receive stimulants and depressants; many of these are fat soluble. The fat-soluble drugs absorb faster but are excreted more slowly because of lower levels of intracellular fluid. Medications are unevenly distributed in the body, and the anticipated actions are unpredictable because fewer receptor sites react to the presence of the drug.

Digestion can be assessed by questioning the patient about food intake and the effects of the presence of food in the stomach. Older adults have decreased stomach motility, decreased gastric secretions, and slower stomach emptying time. Food may remain in the esophagus for longer periods. The esophagus and lower stomach lose muscular tone and dilate slightly. This phenomenon is referred to as "antral stretch" and simulates fullness and satiety.

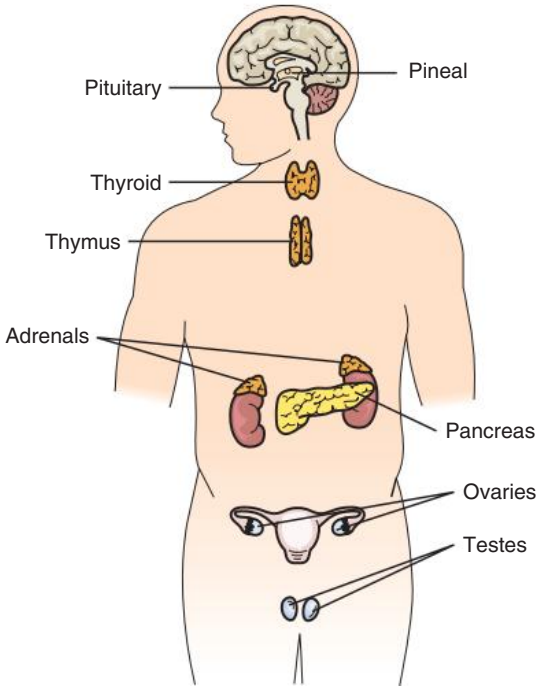
The perioperative nurse should ask the patient about the use of antacids and laxatives. Frequent use of antacids may indicate swallowing or stomach problems that should be investigated. Esophageal reflux in the presence of a hiatal hernia may need to be assessed preoperatively to prevent aspiration of gastric secretions. The inability to lie flat with food in the stomach may be the first symptom of a high-risk situation. Positioning and rapid-sequence induction of anesthesia may be considerations. Cricoid pressure (Sellick's maneuver) or awake intubation may be necessary to prevent aspiration.

The geriatric patient may use laxatives to maintain bowel regularity. Constipation is caused by decreased motility, lowered intake of bulk and fluids, and inactivity. Oil-based laxatives can lead to malabsorption of the fat-soluble vitamins A, D, E, and K, which further impairs nutritional and general health status. The absorption of nutrients is impaired naturally in older adults as a process of aging because intestinal blood flow is reduced and the absorptive cells lining the intestines are decreased. Diverticulosis and diverticulitis are common (Fig. 9.8). Fiber is an important dietary additive but should be used with caution because it can cause bowel obstruction or diarrhea. Diarrhea in the geriatric patient causes a serious threat to well-being because it may lead to dehydration.

The minimum oral fluid intake should be 1500 mL/day. Some geriatric patients have limited fluid intake. A patient may fear incontinence, have altered sensorium and cognition, be unable to drink fluids independently, or have a decreased thirst sensation as part of the aging process. The serious nature of fluid balance in



• **Fig. 9.8** Diverticulosis.



• **Fig. 9.9** Endocrine glands.

older adults is reflected in unstable electrolyte values and their direct effect on cardiac status.

The perioperative nurse should perform a preoperative assessment of hydration. Signs of dehydration are dry tongue, sunken cheeks and eyes, severe loss of skin turgor, concentrated urine, and in some instances mental confusion. Blood tests may show a urea level greater than 60 mg/dL. A geriatric patient who is dehydrated should receive preoperative intravenous (IV) fluids to prevent complications.

Endocrine System

The endocrine system interfaces with all major systems of the body. The assessment of endocrine functioning is complicated by the normal age-related changes in other body systems. The endocrine system consists of the thyroid gland; the parathyroid gland; the pancreas; the adrenal, pituitary, and pineal glands; and the ovaries or testes (Fig. 9.9).

Thyroid hormone production decreases by age 60 years in men, whereas women experience decreased production by age 70 years. By 80 years of age the thyroid gland reduces thyroid hormone production by 50%. The effects of this decreased production may be dry skin, memory lapse, temperature intolerance, lethargy, and appetite disturbance. Many signs and symptoms of thyroid disease may be confused with the normal aging process. Comorbidity may lead to abnormal laboratory test results in a patient with normal thyroid function.

Insulin is produced by the beta cells in the pancreas and affects the metabolism and storage of glucose. In healthy patients, glucose levels in the blood cause the pancreas to release insulin. The response of the pancreas is slowed in older adults, and the release of insulin may not be triggered by the same stimulus. Many geriatric patients have diabetes mellitus with impaired glucose metabolism.

A precursor to diabetes is metabolic syndrome, characterized by elevated triglycerides, low high-density lipoprotein, hypertension, high uric acid levels, and high blood glucose. The patient has a larger abdomen-to-hip ratio caused by fatty deposits on the abdominal viscera fat buildup in the skeletal muscles. Males are affected more than females. Increased exercise and an appropriate diet can forestall conversion to diabetes in geriatric patients.[7]

Diabetes mellitus may be caused by deficient insulin production, insensitive insulin receptors, altered insulin release mechanisms, or inactivation of circulating insulin. An imbalance in blood glucose levels during the surgical procedure may predispose the patient to an unwanted outcome. Patients with diabetes mellitus often experience more postoperative infections and complications than do patients without diabetes.[7] Uncontrolled blood glucose metabolism has negative implications for all major body systems. Therefore ongoing assessment is important to attain expected outcomes.

Genitourinary System

Assessment of the genitourinary system includes the bladder, urethra, ureters, kidneys, reproductive history, and genitalia. The first noticeable sign of a problem with the genitourinary system may be the odor of urine on clothing. The odor may be caused by lack of cleanliness but is usually from incontinence. More than 30% of the older population experience some form of urinary incontinence, but many are reluctant to discuss this problem and may try to avoid it. The problem may stem from stress incontinence, confusion, neurologic disorders, urinary tract infection, or immobility that prevents the patient from getting to the bathroom quickly.

The geriatric patient may fear loss of bladder control during the surgical procedure. Previous bladder or prostate gland surgery may predispose a patient to involuntary urine release. The perioperative nurse should include this situation in the plan of care. The problem may be minimized during the surgical procedure if the patient has an opportunity to empty the bladder preoperatively. The nursing diagnoses should reflect not only urinary incontinence but also the associated anxiety level of the patient.

Assessment of the genital area should include observation of the perineum for redness and excoriation. The bladder should be palpated with the patient in the supine position. The presence of a distended bladder after the patient has voided may indicate

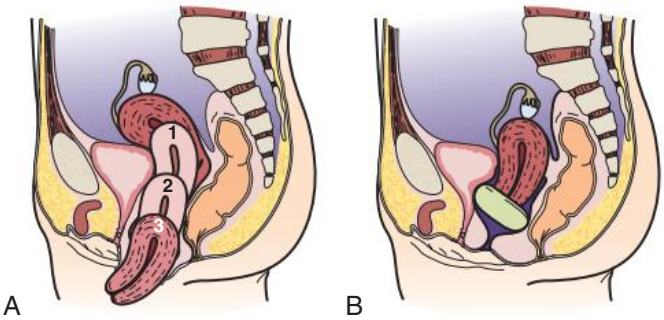
urinary retention with an overflow condition. This condition should be checked preoperatively before the patient is catheterized in the OR. The urethra could be inadvertently traumatized if an obstruction (e.g., tumor, enlarged prostate gland) is present.

The effectiveness of the kidneys decreases as the patient ages. By the time a person reaches 50 years of age, renal blood flow and glomerular filtration rate decrease by as much as 50%. Although no overt signs of a disease process may be found, the perioperative nurse should be aware that the older patient is at increased risk for renal insufficiency and is highly susceptible to fluid overload, dehydration, and renal failure.

The perioperative nurse should make a baseline assessment of intake and output. During the surgical procedure, urinary output may be used to monitor the renal status of the patient. Renal impairment may delay the excretion of drugs by the kidneys and further complicate fluid balance. The urine should be assessed for color, concentration, presence of particulate matter, and odor. Urinary output during the procedure should be at least 30 mL/hr; more urine may be produced if the patient is taking diuretics or medications for blood pressure or cardiac control. Monitoring urinary output is difficult if the patient does not have an indwelling catheter or experiences urinary incontinence during the procedure. Postoperative care should include emptying the bladder to evaluate the expected outcome of adequate urinary output.

The reproductive assessment consists of the number of pregnancies a woman had during her childbearing years. Data about the method of birth should be included. Childbirth via cesarean section or a previous gynecologic surgery may indicate the possibility of pelvic adhesions that may be encountered if the planned surgical procedure includes entering the peritoneal cavity. Multiple vaginal births may cause uterine and bladder prolapse. The presence of an intravaginal pessary for uterine or bladder elevation should be noted (Fig. 9.10).[a]

Female patients scheduled for surgery to obliterate the vagina to support pelvic organs should be counseled concerning the inability for coital function postoperatively. Surgical closure of the vagina is referred to as *vaginal colpocleisis* or *LeFort's procedure* and involves strengthening the levator muscles and high perineorrhaphy. The patient's physiologic condition dictates whether full or partial colpocleisis is performed. This method is not the first choice for pelvic organ support but may be the best option in a very ill patient who is no longer sexually active.



• **Fig. 9.10** **A,** Uterine prolapse. **B,** Donut pessary in place for correction of uterine prolapse.

The use of estrogen replacement therapy should be documented with the current dosage and the last doses taken. The possibility of osteoporosis and heart disease is greater in older women who have not had estrogen replacement after menopause.

The breasts of both male and female patients should be palpated for masses. The male patient may exhibit gynecomastia, which is an increase of breast tissue caused by decreased production of testosterone. Previous mammograms should be available if breast surgery is planned. Any hormonal therapy should be noted in the assessment. If a biopsy of the breast is performed, the specimen may be tested for estrogen receptor sites. The loss of fibrous breast tissue in the woman is normal. The main palpable finding is the terminal milk ducts, which feel like strands or spindles. Masses are not a common finding and should be investigated.

Nulliparous women and those with a history of hormone replacement therapy may be predisposed to breast cancer. Nipple discharge or retraction may indicate a serious condition. The breasts of the older adult woman may be pendulous and flaccid. Prepping and draping may be slightly more difficult because of sagging skin and lack of muscle tone.

In males, size of the genitalia may be diminished. The penis may be smaller, and the testes descend lower into the scrotum because the rugae are decreased or absent. Pubic hair may be sparse, pale, and coarse. The ability to achieve an erection may be decreased or absent, and the ability to ejaculate may be diminished. Orgasm may still be possible without the presence of an erection. The ejaculate may flow retrograde into the bladder. Assessment should include the use of erectile dysfunction drugs, both prescribed and over-the-counter "male enhancement" forms. These drugs affect the cardiovascular system and may have an effect on the anesthetic process.

The prostate may be enlarged, and the incidence of prostate cancer increases with age. The male geriatric patient may experience embarrassment during a prostate examination; all efforts should be made to preserve his dignity.

Positioning for this examination may be difficult because of inflexible joints. The patient can be placed in a lateral, modified jackknife or a modified dorsal recumbent position. The presence of stool may hinder the palpation.

For many prostate biopsies, transrectal ultrasound and needle aspiration are used. Rectal sphincter tone should be assessed in the patient who is undergoing a transrectal procedure. Anal tears, hemorrhoids, fissures, and defects in the musculature should be documented in the assessment data. Any stool present on the examiner's gloved finger should be tested for occult blood to establish the baseline; otherwise, postoperative bleeding could be wrongly assessed as a problem caused by the surgical procedure. Baseline data may help resolve the situation. Keep in mind that inserting a urinary catheter into the urethra may be impeded by an enlarged prostate gland. If difficulties are encountered, the surgeon should be consulted and a stylet used.

The female genitalia should be assessed both externally and internally. The patient should be placed supine in a modified lithotomy position. Spinal curvature or respiratory difficulty may prevent the patient from lying flat, and arthritic joints make lithotomy positioning painful. Care should be exercised not to create embarrassment during the examination. The vulvar area should be inspected. The mons and labia appear smaller and looser because of the loss of subcutaneous fat pads and the

[a]Pessaries are sometimes used for conservative treatment of prolapsed pelvic organs. Some women use a pessary to minimize urinary incontinence. Patients are taught to remove the device for cleaning before bedtime and replace it in the morning. Pessaries are useful for the patient who cannot withstand a surgical procedure for prolapse, cystourethrocele, or rectocele.

decrease in estrogen production. Lesions and discolorations should be noted. The skin of the perineum may be shiny, atrophic, and dry. The prepuce and clitoris may be atrophied, but orgasm is still possible. The vaginal opening may appear small, dry, and inelastic. A previous history of gynecologic surgery, such as hysterectomy or oophorectomy, should be obtained. The absence of the uterus or ovaries does not preclude examination of the vaginal vault. The anus should be inspected for tears, fissures, and hemorrhoids.

The internal assessment of the female genitalia includes a gentle examination that involves insertion of a gloved, well-lubricated finger into the vagina. The vagina may feel shortened. The position of the bladder, rectum, and cervix should be ascertained. Protrusion of the bladder, rectum, or cervix may be present because the patient experiences a loss of muscle tone with age. The abdomen is palpated as the uterus is carefully elevated. The uterus atrophies as part of the aging process; enlargement is caused by disease. The endometrium still responds to the stimulation of hormonal therapy, causing uterine bleeding. The adnexa are identified, and no masses should be palpable.

The use of a smaller, prewarmed, well-lubricated speculum is usually necessary for visualization of the cervix and for obtaining a Papanicolaou (Pap) smear. Pediatric instrumentation may be needed. The vaginal lining looks thin, smooth, dry, and atrophied. Care is essential to prevent trauma when fingers or instruments are inserted into the vagina. Discharge and foul odors are abnormal and should be reported. Vaginal bleeding is a sign of a pathologic condition in the older, postmenopausal woman.

Sexuality in older adults is an often overlooked and ignored reality. The activity between geriatric sex partners may vary in performance, but sexual pleasure is not abandoned because of advancing age. Intercourse may not take place in the same way as when the partners were young, but sexual contact and mutual gratification remain pleasurable. Many geriatric patients have been forced to deny their sexuality because of the loss of their sex partner. Self-gratification may be practiced but is not openly discussed because of the personal nature of the act.

The subject of sexuality should be approached gently, without jokes or condemnation. Dislocations of total hip joint prosthetics can occur during sexual intercourse. A surgical procedure—such as colpocleisis, orchiectomy, or vulvectomy—that may alter sexual habits can be devastating. Empathy is critical to the patient's adjustment to a change of lifestyle. Counseling may be necessary to assist the patient and the sex partner in expressing concerns. The perioperative nurse should be prepared to answer questions and listen to patients as they express a sense of loss. When appropriate the plan of care should reflect the nursing diagnosis of sexual dysfunction or ineffective sexuality patterns.

Nervous System

Assessment of the nervous system includes the brain, spinal cord, peripheral nerves, and sensory organs. The nervous system is uniquely interdependent with every system of the body. Age-related changes in the brain consist of a decreased number of neurons, a decreased rate of impulse transmission, an increased reflex response time, and a decreased brain mass.

The perioperative nurse should assess the geriatric patient and establish a baseline of neurologic function. Any deviation from baseline during the surgical procedure may indicate the presence of an additional or new pathologic condition involving the brain (e.g., stroke). Postoperatively, the ongoing assessment monitors the risk for a postprocedure deficit caused by medication or a pathologic condition.

The spinal cord and peripheral nerves are assessed together. During the functional assessment the patient is observed ambulating, sitting, standing, maintaining posture, making intentional hand motions, and performing cooperative and purposeful actions such as writing. The perioperative nurse is able to observe for tremor, gait disturbance, shuffling of feet, unilateral weakness, or an alteration in mobility caused by a neurologic deficit. An assessment of the medications taken at home is important to determine the presence of transient nervous system side effects such as shaking and intention tremor. Smoking can cause a temporary decrease in cerebral blood flow and result in dizziness that may mimic a neurologic problem.

The sensory changes associated with aging involve decreased pressure and pain perception, difficulty differentiating between hot and cold, hearing loss, decreased visual acuity, and alterations in the senses of smell and taste and in spatial perception during locomotion. Preoperative assessment of tactile sensory conditions enables the nurse to develop a plan of care that reflects the need for protection of bony pressure points and for caution during the use of heat-producing or cold-producing equipment such as a hypothermia or hyperthermia mattress.

If a patient has sensory impairments such as a visual disturbance, a hearing loss, or altered spatial perception, there is a high risk for injury caused by falls. Patients with cataracts may be sensitive to the glare from bright OR lights. Allowing the patient to wear hearing aids and spectacles to the OR helps him or her adapt to the surgical environment. Unexpected outcomes caused by sensory alteration can be prevented with a plan of care that considers the combined baseline abilities and sensory needs of the patient. For example, an assessment of hearing ability dictates the need to facilitate communication.

Intraoperative Considerations

Special precautions are indicated in caring for geriatric patients in the OR. The following factors should be considered:

- *Hypothermia:* Geriatric patients are at risk when their core body temperature falls below 96.8° F (36° C). A decreased basal metabolic rate, limited cardiovascular reserves, thinning of the skin, and reduced muscle mass affect the production and conservation of body heat. Measures must be taken to prevent inadvertent hypothermia caused by environmental factors. Precautionary measures include raising room temperature; using warm blankets and devices to circulate warmed air over body surfaces not included in the surgical site; warming anesthetic gases, solutions, and IV fluids; and covering the patient's head.
- *Positioning:* Patients should be lifted, not pulled, during transfer to and from the OR bed and during positioning on the OR bed. Skin is sensitive to abrasion because of decreased dermal thickness and turgor (elasticity). Joints may be stiff or painful because of calcification or degenerative osteoarthritis. Support of the back and neck prevents discomfort from osteoporosis, kyphosis, or rheumatoid arthritis. Hyperextension of the neck during thyroidectomy can cause damage to the vertebral artery or bony structures. Padding and air supports protect pressure points and bony prominences. Circulation and respiration must not be further compromised. Decreased cardiac output, arteriosclerosis, venous stasis, reduced vital

lung capacity, and reduced tissue oxygenation are characteristic changes in older adults.

- *Antiembolic measures:* Slow circulation and hypotension predispose older adults to thrombus formation and emboli. Antiembolic stockings or a sequential compression device on the legs help decrease this risk.
- *Monitoring:* A decrease in renal circulation and excretory ability affects electrolyte balance and the excretion of drugs. Fluid and blood losses are not well tolerated, and hypovolemia can progress rapidly. Blood loss and urinary output must be monitored. Blood gases and electrolytes may need to be monitored, depending on the type of surgical procedure and the patient's preoperative condition. The reaction to any anesthetic agents and drugs is closely monitored in all patients. Fluctuations in cardiac rate and rhythm may portend an impending crisis.

Anesthesia Considerations

Geriatric patients present a special challenge to the anesthesia provider. Physiologic function gradually deteriorates with age but not in a predictable progression. The aging process is not a disease but a fundamental biologic alteration. In geriatric patients, disease is superimposed on senescent changes. Elders are more prone to multiple organ system failure. Changes in the central nervous system produce effects on other body systems.

Reactivity to stimuli decreases with advancing years. These patients therefore experience an altered response to stress, which is exemplified by a high pain threshold. They are more susceptible to the action of all drugs. Abnormal sleeping and breathing patterns, with the production of apnea by hyperventilation, are accentuated by opioids. These phenomena translate to a need for lower doses of anesthetics and opioids for analgesia; the minimum anesthetic concentration required declines progressively with advanced age.

In older adults, oxygen masks may be difficult to fit because of the loss of teeth or bony substance in the jaw. Induction may be prolonged and ventilation made difficult because of chronic obstructive pulmonary disease such as emphysema. With a rapid fall in blood pressure, patients are susceptible to hypoxia, stroke, renal failure, and the development of myocardial infarction. The problems of anesthetization are augmented because surgical procedures tend to be major and take longer; some procedures pertain to malignant tumors, with additional surgery necessary.

A decrease in muscle mass, including the myocardium, with a corresponding increase in body fat takes place in the aging process; most anesthetics are fat soluble. Cardiac output and pulmonary capacity also diminish with age, with a decline in maximal oxygen uptake. In addition, anesthetics may reduce oxygen to the heart, kidneys, and brain, and geriatric patients are prone to hypotension, hypothermia, cerebral edema, and hypoxemia postoperatively. These fundamental physiologic changes necessitate a reduction of anesthetic dosages in geriatric patients.

Surgical mortality is higher in older adults than in the general population, especially if the surgery is an emergency procedure that does not allow sufficient time for a thorough preoperative evaluation and preparation. Complications related to the cardiovascular system and cerebral circulation often are followed by respiratory problems, aspiration, and infection. Surgical morbidity can be reduced, however, with skillful anesthesia management. Terminally ill patients with do-not-resuscitate (DNR) or allow-natural-death (AND) orders should have a discussion with the anesthesia provider and the surgeon. The patient has the right to keep the DNR or AND order in effect for the OR. Everyone must be on the same page and honor the patient's wishes if resuscitation is questioned.

Postoperative Considerations

The health status of geriatric patients is compromised by the interaction of drugs and anesthetics and by the surgical procedure itself. The following situations must be monitored postoperatively:

- *Drug interactions:* Tolerance may be poor and detoxification is slow. Drugs metabolize slowly in the liver and are excreted slowly by the kidneys. Fat-soluble drugs have a prolonged duration because they are absorbed by body fat, which increases with aging. Many anesthetic agents are fat soluble and are myocardial and respiratory depressants. Narcotics, opioids, and sedatives interact with anesthetics. Patients must be monitored for hypoxia because oxygenation to the heart, kidneys, and brain is less efficient. General anesthetics and some drugs cause transient mental dysfunction.
- *Aspiration:* Older adults may have difficulty swallowing because of dry mucous membranes, reduced salivation, and reduced esophageal peristalsis. Coughing is less productive because of muscular atrophy in the chest and rigidity of the ribcage. Patients must be watched for aspiration.
- *Infection:* Respiratory, urinary, or gastrointestinal tract infections may develop as a result of immunodeficiency. Pneumonia can be fatal. Poor dental hygiene may be the source of systemic infection. Healing is further delayed if an infection develops in a wound already compromised by a reduced vascular supply. The fever associated with infection in younger patients may not be as obvious in geriatric patients. Elevation of white blood cell count may be a better indicator if the patient is not immunocompromised as the result of some other disease.
- *Catherization:* A Foley catheter may be needed for a period of time to monitor fluid input and output. Use of a Foley will be determined by the surgeon or anesthesia provider based on the length of the surgical procedure.

Geriatric patients need a thorough preoperative assessment, an experienced anesthesia provider, considerate and knowledgeable caregivers, meticulous aseptic and sterile techniques, and careful postoperative management. Patients and their family or significant others should be included in the development of the postoperative discharge plan. Planning should incorporate follow-up care with the surgeon.

10 Physical Facilities

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify specific areas within the surgical suite in which attire and behaviors affect the manner of care delivery.
- Discuss how environmental layout contributes to aseptic technique.
- Describe methods of environmental controls that contribute to an aseptic environment.
- Describe the specialty rooms used for endoscopy, minimally invasive procedures, and urology.

KEY TERMS AND DEFINITIONS

Cesarean delivery The birth of a baby via an abdominal incision.
Control desk Authorized personnel use this centralized area in the surgical suite to facilitate surgical procedures, organize patient flow, disseminate information, and arrange departmental activities. Located in the unrestricted area, it commonly borders the semirestricted corridors.
Displacement ventilation The rate of positive pressure air exchanges to fresh air displacement in an OR related to the size of the room where anesthesia is delivered. Procedure rooms (formerly class A ORs) are 15:3; larger rooms up to 600 ft^2 are 20:4.
Endoscopic procedures Surgical procedures that use natural body orifices or percutaneous techniques with fiberoptic lighting to use with cameras and long specialized instruments during tissue manipulation and invasive intervention (e.g., colonoscopy, bronchoscopy).
HVAC The system for controlling environmental temperature and humidity. This is an acronym for heating, ventilation, and air conditioning.
Hybrid operating room An operating room with permanently installed equipment for imaging during the surgical procedure.
Interventional radiographic procedure A specialized surgical procedure that permits the use of radiologic imaging during tissue manipulation and invasive intervention through small incisional portals.
Laminar airflow A unidirectional flow of clean air from a higher plane to lower exhaust grilles. The uninterrupted flow permits higher air changes per hour (ACH) for a cleaner environment around the sterile field.
Minimally invasive surgical (MIS) procedure Surgical procedures that use small incisions and fiberoptic lighting with cameras and long specialized instruments during tissue manipulation and invasive intervention (i.e., laparoscopy or mediastinoscopy).
Operating room (OR) A specially equipped room where many types of surgical procedures are performed. This room is one part of the restricted area of the surgical suite.
Procedure room A room designated for a specific collection of surgical procedures that may not require the same equipment and supplies as the main ORs. This room is one part of the unrestricted area of the surgical suite and may border the semirestricted area. Formerly known as class A ORs.
Restricted surgical suite Areas where scrub suits, hair covers, OR-specific closed-in shoes, and masks are worn. Can only be accessed through a semirestricted area.
Semirestricted surgical suite Areas where scrub suits, hair covers, and OR-specific closed-in shoes are worn.
Sterile core A special room within the suite where sterile supplies are stored for ease of use. This room is one part of the restricted area of the surgical suite.
Substerile room A room with a double sink separated from the OR by a door and where select clean and contaminated activities take place during the surgical procedure. Some substerile rooms have warming cabinets for solutions or blankets and a steam autoclave. A disposal sink for contaminated fluids might be in here (e.g., hopper). This room is one part of the restricted area of the surgical suite.
Suite A collection of rooms that are used interactively during a surgical procedure in which each room has a specific purpose (e.g., OR, substerile room, scrub sink room, and sterile storage core).
Thermal plume An invisible layer of heat emanating from the equipment, team members, and the patient that can change the airflow and particulate distribution in the presence of laminar air diffusers.
Unrestricted surgical suite Areas where street clothes and shoes are permitted.

Physical Layout of the Surgical Suite

Efficient use of the physical facilities is important. The design of the surgical **suite** offers a challenge to the planning team to optimize efficiency by creating realistic traffic and workflow patterns for patients, visitors, personnel, and supplies. The design also should allow for flexibility and future expansion. Architects consult surgeons, perioperative nurses, and surgical services administrative personnel before designating functional space within the surgical suite.

Type of Physical Plant Design

Most surgical suites are constructed according to a variation of one or more of four basic designs:

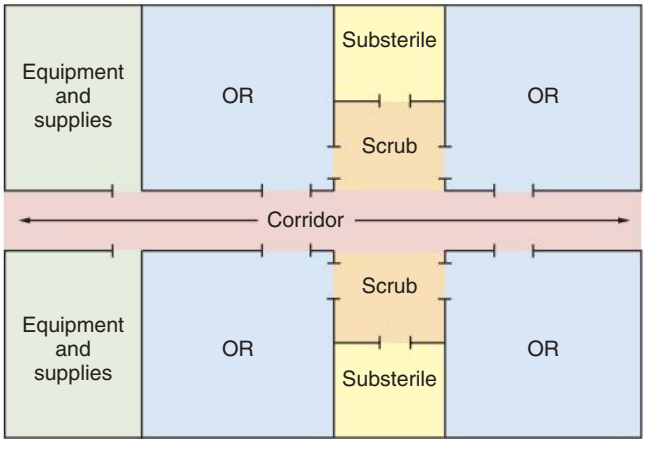
1. Central corridor, or hotel style (Fig. 10.1).
2. Central core, or clean core plan with peripheral corridor (Fig. 10.2).
3. Combination central core and peripheral corridor, or racetrack plan (Fig. 10.3).
4. Grouping, or cluster plan with peripheral and central corridor (Fig. 10.4).

Each design has its advantages and disadvantages. Efficiency is affected if corridor distances are too long in proportion to other space, if illogical relationships exist between space and function, and if inadequate consideration was given to storage space, material handling, and personnel areas.

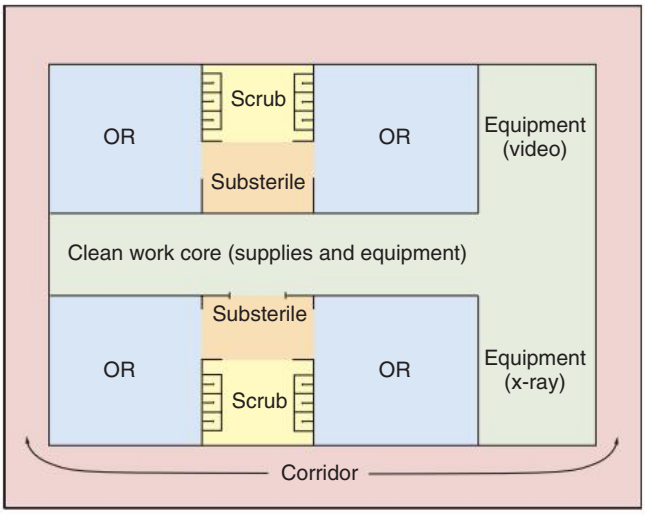
Location

The surgical suite is usually located in an area accessible to the critical care surgical patient areas and the supporting service departments, the central service or sterile processing department, the pathology department, and the radiology department. The size of the hospital is a determining factor because locating every desirable unit or department immediately adjacent to the surgical suite is complex.

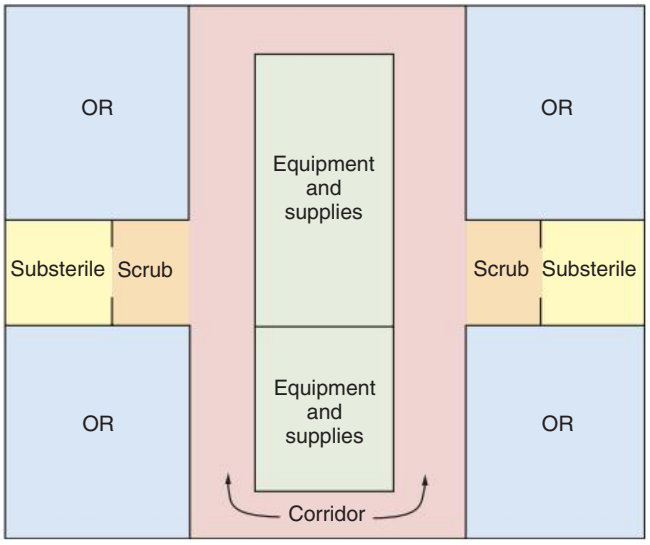
A terminal location is preferred to prevent unrelated traffic from passing through the suite. A location on a top floor is not necessary for microbial control because all air is specially filtered to control dust. Traffic noises may be less evident above the ground floor. Artificial lighting is controllable, so the need for daylight is not a factor; in fact, daylight may be a distraction during the use of video equipment and other procedures that require a darkened environment. Most surgical suites have solid walls without windows. However, some ambulatory surgery rooms have windows to create an ambiance of openness in the suite.



• **Fig. 10.1** Central corridor, hotel style.



• **Fig. 10.2** Central core, peripheral corridor style.

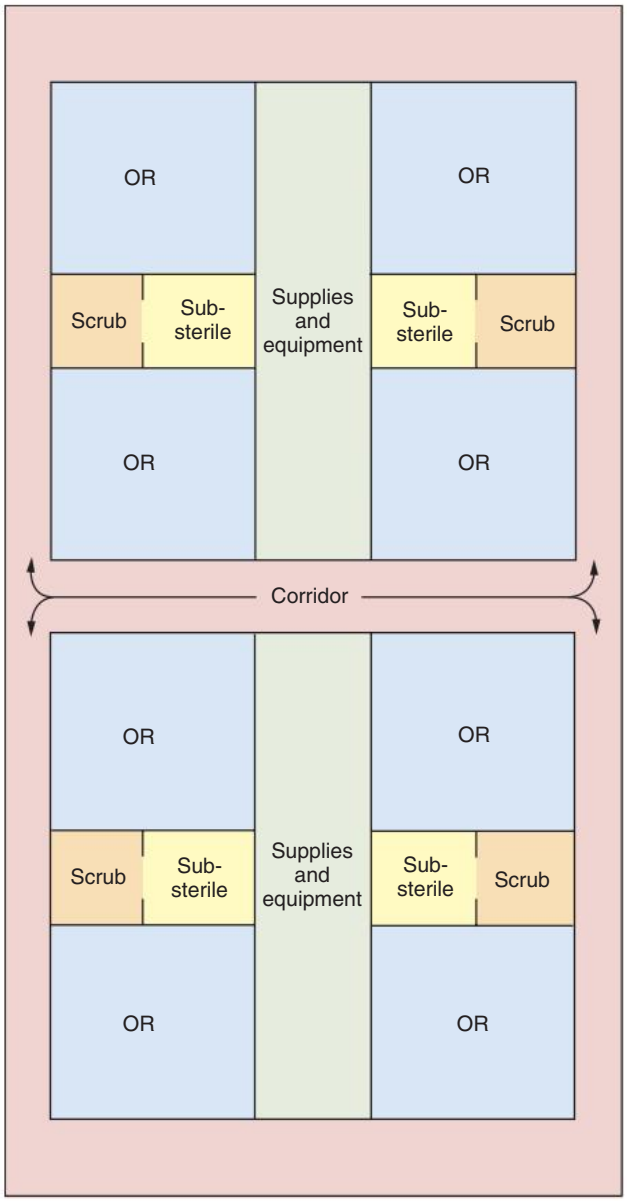


• **Fig. 10.3** Central corridor, racetrack style.

Space Allocation and Traffic Patterns

Space is allocated within the surgical suite to provide for the work to be done, with consideration given to the efficiency with which it can be accomplished. The surgical suite should be large enough to allow for correct technique yet small enough to minimize the movement of patients, personnel, and supplies.

Provision must be made for traffic control. The type of design predetermines traffic patterns. Everyone—staff, patients, and visitors—should follow the delineated patterns in appropriate attire. Signs should be posted that clearly indicate the attire and



• **Fig. 10.4** Cluster combination, peripheral and central corridor style.

environmental controls required (Table 10.1). The surgical suite is divided into three geographic areas that are designated by the physical activities performed in each area.

Unrestricted Area

In the **unrestricted surgical area** street clothes are permitted. A corridor on the periphery accommodates traffic from outside, including patients. This area is isolated by doors from the main hospital corridor and elevators and from other areas of the surgical suite. It serves as an outside-to-inside access area (i.e., a transition zone). Traffic, although not limited, is monitored at a central location. The **control desk** is accessible from the unrestricted area.

Semirestricted Area

In the **semirestricted surgical area** traffic is limited to properly attired, authorized personnel. Scrub suits and head/beard coverings are required attire. This area includes peripheral support areas, central processing, and access corridors to the **operating rooms (ORs)**. The patient's hair is also covered. Bald heads are covered to prevent distribution of dead skin cells and dander that carry microorganisms.

Restricted Area

In the **restricted surgical area** masks are required to supplement OR attire where open sterile supplies and scrubbed personnel are located. Sterile procedures are carried out in the OR and **procedure rooms**. There are also scrub sink areas and **substerile rooms** or clean core areas where unwrapped supplies are sterilized. Personnel entering this area for short periods, such as laboratory technicians, accompanied patient support personnel, and maintenance personnel, may wear clean surgical cover gowns or jumpsuits to cover street clothes. Hair, head, and beard covering is worn, and masks are donned as appropriate.

Transition Zones

Both patients and personnel enter the semirestricted and restricted areas of the surgical suite through a transition zone. This transition zone, inside the entrance to the surgical suite, separates the semirestricted OR corridors from the rest of the facility. Masks, caps, shoe covers, and cover gowns (or jumpsuits) may be located on a cart near transition zones adjacent to restricted areas. Nonsurgical personnel who need to enter the restricted zone can

TABLE 10.1 Environmental Controls in the Surgical Suite

Environmental Controls	Class A OR (Procedure Room)	Class B and C OR	Cesarean Delivery Room	Storage Room	PACU
Pressure	Positive	Positive	Positive	Positive	N/A
ACH	15	20	20	4	6
OA	3	4	4	2	2
Humidity[a] (%)	20-60	20-60	20-60	20-60	20-60
Temperature (° F)	70-75	68-75	68-73	60-73	70-75

[a]Note: Humidity is expected to decrease as low as 20% by the 2018 edition of the AIA Guidelines. The rationale is that the old 30% to 60% is based on the use of flammable anesthetics and the risk for fire by static spark, which is not a consideration in modern times.

ACH, Air changes per hour; *OA,* outside air; *N/A,* (ventilated fresh-air); *PACU,* postanesthesia care unit.

Modified from the Facility Guidelines Institute: *Guidelines for design and construction of health care facilities,* Chicago, 2018, The Institute (website). www.fgiguidelines.org.

don a cover gown or jumpsuit, cap, shoe covers, and mask before proceeding to the designated OR.

Preoperative Admission and Holding Unit

A designated unit in the unrestricted zone should be available for preoperative patients to change from street clothes into a gown and wait with their families before their surgical procedure. The decor should create a feeling of warmth and security. Lockers should be provided for safeguarding patient clothing. The location of the area should shield the patient and family from potentially distressing sights and sounds. Lavatory facilities and handwashing stations must be available. Alcohol-based hand-rub dispensers should be conveniently located in each patient care cubicle.

The area must ensure privacy and offer 80 ft^2 per patient of space to accommodate a transport cart.[a] It may be compartmentalized with individual cubicles or be an open area with curtains. Curtains do not deflect sound and offer little privacy when the nurse is performing the assessment and having conversations with the patient. Curtains also accumulate dust and particulate and should be laundered on a regular basis.

Insertion of intravenous (IV) lines may be done here. In some cases, nerve blockades for pain management may be done in the holding area as ambulatory procedures. These procedures require good lighting. Each cubicle is equipped with oxygen, suction, and devices for monitoring blood pressure. A crash cart should be easily accessible for emergencies.

A nurses' station within the area provides close patient observation and dispensers for medication storage. Computer access to patient electronic medical records (EMRs), such as laboratory reports, and to patient care documentation facilitates documentation in patient records. Care is taken not to have loud conversations at the nurses' station. Private information may be overheard by patients and families.

Assignment and scheduling boards should not be within view of the patients to avoid breaching privacy standards. When wipe-off boards are used for daily scheduling, care is taken not to use patient names. Coordination of the holding room staff and the personnel managing the surgical schedule is essential to prevent delays. More information about preoperative patient care areas is available in Chapter 21.

Some preoperative holding units serve as ambulatory care areas after the surgical procedure. Patients who are admitted in the morning are brought back to the holding unit to recover. They can go home a few hours after the surgical procedure when their health status is stable.

Induction Room

Some surgical suites have an induction room within the restricted area adjacent to a group of ORs, where the patient is prepared for anesthesia administration preoperatively and before actual induction of general anesthesia and airway management. Families of patients are not permitted in this area. Appropriate surgical attire is required, including a mask.

Peripheral IV lines, central lines, and invasive arterial monitoring lines are inserted, and regional anesthesia (i.e., epidural catheter for postoperative pain management) may be placed in the induction room. Performing these procedures in an induction room saves actual OR time, which is more costly. Induction rooms are more common in larger facilities, where procedures such as open heart surgery or transplantation are performed.

In some induction rooms (not all), patients are premedicated and stabilized on the same OR bed that will be used for the procedure. The OR bed is used as the transport vehicle to the OR, where it is connected and locked to a base unit permanently mounted in the floor. This minimizes the number of times critically ill patients are moved from one surface to another.

Postanesthesia Care Unit

The postanesthesia care unit (PACU) may be outside the surgical suite, or it may be adjacent to the suite so that it may be incorporated into the unrestricted area with access from both the semirestricted area and an unrestricted corridor. In the latter design, the PACU becomes a transition zone for the departure of patients. Space allotted should equal a minimum of 1.5 beds per OR.

Hospitals and ambulatory care facilities accommodate patients and their families during the perioperative waiting period. Some facilities have small private conference rooms where the surgeon can meet with families postoperatively. A designated waiting area is provided near the PACU for families of surgical patients. Some facilities permit certain family members to sit with recovering patients when they are stable but not ready for release. More information about the PACU can be found in Chapter 30.

Peripheral Support Areas

Adequate space must be allocated to accommodate the needs of OR personnel and support services. The need for equipment, supply, and utility rooms and housekeeping determines support space requirements. Equipment and supply rooms should be decentralized and placed near the appropriate ORs.

Control Desk

From a central control point, traffic in and out of the surgical suite may be observed. This area usually is within the unrestricted area but adjacent to the semirestricted corridor. The clerk-receptionist is located at the control desk to coordinate communications. A pass-through window may be used to stop unauthorized people; to schedule surgical procedures with surgeons; and to receive drugs, blood, and various small supplies. A computerized pneumatic tube system within the hospital can speed the delivery of small items and paperwork, thus eliminating some courier services, such as from the pharmacy to the control desk. Tissue specimens and blood samples also can be sent to the laboratory through some tube systems. The tubes used to send items should be periodically cleaned with an approved disinfectant solution.

Computers and printers may be located in the control area. Information systems and computers assist in financial management, statistical recording and analysis, scheduling of patients and personnel, materials management, and other functions that evaluate the use of facilities. An integrated computer system interfaces with other hospital departments, such as the laboratory, pathology, or patient care division. It may have an intranet connection that allows surgeons to schedule surgical procedures directly from their offices.

[a]The 2018 *Guidelines for Design and Construction of Health Care Facilities* by the Facility Guidelines Institute is available online at www.fgiguidelines.org

Retrieval for review of patient records gives the perioperative nurse manager the opportunity to evaluate the patient care given and documented by nurses. Personnel records can be maintained. Other essential records can be stored in and retrieved from computer databases on a password-controlled basis. The central processing unit for the OR computer system usually is located in or near the control desk. A fax and/or scanner machine may be available for the electronic transfer of documents, records, and patient care orders between the OR and surgeons' offices.

Security systems usually can be monitored from the control desk. Alarms are incorporated into electrical and piped-in systems to alert personnel to the location of a system failure. A centralized emergency call system facilitates summoning help. Some facilities have a panic button to summon the security department. Narcotics, opioids, and prescription pads are kept in locked cabinets and can be signed out only by appropriate personnel.

Access to exchange areas, offices, and storage areas may be limited during evening and night hours and on weekends. Doors may be locked. Some hospitals use alarm systems, video surveillance in hallways and ORs, and electronic metal detection devices to control intruders and prevent theft or vandalism. Computers and records must be secured to protect patient confidentiality.

Offices

Offices for the administrative patient care personnel and the anesthesia department should be located with access to both unrestricted and semirestricted areas. Most administrative offices are located near the control desk. The administration staff frequently needs to confer with outside people (e.g., sales representatives) and needs to be kept informed of activities within all areas of the surgical suite.

Locker Rooms and Lounges

Dressing rooms with secure lockers are provided for both male and female personnel to change from street clothes into OR attire before entering the semirestricted area and vice versa. The area should be secure from unauthorized personnel. Doors separate this area from lavatory facilities and adjacent lounges.

Walls in the lounge areas should have an aesthetically pleasing color or combination of colors to foster a calming atmosphere. A window view of the outdoors is psychologically desirable because many staff members arrive for the day shift when it is still dark outside. Affect is enhanced by natural sunlight. Some personnel bring a meal, so a refrigerator designated only for food should be located in this room. A routine refrigerator cleaning schedule should be established. Antiseptic hand-rub dispensers should be conveniently located at the entrance and near all food storage areas.

Dictating equipment, computers, and telephones should be available for surgeons in the physicians' lounge or in an adjacent semirestricted area.

Conference Room/Classroom

Ideally, a conference room or a classroom is located within the semirestricted area with entrance and exit doors to unrestricted areas. This room is used for patient care staff in-service educational programs and is used by the surgical staff for teaching. Closed-circuit television and video equipment also may be available for self-study. The departmental reference library may be housed here. Tables and chairs for staff should be sturdy and easily cleanable. Shoe covers and masks should not be worn in this room. Antiseptic hand-rub dispensers should be conveniently located at the entrance.

Some facilities permit covered beverages and small snacks during meetings. Departmental holiday parties or special event celebrations may be set up in here.

Consultation Room

Some surgical suites have small meeting rooms where a surgeon can have a private conversation with the patient's family. These are usually located in the unrestricted area near the PACU.

Support Services

The size of the health care facility and the types of services provided determine whether laboratory and radiology equipment is needed within the surgical suite.

Laboratory

A small laboratory where the pathologist can examine tissue specimens and perform frozen sections expedites the decisions that the surgeon must make during a surgical procedure when a diagnosis is questionable. A designated refrigerator for storing blood for transfusions also may be located in this room. Tissue specimens may be tested here by frozen section before they are delivered to the pathology department for permanent section.

Radiology Services

Special procedure rooms may be outfitted with x-ray and other imaging equipment for diagnostic and invasive radiologic procedures or insertion of catheters, pacemakers, internal defibrillators, and other devices. The walls of these rooms contain lead shields to confine radiation. Although most facilities have converted to digital imaging, a darkroom for processing x-ray films usually is available within the surgical suite for immediate processing of scout films or contrast dye studies of organ systems.

Work and Storage Areas

Clean and sterile supplies and equipment are separated from soiled items and trash. If the surgical suite has a clean core area, only clean or sterile items are stored there. The air handlers are set to positive pressure as in the restricted area, so the doors should always remain closed when traffic is not entering or leaving.

Soiled items are taken to the decontamination area for processing before being stored, or they are taken to the disposal area. The air handlers in the contaminated areas are set to negative pressure as in the corridors, so the doors should remain closed when personnel are not entering or leaving. Ventilation should be six air exchanges with two fresh per hour. Work and storage areas are provided for handling all types of supplies and equipment, whether clean or contaminated.

Anesthesia Work and Storage Areas

Space must be provided for storing anesthesia equipment and supplies. Gas tanks are stored in a well-ventilated (a minimum of eight air exchanges per hour), negative-pressure area separated from other supplies. Care is taken not to allow tanks or cylinders to be knocked over or damaged. They should stand upright in a secure stable base for safety. Full and empty gas tanks should be stored in separate areas to prevent confusion about supplies.

Nondisposable items must be thoroughly decontaminated and cleaned after use in an area separate from sterile supplies. A separate workroom usually is provided for care and processing of anesthesia equipment. Dirty and clean supplies must be kept separated.

The storage area includes a secured space for anesthetic drugs and agents. Some facilities have drug-dispensing machines that require positive identification to obtain medications for patient use. Larger facilities have a pharmaceutical station where a pharmacist dispenses drugs on a per-case basis. Signatures are required for controlled substances. Unused drugs are returned to the pharmacist for accountability.

Housekeeping Storage Areas

Cleaning supplies and equipment need to be stored; the equipment used within the restricted area is kept separate from that used to clean the other areas. Therefore more than one storage area may be provided for housekeeping purposes, depending on the design and size of the surgical suite. Sinks are provided, as are shelves for supplies. Trash and soiled laundry receptacles should not be allowed to accumulate in the same room where clean supplies are kept; separate areas should be provided for these. Conveyors or designated elevators may be provided for prompt removal of bags of soiled laundry and trash from the suite. The ventilation is set to negative pressure with 10 air exchanges per hour with two fresh.

Central Processing Area

Conveyors, dumbwaiters, or elevators connect the surgical suite with a central processing area on another floor of the hospital. If efficient material flow can be accomplished, support functions can be removed from the surgical suite. Effective communications and a reliable transportation system must be established. Some ORs send all of the instruments and supplies to the sterile processing department for cleaning, packaging, sterilizing, and storing. This system eliminates the need for some work and storage areas within the surgical suite, but exchange areas must be provided for carts. The movement of clean and sterile supplies must be kept separate from that of contaminated items and waste by means of space and traffic patterns. The ventilation is set to positive pressure with four air exchanges per hour with two fresh.

Utility Room

Some hospitals use a closed-cart system and take contaminated instruments to a central area outside the surgical suite for cleanup. This room contains a washer-sterilizer, sinks, cabinets, and all necessary aids for cleaning. If the washer-sterilizer is a pass-through unit, it opens also into the general workroom, which eliminates the task of physically moving instruments from one room to another.

General Workroom

The general work area should be as centrally located in the surgical suite as possible to keep contamination to a minimum. The work area may be divided into a cleaning area and a preparation area. If instruments and equipment from the utility room are received from the pass-through washer-sterilizer into this room, an ultrasonic cleaner should be available here for cleaning instruments that the washer-sterilizer has not adequately cleaned. Otherwise, the ultrasonic cleaner may be in the utility room.

Instrument sets, basin sets, trays, and other supplies are wrapped for sterilization here. Internal biologic and external chemical indicators are used. The preparation and sterilization of instrument trays and sets in a central room ensures control. This room also contains the stock supply of other items that are packaged for sterilization. The sterilizers that are used in this room may also open into the next room, the sterile supply room. This arrangement helps to eliminate the possibility of mixing sterile and nonsterile items.

Storage

Technology nearly tripled the need for storage space in the twenty-first century. Many older surgical suites have inadequate facilities for storage of sterile supplies, instruments, and bulky equipment. Those responsible for calculating adequate storage space for instruments; sterile and unsterile supplies; and mobile equipment, such as special OR beds, specialty carts, and equipment, should consider the size of the entire surgical suite. American Institute of Architects (AIA) 2018 Guidelines state that a minimum of 150 ft^2 or 50 ft^2 per OR, whichever is greater, should be dedicated to equipment storage to prevent accumulation of machines and supplies in hallways. Blocked hallways prevent rapid transfer of crash carts and emergency equipment. Particulate can accumulate on machinery.

The OR storage space does not include additional storage space needed for postanesthesia equipment. Anesthesia storage should be considered separately. Use of a case cart system may slightly decrease the amount of instrument space needed. Plans should include accommodation for the size of each type of case cart used and the numbers that will be in the suite at a given point in the daily surgical schedule.

Sterile Supply Room

Most hospitals keep a supply of sterile drapes, sponges, gloves, gowns, and other sterile items ready for use in a sterile supply room within the surgical suite. As many shelves as possible should be freestanding from the walls, which permits supplies to be put into one side and removed from the other; thus older packages are always used first. However, small items must be contained in boxes or bins to prevent them from falling to the floor. Inventory levels should be large enough to prevent running out of supplies, yet overstocking of sterile supplies should be avoided. Storage should be arranged to facilitate stock rotation. Consideration is given to items that have an expiration date. Unstable elements, such as sutures or chemically treated supplies, will expire and be unsuitable for patient use if not rotated during stocking.

The sterile storage should be as close as possible to the sterile processing area and should be under positive pressure with four total air exchanges per hour with two exchanges of fresh air. Access to the sterile storage area should be limited; it should be separated from high-traffic areas and the doors should be closed. Humidity (20% to 60%) and temperature (72° F to 75° F [22° C to 23.9° C]) should be controlled. Humidity in excess of 70% causes concern for condensation within sterile packages and may permit microorganism transfer by capillary action.

Instrument Room

Most hospitals have a separate room or a section of the general workroom designated for storing nonsterile instruments. The instrument room contains cupboards in which all clean and decontaminated instruments are stored when not in use. Instruments usually are segregated on shelves according to surgical specialty services.

Sets of basic instruments are usually cleaned, assembled, and sterilized after each use. Special instruments such as intestinal clamps, kidney forceps, and bone instruments may be wrapped

separately or incorporated into specialty sets. Some surgeons have trays designated for their use and are labeled with their names. These are stored with the specialty instruments.

Scrub Room

An enclosed area for preoperative cleansing of hands and arms should be provided adjacent to each OR. Scrub solutions, soaps, and scrub brushes are located near the sinks. Water spills and drips on the floor are particularly hazardous. Skid-proof mats should be in place in front of each scrub sink. An enclosed scrub room is a restricted area within the surgical suite. Paper towel dispensers and mirrors should be located in this area. Trash receptacles, limited to only those items used within this room, should be emptied several times per day. Some facilities have boxes of additional caps, masks, shoe covers, and eye protection in the event of biologic contamination requiring a change of these items during a procedure. The contaminated item should be discarded in the biohazard trash bin in the OR after changing.

Operating Room

Each OR, regardless of size, is a restricted area because of the need to maintain a controlled environment with minimal traffic for sterile and aseptic techniques (Fig. 10.5).

Categories of Operating Rooms

The American College of Surgeons (ACS) describes OR facilities based on the types of procedures performed therein. The 2018 AIA Guidelines in cooperation with the ACS use specific criteria when determining safe environmental factors for surgical facilities and include provision for all types of surgical interventions and the use of anesthetic agents. The criteria include minimal floor space, types of anesthetics used, and circumferential clearance around the OR bed. The types of ORs with minimal floor space are as follows:

- *Procedure room:* 160-ft^2 floor area with 12-ft minimum clear dimensions at the head, sides, and foot of the OR bed. Local anesthesia used here.
- *General OR:* 270 to 400-ft^2 floor area with 15 to 20-ft minimum clear dimensions at the head, sides, and foot of the OR bed. Local, general, and regional anesthesia used here.

Other ORs range in size from 600 to 650 ft^2 with a 24 to 25-ft width or larger to accommodate multiple ceiling-mounted booms, monitors, and high-technology equipment such as robotics and controlling consoles.

• **Fig. 10.5** Basic OR. (Courtesy Grey McVicar. In Lewis SL, et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 8, St. Louis, 2011, Mosby.)

Size Determinations

The size of individual ORs varies according to use. Procedure rooms are commonly used for smaller operations performed with topical, local, or limited regional blocks that have minimal equipment needs. Many ambulatory centers have procedure rooms that fit this usage.

General ORs are better suited for procedures in which the patient may be sedated and physiologically supported with IV medication. General anesthesia and spinal or epidural blocks can be used. Intermediate to complex procedures are performed in these rooms. Additional space is appropriate where the potential for larger equipment and longer procedures is possible.

It is desirable to have the ORs in a hospital setting the same size so that they can be used interchangeably to accommodate elective and emergency surgical procedures. Large general ORs provide adequate space for typical surgeries with at least 400 ft^2 of clear floor space. Approximately 20 ft^2 of space should be planned between fixed cabinets and shelves on two opposing walls if possible. A specialized room, such as one equipped for cardiopulmonary bypass or trauma, may require as much as 600 ft^2 of useful space.

A room may be designed for a specialty service if use by that service will be high. The room must accommodate equipment, such as lasers, microscopes, or video equipment, either fixed (permanently installed as in **hybrid operating room**) or portable (movable). Portable equipment requires more floor space.

Some rooms are designated for special procedures, such as gastrointestinal endoscopy, **interventional radiologic procedures and studies**, or the application of casts. Other rooms have adjacent areas used for specific purposes, such as visitor viewing galleries, or for installing special equipment, such as monitors or x-ray devices for imaging.

Operating Room Humidity

An air-conditioning system controls humidity via the heating, ventilation, and air-conditioning (**HVAC**) system. High relative humidity (weight of water vapor present) should be maintained between 20% and 60%. Moisture provides a conductive medium and allows a static charge to flow to ground as fast as a spark is generated. Humidity in excess of 70% can permit condensation inside sterile packaging.

Operating Room Temperature

OR temperature is maintained within a range of 68° F to 75° F (20° C to 24° C). A thermostat to control room temperature can be

advantageous to meet patient needs; for example, the temperature can be increased to prevent hypothermia in pediatric, geriatric, and burn patients. Overmanipulation of controls can result in calibration problems. Controls should not be adjusted solely for the comfort of team members; patient normothermia is a strong consideration. Only the maintenance department can regulate temperature in some surgical suites; this department should be called early enough to reset the temperature for patients at risk for hypothermia, such as pediatric, geriatric, or burn patients.

Substerile Room

A group of two, three, or four ORs may be clustered around a central scrub area, work area, and a small substerile room. Only if the latter room is immediately adjacent to the OR and separated from the scrub area is it considered the substerile room throughout this text.

A substerile room adjacent to the OR contains enclosed storage cupboards, a sink, a warming cabinet, and a steam sterilizer. Most warming cabinets have two chambers—one for blankets and one for solutions. The blanket chamber should not be set to heat greater than 130° F (54° C). The solution warming chamber should be set to 110° F (43.3° C) to prevent thermal burns to patients. Each manufacturer of patient-use irrigation and IV solutions sets parameters for the temperature and duration of heating permitted for their products. Any warmed solution taken out of the warming cabinet and allowed to reach room temperature cannot be returned for reheating. Solutions should be labeled with the date for removal from the cabinet as an expired product.

AORN guidelines for 2019 recommend that immediate-use steam sterilization (IUSS; i.e., flashing) is used only if there is no other option. Although cleaning and sterilizing facilities are centralized, either inside or outside of the surgical suite, a substerile room with this equipment offers the following options:

- The circulating nurse can do emergency cleaning and sterilization of small items here, which reduces waiting time for the surgeon and reduces anesthesia time for the patient. The circulating nurse, or scrub person if necessary, can lift sterile articles directly from the sterilizer onto the sterile instrument table without transporting them through a corridor or another area. IUSS closed containers can be used.
- It allows the circulating nurse to stay within the room.

Rooms adjacent to orthopedic or cast rooms should have a sink with a plaster trap for disposal of casting solutions.

The substerile room also usually contains a combination blanket and solution warmer and cabinets for storage. Empty sterile specimen containers and labels may be conveniently stored in this room. Slips for charges or other records may be kept here. Individual hospitals may find it convenient to keep other items in this room to allow the circulating nurse to remain in or immediately adjacent to the OR during the surgical procedure.

Doors

Doors should be 4 ft wide or larger for ease in moving patients on carts and in beds. Ideally, sliding doors should be used exclusively in the OR for the main corridor. They eliminate the air currents caused by swinging doors. Microorganisms that have previously settled in the room are disturbed with each swing of the door. The microbial count is usually at its peak at the time of the skin incision because this follows disturbance of air from gowning, draping, movement of personnel, and opening and closing of doors.

Sliding doors should not recede into the wall like pocket styles but should be of the surface-sliding type. Fire regulations mandate that sliding doors for ORs can be swung open if necessary. Doors do not remain open either during or between surgical procedures. The room air-handlers generate higher pressure than in the halls to minimize the amount of dust and debris pulled in toward the sterile field. Closed doors decrease the mixing of air within the OR with that in the corridors, which may contain higher microbial counts. Air pressure in the room also is disrupted if the doors remain open.

When construction or renovation is in process, always keeping the doors closed when not transporting patients is important because the ORs are ventilated with positive pressure. The air-handling systems are strained because of the disrupted processes and are further compromised when the airflow is allowed to equalize. This causes unstable temperature and humidity control. The desired temperature should be between 68° F and 75° F, with a relative humidity of 20% to 60%.

The door to the substerile area is usually a swinging style door with a small window. These doors are not used for moving patients in and out of the OR and should remain closed. During the surgical procedure, the microbial count rises every time doors swing open from either direction. Also, swinging doors may touch a sterile table or person. The risk for catching hands, equipment cords, or other supplies is increased. Always look through the window before opening this door to prevent contamination or injury.

Ventilation

The OR ventilation system must ensure a controlled supply of filtered air under positive pressure. The primary concerns for flow of ventilation include how the air is distributed, filtered, and exhausted. Air changes per hour (ACH) is an important concern based on the size of the individual OR. HVAC manufacturers continually study the best ways to ventilate ORs and provide ventilation systems compatible with the needs of the sterile team for aseptic air quality.

Air changes and circulation provide fresh air and prevent accumulation of anesthetic gases and microbiologic particles in the room.[1] Concentration of gases depends solely on the proportion of pure air entering the air system to the air being recirculated through the system using **displacement ventilation**. Fifteen ACH with three exchanges of outside air (OA; 15:3) is recommended for procedure rooms. General ORs and **cesarean delivery** suites require 20 ACH with four OA exchanges (20:4) according to the 2018 AIA Guidelines for Design and Construction of Health Care Facilities.[b] A gas scavenger system is used to prevent the buildup of waste anesthetic gases where general inhalation anesthesia is used. The scavenger attaches directly to the outflow of the anesthesia machine.

Various types of scavengers, vacuum systems, and smoke evacuators are used throughout the OR to minimize air pollutants that are health risks for patients and perioperative team members. The American Society of Heating, Refrigeration, and

[b]The 2018 *Guidelines for Design and Construction of Health Care Facilities* by the Facility Guidelines Institute is available in its entirety online at www.fgiguidelines.org.

Air-conditioning Engineers (ASHRAE) sets the standard for safe ventilation.

If new air ducts are installed, they should be thoroughly cleaned before activation to prevent the dispersal of particulate material into the air. The risk for airborne contaminants is significantly increased.

PROS/CONS

OR Ventilation and Foot Traffic

Pros

- Laminar airflow ventilation systems are designed to reduce airborne contaminates. The systems have a unidirectional flow of clean air from a higher plane to lower exhaust grilles.
- Uninterrupted laminar airflow permits higher air exchanges, which relates to cleaner air and fewer airborne contaminates. Fewer contaminates in the air may result in fewer surgical site infections (SSIs).
- Internal OR ventilation systems (HVAC) are set at positive pressure and the hallways are set to negative pressure to minimize the amount of air moving into the room as the door is opened.
- OR doors must be kept closed at all times unless absolutely necessary and foot traffic kept to a minimum for the ventilation system to work properly.
- Foot traffic can be described by the amount of movement around the room, personnel in and out of the room, and how many persons are in the room at one time.
- The Joint Commission as part of its SSI Change Project is promoting a reduction in OR traffic as an effective practice to reduce SSIs.
- Common reasons for door movement and heavy foot traffic are gathering supplies, information, communication, employee breaks, vendors, change of personnel, and social visits.
- Education about facility ventilation systems and how foot traffic and opening and closing doors can decrease the rate of SSIs.

Cons

- Maintaining proper airflow is a problem for every OR. Airflow can be interrupted by foot traffic and opening and closing of OR doors.
- Propping OR doors open causes the airflow to equalize and prevents the positive pressure in the room from moving potential contaminates away from the field.
- Door movement and foot traffic cause air turbulence that sends contaminates from the floor into the air. This can disperse contaminates leading to a possible SSI.
- Research has identified that elevated airborne bacterial counts were higher when OR doors were opened and closed more often and foot traffic was excessive.
- Foot traffic can be kept to a minimum by having PRN items in the room, implants, posting "Do not enter" signs, using the phone for communication, and discouraging social visits during surgical procedures.
- Health care staff should be monitored to keep foot traffic to a minimum.

Ultraclean laminar airflow is installed in some ORs to combat airborne particulate contamination by providing 70 to 160 ACH. **Laminar airflow** is a high-pressure, unidirectional air-moving diffuser housed in a cluster in a wall or ceiling enclosure. It is designed to flow uninterrupted from the cleanest area to the less clean area into air return grilles in the lower sidewalls. Cool air from the laminar diffuser travels more quickly than isothermic air. Care is taken to continually monitor the patient's temperature for any hypothermic effect. Hypothermia can support the development of a surgical site infection (SSI).[2] Laminar airflow systems are expensive to install and maintain.

The airflow is divided into tiny linear columns of cool clean air that generates little velocity and blowing as it courses toward the sterile field. Objects that emit **thermal plume**, such as spotlights, persons, or equipment, cause the air currents to move in a different direction.[3] *Horizontal airflow* passes from the wall diffuser to an opposite lower return grille. Objects in the air pathway shed particulate into the clean airstream (Fig. 10.6). *Vertical airflow* styles have fewer obstacles to the line of direction of the air.

Vertical downward airflow is designed to flow from the top of the room; flow over the patient, lights, and equipment; and continue downward, forming a canopy toward the lower corners of the room where the air return grilles are located. Studies have shown an 89% reduction in colony-forming units when vertical laminar airflow is used appropriately. This includes making sure that the open instrument tables are well within the confines of the airflow canopy.[3] One additional consideration is when the surgeon and team are directly over the patient to view the surgical site. Particulate from the nonsterile head/cap/mask and neck are passed directly into the sterile field depositing cells into the patient.[3] Wearing skull caps rather than the bouffant style hats permits additional shed when hair extends at the nape of the neck.

• **Fig. 10.6** Human thermal plume pattern that can alter laminar airflow.

In contemporary ORs that use laminar airflow, three styles of vertical downward-directed airflow originate in the ceiling directly clustered over the field with slightly different effects.

1. Standard vertical laminar flow provides a narrow boundary of operating space that begins at the ceiling and interfaces with the field, personnel, and ambient room air before it is exhausted through air return grilles (Fig. 10.7).
2. Air curtained vertical flow uses a peripheral secondary airflow at a higher velocity to widen and frame the primary laminar flow from the ceiling to the lower pressure air return grilles in the base of the walls (Figs. 10.8 and 10.9).
3. Physical curtained vertical flow uses air foils hanging from the ceiling on four sides to maintain the downward direction of airflow. The air funnels down toward the field, flowing around and behind the team (Fig. 10.10).

Obstacles to Laminar Airflow Effectiveness

Objects that pass between the flow of clean air and the sterile field around the patient shed particles that can contaminate the surgical site. Heat emanating and rising from the team members, the patient, and equipment—referred to as *thermal plume*—changes the course of the laminar flow (Fig. 10.11). Several physical barriers and events that interrupt airflow and return include the following:

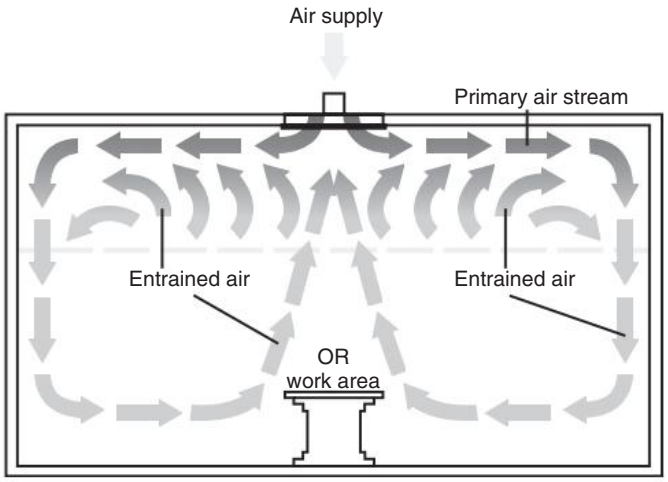
- Spotlights over the field
- Ceiling booms with surgical machinery and equipment
- Mayo stands over the patient
- Microscopes, articulated laser arm, and C-arm
- Personnel and patient thermal plume
- Opening and closing the OR door (sliding and swinging doors; proportionately higher with swinging doors)

Laminar airflow was first trialed during hip replacement surgery by Sir John Charnley in Great Britain in the 1950s. Charnley believed that if particulate could be removed from the air, the 7% infection rate could drop. His studies showed that the infection rate did fall to less than 2%. Although the laminar system contributes to removing particulates, the improvements in sterile technique and appropriate antibiotic therapy overall may have a larger effect on infection rate.[4]

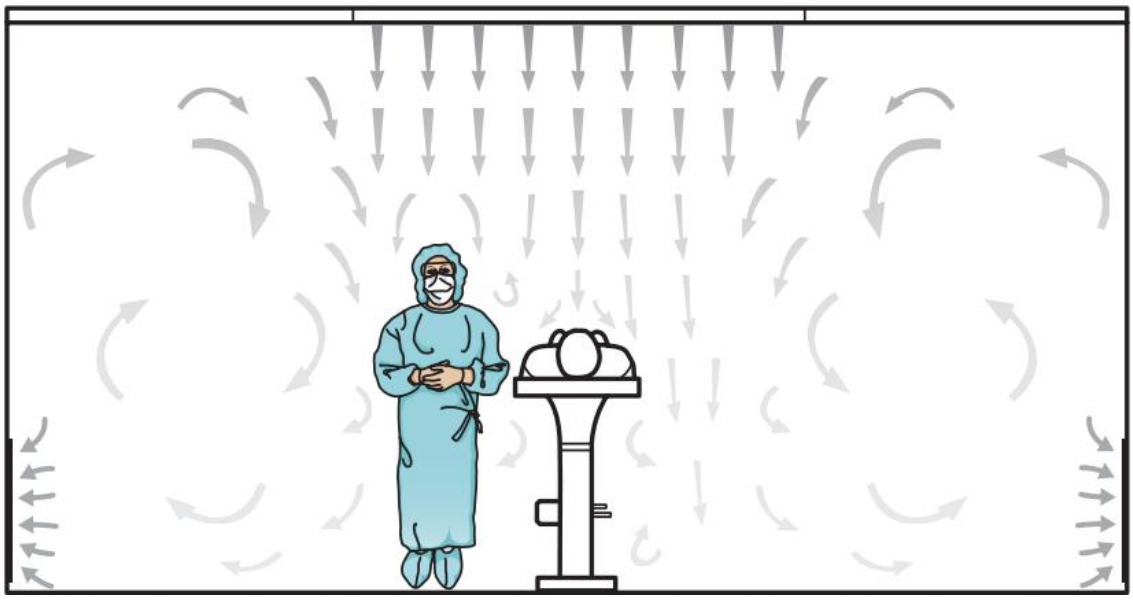
Research has shown that the particulate dispersal is proportionate to the number of personnel in the room, the opening and closing of doors (and their type), placement of instrument tables, and attire worn.

Other types of filtered air-delivery systems that have a high rate of airflow are as effective in controlling airborne contamination. Filtration through high-efficiency particulate air (HEPA) filters can be 99.7% efficient in removing particles that are larger than 0.3 mm. These microbial filters in ducts filter the air, practically eliminating all dust particles. The ventilating system in the surgical suite is separate from the hospital's general system and is to be cleaned, inspected, and maintained on a preventive maintenance (PM) schedule.

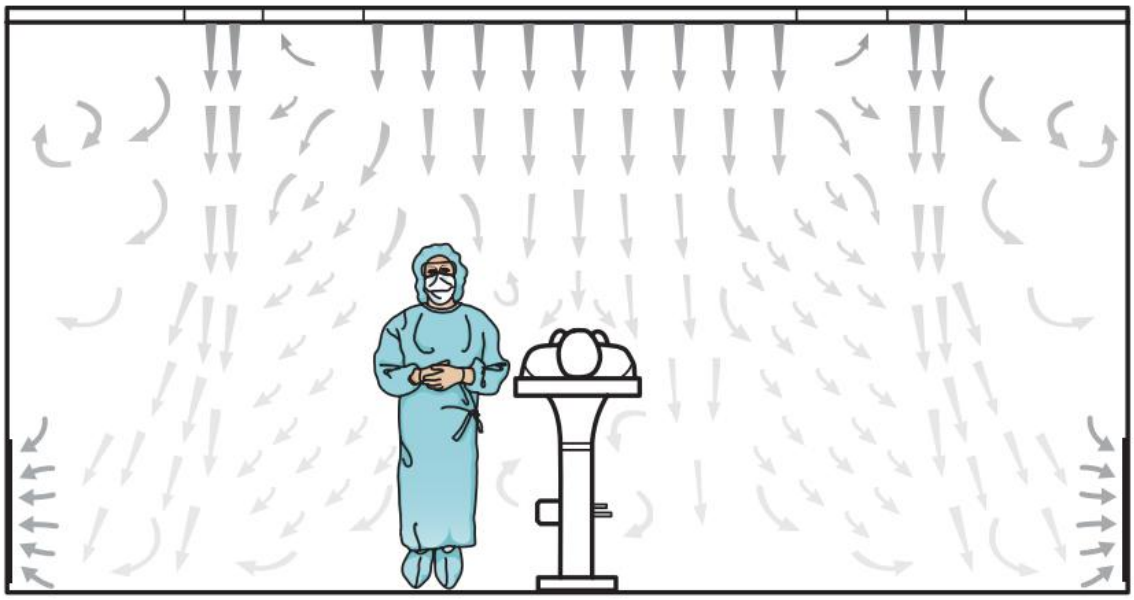
Positive air pressure in each OR is greater than that in corridors, scrub areas, storage, and substerile rooms. Positive pressure forces air from the room. The air enters at the ceiling and leaves through the grilles at floor level. Microorganisms and particulate in the air can enter the room unless positive pressure is maintained. Closed doors maintain this environment and prevent equalization of air pressure. The recommended parameters include



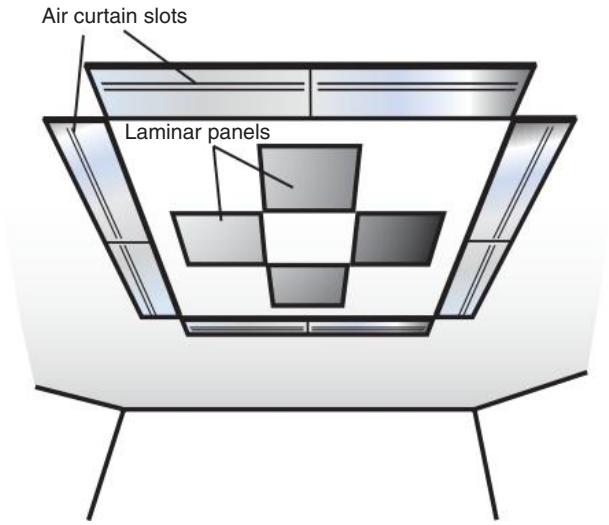
• **Fig. 10.7** Horizontal airflow pattern.



• **Fig. 10.8** Vertical airflow pattern with no air curtain.



• **Fig. 10.9** Vertical airflow pattern with downdraft air curtain.



• **Fig. 10.10** Ceiling view of vertical airflow diffusers with air curtain vents around periphery.

a dual filtration system with two filters in succession. The first filter should be at least 30% efficient, and the second filter should be at least 90%. Filter changes and duct cleaning should be on a PM schedule with OR maintenance.

Floors

In the past, floors were conductive enough to dissipate static from equipment and personnel but not enough to endanger personnel from shock or cause explosions from flammable anesthetic gases. Conductivity is not a prime concern in contemporary OR design because explosive anesthetic gases, such as cyclopropane, are no longer used.

The most common flooring used is seamless polyvinyl chloride that is continued up the sides of the wall for 5 or 6 inches and welded into place. These materials should not degrade or stain with age and cleaning. Metal oxides can be incorporated to decrease the slipperiness of the surface when wet.

A variety of hard plastic, seamless materials are used for minor procedure room floors. The surface of all floors should not be porous but suitably hard for cleaning with the flooding, wet-vacuuming technique. Personnel fatigue may be related to the type of flooring, which can be too hard or too soft. Cushioned flooring is available. The floor should be slip-proof when wet because surgical hand cleansing causes splashes and spills around the scrub sink and into the OR, where the hands are dried.

Most of the glues and adhesives used in the installation of the flooring are malodorous and potentially toxic. During construction or renovation, care is taken to vent these fumes from the area. A minimum of 2 weeks may be needed to fully rid the area of the smell before it can be safely used for patient care.

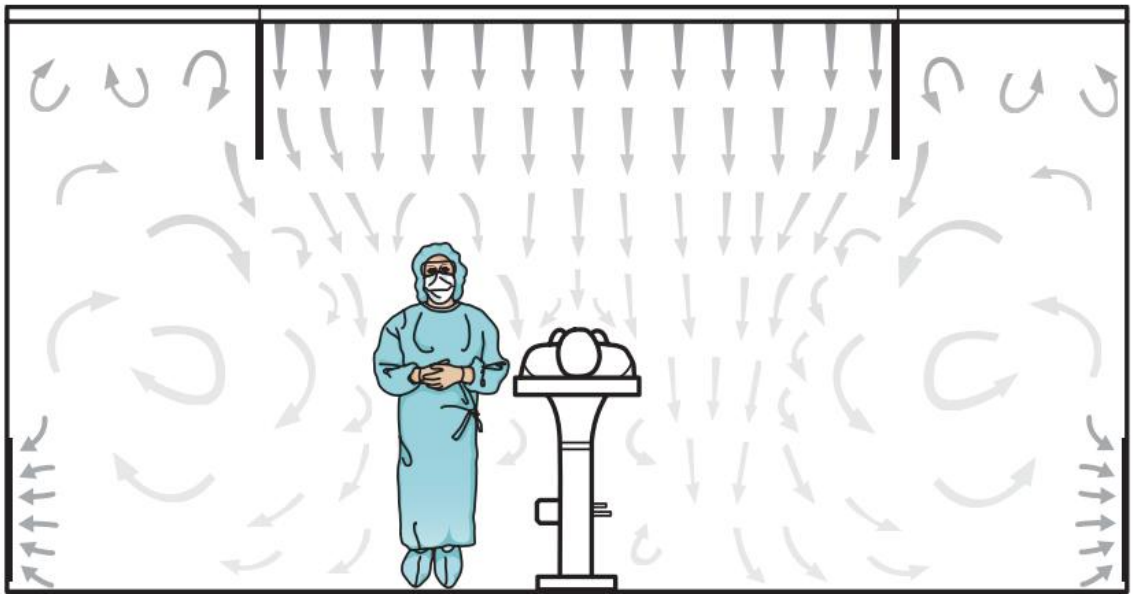
Floors in older buildings may need reinforcement to support larger and more sophisticated equipment. Some of the wiring may be run in conduits under the floor.

Walls and Ceiling

Finishes of all surface materials should be hard, nonporous, fire-resistant, waterproof, stain-proof, seamless, nonreflective, and easy to clean. The ceiling should be a minimum of 10 ft high and have seamless construction. The height of the ceiling depends on the amount and types of ceiling-mounted equipment. The ceiling color should be white to reflect at least 90% of the light in even dispersion.

Walls should be a pastel color, with paneling made of hard vinyl material that is easy to clean and maintain. Seams should be sealed with a silicone sealant. Laminated polyester or smooth painted plaster provides a seamless wall; epoxy paint has a tendency to flake or chip. Dust and microorganisms can collect between tiles because the mortar between them is not smooth. Most grout lines, including those made of latex, are porous enough to harbor microorganisms even after cleaning. Tiles can also crack and break. A material that is able to withstand considerable impact also may have some value in noise control. Stainless steel cuffs at collision corners help prevent damage.

Walls and ceilings often are used to mount devices, utilities, and equipment in an effort to reduce clutter on the floor. The ceilings should be reinforced with steel beams to support the load.



• **Fig. 10.11** Vertical airflow pattern with short physical barrier as air director.

In addition to the overhead operating light, the ceiling may be used for mounting an anesthesia service boom, operating microscope, x-ray image intensifier, electronic monitor, and a variety of hooks, poles, and tubes. Demands for ceiling-mounted equipment are diversified.

Suspended track mounts are not recommended because they engender fallout of dust-carrying microorganisms each time they are moved. If movable or track ceiling devices are installed, they should not be mounted directly over the OR bed but away from the center of the room and preferably recessed into the ceiling to minimize the possibility of dust accumulation and fallout.

Piped-In Gases, Computer Lines, and Electrical Systems

Vacuum for suction, anesthetic gas evacuation, compressed air, oxygen, and nitrous oxide may be piped into the OR. For safety, the hoses used to pipe in the gases and evacuate waste anesthetic gas are color coded (Fig. 10.12). The pin-index safety outlets may be located on the wall or suspended from the ceiling in either a fixed rotating boom or a retractable column. The anesthesia provider needs at least two outlets for oxygen and suction and one for nitrous oxide. The pin-index safety connectors that fit into the outlets have different shapes to prevent placing the wrong gas supply to the anesthesia machine (Fig. 10.13). To protect other rooms, the supply of oxygen and nitrous oxide to any room can be shut off at control panels in the corridor should trouble occur in a particular line. A panel light comes on, and a buzzer sounds in the room and in the maintenance department. The buzzer can be turned off, but the panel light stays on until the problem is corrected. The buzzer should be tested on a routine schedule and should remain active at all times. Turning off the sound could lead to unsafe operating conditions.

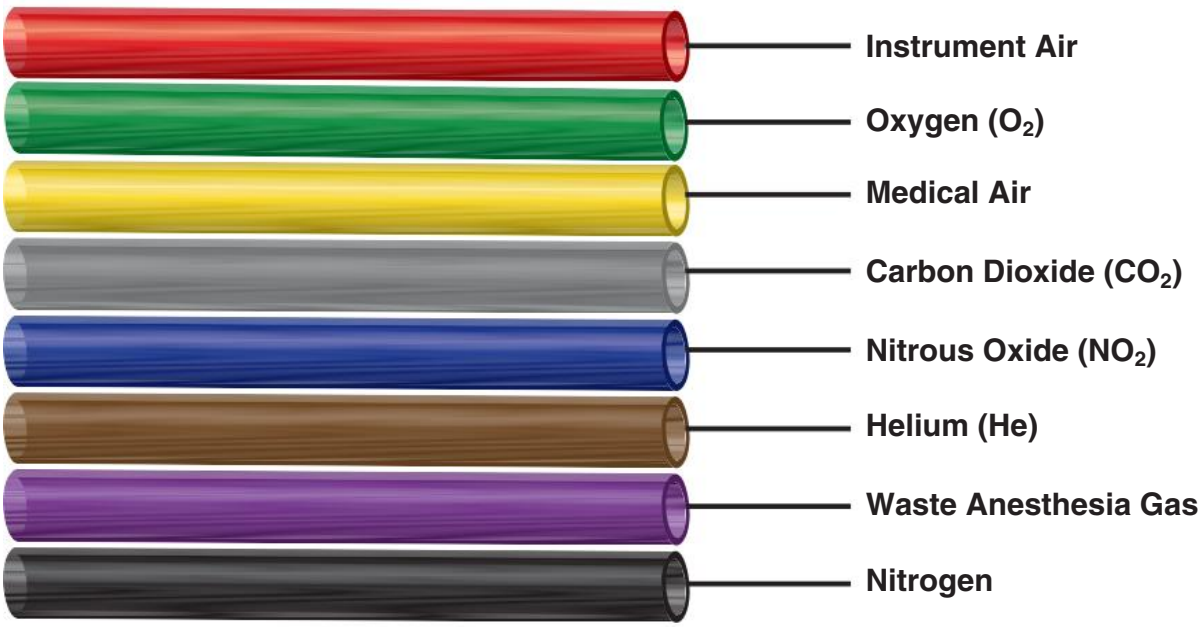
Computers are widely used in the OR. They are commonly located adjacent to the anesthesia machine and the circulating nurse's desk. Most facilities have wireless access to the Internet and the in-house intranet. Both the circulating nurse and the anesthesia provider can document patient care and charges in the medical record. Additional computers can be used in specialties such as neurosurgery or orthopedics to display computed tomography (CT) images during the intraoperative care period. Digital x-rays can be displayed directly from the radiology department. Care is taken not to use the keyboard with soiled hands or soiled examination gloves. The keyboard should be of a design that permits adequate cleaning between patients. Seamless touch keypads or keyboard covers are easiest to maintain and clean.

Electrical outlets are grounded and must meet the requirements of the equipment that will be used. Some machines require 220-V power lines; others operate on 110 V. Electrical receptacles are color coded to show usability during a power outage. The white or ivory outlets are for general use. The red outlets are designed to work through the emergency power system's generator (Fig. 10.14). All equipment used for patient physiologic maintenance should be plugged into the red outlets.

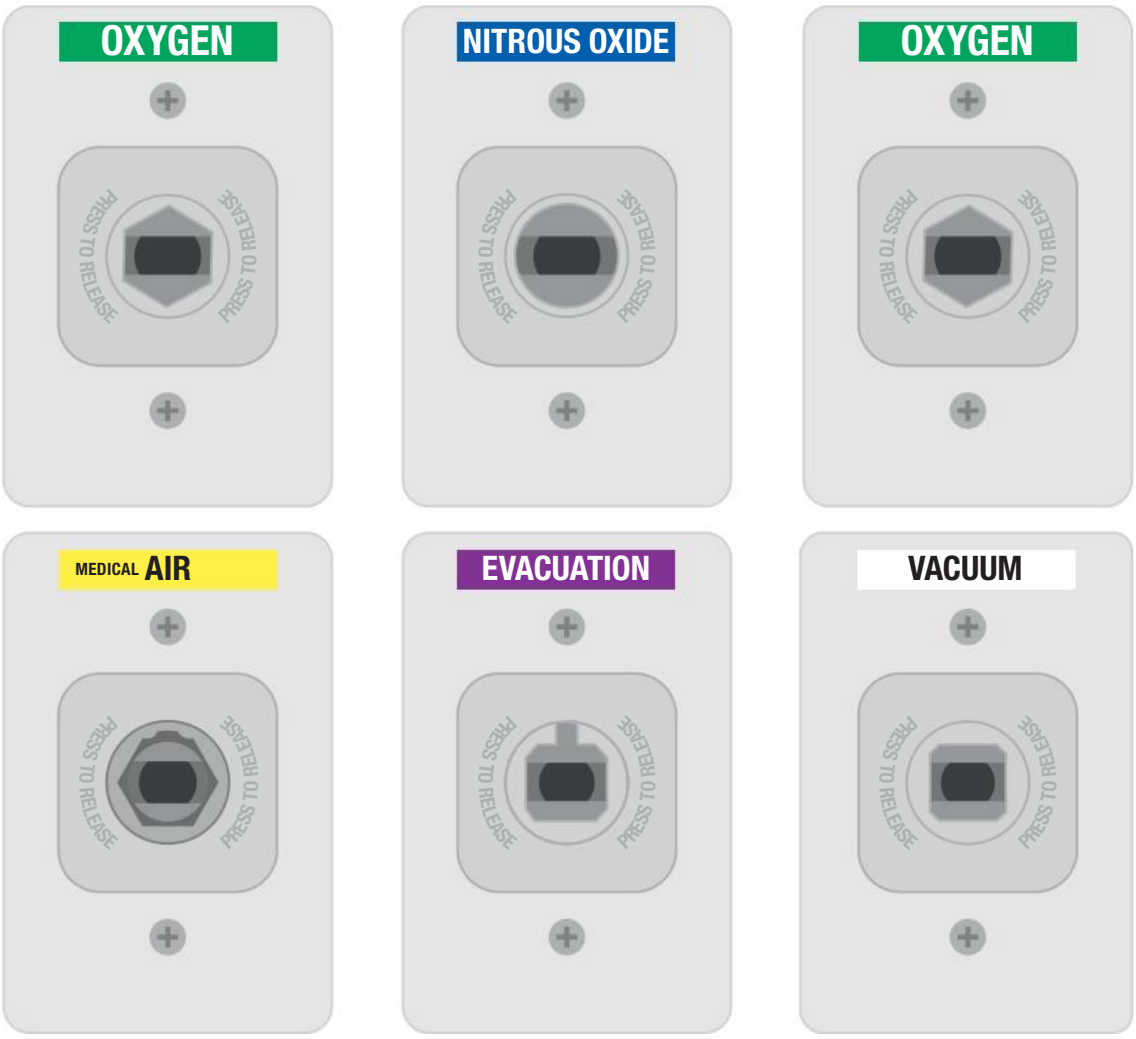
Permanently mounted fixtures, such as a clock and x-ray view boxes, can be recessed into walls and wired in rather than plugged into outlets. Electrical cords that extend down the wall or across the floor are hazardous. Ceiling-mounted booms are strategically placed for bringing piped-in gases, vacuum lines, and electrical outlets close to the OR bed. They eliminate the hazard of tripping over cords.

Multiple electrical outlets should be available from separate circuits. This minimizes the possibility of a blown fuse or a faulty circuit shutting off all electricity at a critical moment. All personnel must be aware that the use of electricity introduces the hazards of electric shock, power failure, and fire. Faulty electrical equipment may cause a short circuit or the electrocution of patients or personnel. These hazards can be prevented by taking the following precautions:

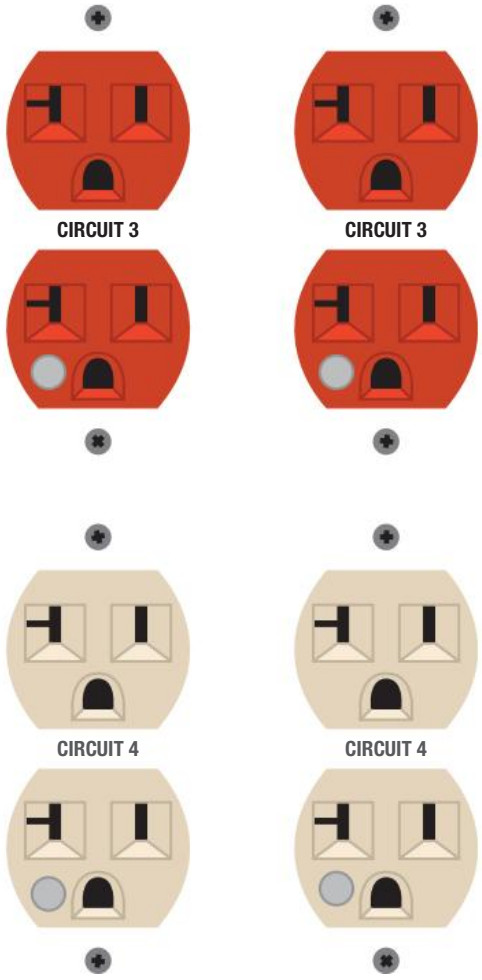
1. Use only electrical equipment designed and approved for use in the OR. Equipment must have cords of adequate length and adequate current-carrying capacity to avoid overloading.
2. Test portable equipment immediately before use.
3. Discontinue use immediately if any malfunction takes place, and report any faulty electrical equipment.
4. If a ground fault buzzer sounds, unplug the last device engaged and remove it from service.



• **Fig. 10.12** Color-coded hoses for the anesthesia gas machine.



• **Fig. 10.13** Outlets for anesthetic hose connections. Each portal has a different shape to prevent error during connection.



• **Fig. 10.14** Electrical receptacles are color coded—red for emergency use and white/ivory for general use.

Fire safety systems are installed throughout the hospital. All personnel must know the fire rules. They must be familiar with the location of the alarm box and the use of fire extinguishers. Additional information concerning OR fires can be found in Chapter 13.

Lighting

General illumination is furnished with static ceiling lights and mobile spotlights. Most room lights are white fluorescent, but they may be incandescent. Lighting should be evenly distributed throughout the room without harsh shadows, especially in the working area of the sterile field. The anesthesia provider must have sufficient light, at least 200 foot-candles, to adequately evaluate the patient's color. Intraoperatively, the lighting should not cause the organs to appear discolored.

For minimized eye fatigue, the ratio of intensity of general room lighting to that at the surgical site should not exceed 1:5, preferably 1:3. This contrast should be maintained in corridors and scrub areas, and in the room itself, so the surgeon becomes accustomed to the light before entering the sterile field. Color and hue of the lights also should be consistent. Some facilities use a green light system to balance the color.

Illumination of the surgical site depends on the quality of light from an overhead spotlight source and the reflection from the drapes and tissues. Drapes should be blue, green, or gray to avoid eye fatigue. White glistening tissues need less light than dull dark tissues. Endoscopic cameras have a built-in white-balancing feature to facilitate a natural color of the organs visualized. Light, either endoscopic or in open procedures, must be of such quality that the pathologic conditions are recognizable. Some lighting systems have video cameras installed that can be connected to monitors for observation by nonsterile personnel outside the field. The view is close to the same field of vision of the surgeon and first assistant.

The overhead operating light must:

- Make an intense light, within a range of 3700 to 15,000 foot-candles (40,000 to 160,000 lux), into the incision without glare on the surface. It must give contrast to the depth and relationship of all anatomic structures. The light should be equipped with an intensity control with a minimum of four brightness levels. The surgeon asks for more light when needed. A reserve light should be available.

  Lighting needs differ when endoscopic equipment with video monitors is used. Lower light power control is beneficial to the team to minimize eye fatigue. Some surgeons have the room lights dimmed for certain procedures.
- Provide a light pattern that has a diameter and focus appropriate for the size of the incision. An optical prism system has a fixed diameter and focus. Other types have adjustable controls mounted on the fixture.

  Most fixtures provide focused depth by refracting light to illuminate both the body cavity and the general operating field. The focal point is where illumination is greatest. It should not create a dark center at the surgical site. A 10-inch to 12-inch (25-cm to 30-cm) depth of focus allows the intensity to be relatively equal at both the surface and the depth of the incision.

  To avoid glare, a circular field of 20 inches (50 cm) in diameter provides a 2-inch (5-cm) zone of maximum intensity in the center of the field with 20% intensity at the periphery.
- Be shadowless. Multiple light sources and reflectors decrease shadows. In some units, the relationship is fixed; other units have separately maneuverable sources to direct light beams from converging angles. Some manufacturers have incorporated sensors in the spotlight to detect when the first assistant or surgeon's head is in the beam and threatening to cast a shadow. The lights sense the obstruction and decrease the beam, preventing a shadow over the surgical site.
- Produce the blue-white color of daylight. Color quality of normal or diseased tissues is maintained within a spectral energy range of 3500° K to 6700° K. Most surgeons prefer a color temperature of about 5000° K, which approximates the white light of a cloudless sky at noon.
- Be freely adjustable to any position or angle with either a vertical or a horizontal range of motion. Most overhead operating lights are ceiling mounted on mobile fixtures. Some have dual lights or dual tracks with sources on each track. These are designed for both lights to be used simultaneously to provide adequate intensity and minimize shadows in a single incision. Many fixtures are adapted so the surgeon can direct the beam by manipulating sterile handles attached to the lamp or by remote control at the sterile field. Automatic positioning facilitates adjustment, and braking mechanisms prevent drift (i.e., a movement away from the desired position).

  Fixtures should be manipulated as little as possible to minimize dispersion of dust over the sterile field. For the best

illumination in the shortest time, the first spotlight should be positioned at the surgical site, followed by the second. Ideally, the light can be maneuvered in a 360-degree rotation as needed, quickly and without effort. Smaller lights commonly are restricted because of wiring bundles.

- Produce a minimum of heat to prevent injuring and drying exposed tissues. Most overhead lights dissipate heat into the room, where it is cooled by the air-conditioning system. Halogen bulbs generate more light and heat than do other types but do not last as long. Prolonged exposure to halogen light can be drying to the patient's tissues. The average halogen bulb lasts 1000 to 3000 hours. The risk for fire from a halogen bulb is significant, and the hot bulb should not be permitted to come in contact with any flammable material or a person's skin.

  Lamps should produce less than 25,000 mW/cm of radiant energy. If multiple light sources are used, collectively they must not exceed this limit at a single site. Beyond this range, the radiant energy produced by infrared rays changes to heat at or near the surface of exposed tissues. A filter globe absorbs some infrared and heat waves over the light bulb or with an infrared cylindric absorption filter of a prism optical system. Nonfiltered lights, particularly halogen, can burn tissue from a distance.
- Be easily cleaned and maintained. Tracks recessed within the ceiling virtually eliminate dust accumulation. Suspension-mounted tracks or a centrally mounted fixture must have smooth surfaces that are easily accessible for cleaning. Light bulbs should have a reasonably long life. Light-emitting diode (LED) lights are semiconductors. LED lights last longer than halogen bulbs and do not generate heat. The average LED light lasts 20,000 hours, and more advanced LED lights last 50,000 hours. New LED fixtures can last a facility up to 10 years.

Changing the bulb should not require additional tools because time may be an issue in a critical part of a surgical procedure. The bulb is usually too hot to touch with the bare hand. Many styles are available that contain several bulbs that provide backup light when one bulb burns out.

A supplemental surgical task light may be needed for a secondary surgical site, such as for the legs or arms during conduit procurement for cardiovascular procedures. Some hospitals have portable explosion-proof lights. These lights should have a wide base and should be tip-proof. Others have satellite units that are part of the overhead lighting fixture. These should be used only for secondary sites unless the manufacturer states that the additional intensity is within safe radiant energy levels when used in conjunction with the main light source. The use of multiple teams in complex multidisciplinary procedures requires adequate lighting for each operating surgeon.

A source of light from a circuit separate from the usual supply must be available for use in case of power failure. This may require a separate emergency spotlight. It is best if the operating light is equipped so that an automatic switch can be made to the emergency source of lighting when the usual power fails. The International Electrotechnical Commission (IEC), requires that new lighting must have the capability to restore power within 5 seconds after shut down. Flashlights with fresh batteries should always be immediately available.

Some surgeons prefer to work in a darkened room with only indirect illumination off the surgical site during minimally invasive procedures. This is particularly true of surgeons working with endoscopic instruments and the operating microscope. If the room has windows to the hall or substerile room, lightproof shades may be drawn to darken the room when this equipment is in use. Because of the hazard of dust fallout from shades, the windows may have blinds contained between two panes of glass with a handle to open or close the louvers in rooms where this equipment is routinely used.

Although the surgeon may prefer the room darkened, the circulating nurse or anesthesia provider must be able to see adequately to observe the patient's color and to monitor the patient's condition. One dim spotlight can be aimed away from the field in the direction of the anesthesia provider. In some circumstances, the x-ray view box can be turned on for additional illumination.

Some surgeons wear an adjustable headlight designed to focus a light beam on a specific area, usually in a recessed body cavity (14 to 20 inches) such as the nasopharynx. Avoid using the headlamp at distances less than 10 inches. Too much heat and drying can harm tissues. The surgeon will don the headlamp and aim the beam before scrubbing. Fiberoptic headlights produce a cool-colored light and reduce shadows. Both the surgeon and first assistant may wear a headlight. The fiberoptic light cable should be clipped to the back of the surgeon's gown and enough length should be provided to prevent pulling on the light source when the surgeon moves. The cable should not be kinked or folded, because the glass fibers will break and stop transmitting light. When not in use the cable should be loosely coiled.

Alternatively, a light source that is an integral part of a sterile instrument, such as a lighted retractor or fiberoptic cable, may be used to illuminate deep cavities or tissues difficult to see with only the overhead operating light. Fiberoptic cables should not be permitted to become detached from the instrument and shine directly on the drape for a prolonged period because a fire may ignite. During operation, do not permit blockage of the cooling vents by drapes or other equipment. Avoid looking directly into the beam as it may cause eye injury. The light source intensity setting should be completely at zero before disconnecting the cable for processing. Care is taken not to touch the connector until it is completely cooled. Refer to the manufacturer's recommendations for cleaning and servicing.

Monitoring Screens

Monitors and computers are designed to keep the OR team aware of the physiologic functions of the patient throughout the surgical procedure and to record patient data. The anesthesia provider or a perioperative nurse uses monitoring devices as an added means to ensure safety for the patient during the surgical procedure.

The screens may be built into portable carts or attached to articulated arms or ceiling booms. They may be plasma or liquid crystal display (LCD) and measure 20 to 22 inches, and in some facilities up to 42 inches. Plasma screens are heavier and do not last as long as LCD versions. Newer screens with surface-conduction electron emitter displays (SEDs) will likely replace LCD and plasma screens in the future. LED screens use light-emitting diodes as pixels and offer clear, bright color pictures. These screens are popular in the OR setting for a detailed image.

More commonly, video monitors serve a number of useful purposes for the surgeon within the OR. They are widely used for teaching surgical techniques. This minimizes the number of visitors in the OR, which, in the interest of sterile technique, is advantageous. In addition, monitors provide a better view for more people to see the surgical procedure from a remote area or through a microscope or endoscope. They can also be used for record keeping and documentation for legal purposes for the

surgeon. Video recording is possible for this purpose. If video recording is done while patients are in the rooms, each patient should have the opportunity to sign a permission form.

As an aid to diagnosis, an audiovisual hookup between the OR and the radiology department permits digital x-rays to be viewed on the monitor in the OR without having to be transported into the OR and mounted on view boxes. With such a hookup, the surgeon gains the advantage of remote interpretive consultation when desired.

A two-way audiovisual system between the pathology laboratory and the OR enables the surgeon to examine the microscopic slide by video in consultation with the pathologist without leaving the OR bed. The pathologist can view the site of the pathologic lesion without entering the OR.

Radiograph Screens or View Boxes

Many facilities have changed from plain film viewing to digital computer monitors. The monitors may be on articulated arms that extend from the wall or ceiling. In this circumstance, lighted view boxes are still useful in the event old films are brought from the archives for comparison with the patient's new digital images. The view boxes also can be used as indirect lighting during low-light procedures.

X-ray view boxes can be recessed into the wall. The viewing surface should accommodate a minimum of four standard-size films. The best location is in the line of vision of the surgeon standing at the OR bed. Lights for view boxes should be of high intensity. A film-holding basket should be placed within reach of each view box station.

Clocks

Two clocks should be in each OR. A standard clock, analog or digital, for basic time observation should be visible from the field. A time-elapsed clock, which incorporates a warning signal, is useful for indicating that one or more predetermined periods of time have passed. This may be used during surgical procedures for total arterial occlusion, with use of perfusion techniques or a pneumatic tourniquet, or during cardiac arrest. Start, stop, and reset buttons should be within reach of the anesthesia provider and the circulating nurse.

Cabinets or Carts

Each OR may be supplied with closed-in stationary cabinetry unless a cart system or pass-through entry is used. Supplies for the types of surgical procedures done in that room are stocked, or every OR may be stocked with a standard number and type of supplies. Having these basic supplies saves steps for the circulating nurse and helps eliminate traffic in and out of the OR. Glass shelves and sliding doors provide ease in finding and removing items.

Many cabinets are made of stainless steel or hard plastic. Wire shelving minimizes dust accumulation. Cabinets should be easy to clean. One cabinet in the room may have a pegboard at the back to hang items, such as table appliances. Gloves used in patient care should be removed when opening the cabinet and removing supplies.

Pass-through cabinets that circulate clean air through them while maintaining positive air room pressure allow transfer of supplies from outside the OR to inside it. They help ensure the rotation of supplies in storage or can be used only for passing supplies as needed from a clean center core. Some pass-through cabinets between the OR and a corridor accommodate supply carts directly from the **sterile core**, which are easily removable for restocking.

In lieu of or as an adjunct to cabinets, some hospitals stock carts with special sutures, instruments, drugs, and other items for some or all of the surgical specialties. The appropriate cart is brought to the room for a specific surgical procedure.

Furniture and Other Equipment

Stainless steel furniture is plain, durable, and easily cleaned. Each OR is equipped with these basic items:

- OR bed with a mattress covered with an impervious surface, foam or gel construction, attachments for positioning the patient, and armboards.
- Instrument tables. These are commonly called *back tables,* although they are actually at the side of the scrub person during the surgical procedure. Some rooms use over-bed tables such as Phelan or Mayfield style.
- Mayo stand. The Mayo stand is a frame with a removable rectangular stainless steel tray. The footplate of the frame slides under the OR bed and the support that holds the tray positions over the sterile field. The Mayo tray is supplied with immediate-need instruments and supplies. The height is adjustable.
- Small tables for gowns and gloves and the patient's skin preparation equipment and catheterization supplies.
- Ring stand for basins. This is optional because most ORs do not use splash basins.
- Anesthesia machine and table for anesthesia provider's equipment.
- Sitting stools and standing platforms that safely stack to give additional height to the user.
- IV poles for IV solution bags. The anesthesia provider may clip the upper drapes to the IV poles.
- Suction canisters, preferably portable on a wheeled base or waste management system that suctions fluids and surgical plume.
- Laundry hamper frame.
- Kick buckets in wheeled bases. Commonly called *sponge buckets.*
- Wastebasket near the circulating nurse's desk, biohazard red trash bins, and clean trash bins.
- Writing surface. This may be a wall-mounted stainless steel desk or an area built into a cabinet for the circulating nurse.
- Computer station. This may be permanently affixed to a hard-wired station or mobile wireless. The keyboard should be positioned so the circulating nurse can observe the sterile field. A scanning device may be incorporated for bar-coded drugs and supplies.

Communication Systems

A communication system is a vital link to summon routine or emergency assistance or to relay information to and from the OR team. Many surgical suites are equipped with telephones, intercoms, call lights, video equipment, and computers. These communication systems may connect the OR with the clerk-receptionist's desk, the nurse manager's office, the holding area, the family waiting room, the PACU, the pathology and radiology departments, the blood bank, and the sterile processing department. These systems make instantaneous consultation possible through direct communication.

Voice Intercommunication System

Telephone and intercom systems are useful for the OR team to communicate with the control desk. Sounds are distorted to the patient in early stages of general anesthesia. Incoming calls over an intercom should not be permitted to disturb the patient at this time. Also, an awake patient should not overhear information about a pathologic diagnosis (e.g., from a voice coming through an intercom speaker box after a biopsy has been performed). Installation of any type of intercom equipment either in the adjacent substerile room or scrub area rather than in the OR helps eliminate sounds that could disturb both the patient and the surgeon.

Call-Light System

This system is used to summon assistance from the anesthesia staff, pathologist, patient care staff, and housekeeping personnel. It is activated in the OR with a hand-operated switch; a light alerts personnel at a central point in the suite or displays at several receiving points simultaneously.

Closed-Circuit Television

Television surveillance is an easy way for the nurse manager to keep abreast of activities in each OR. By means of a video camera with a wide-angle lens mounted high in the corner of each OR, managers may make rounds simply by switching from one room to another by pushing buttons at their desk and viewing a monitor in the office. Signs should be posted to indicate that video surveillance is in process, and the patient should be made aware that this is happening.

Computers

A computer in each OR affords access to EMR information and allows data input by the circulating nurse. The types of hardware and software programs available dictate the capabilities of the automated information system. A keyboard, light pen, or bar-code scanner may be used for input. The computer processes and stores information for retrieval on the viewing monitor and by printout from a central processing unit.

The computer system should be wireless for fast transmission of data and should require a password for each user in the system for security. The staff should be encouraged to log-on and log-off, but the system has idle time parameters, so, if inactive for a period of time, the system automatically logs off the user. Failed password attempts lock out the user for a designated period or may require the system administrator to assign a new password.

The computer database and EMRs help the circulating nurse obtain and enter information that may include the following:

- Schedule, including the patient's name, surgeon, procedure, special or unusual equipment requirements, wound classification, and whether procedure is elective, urgent, or emergency
- Patient EMR, preoperative patient assessment data, nursing diagnoses, expected outcomes, and plan of care
- Results of laboratory and diagnostic tests
- Surgeon's preference card with capability to update
- Inventory of supplies and equipment provided and used
- Charges for direct patient billing
- Intraoperative nursing interventions
- Timing parameters, including all staff activity, procedure, and room turnover
- Incident reports
- Postoperative care in the PACU

The computerized patient information generated in the OR may interface with the hospital-wide computer system.

Caution: The printer should not be located in direct patient care areas. Printers use toner powder that can become airborne in the OR and cause contamination. According to the Safety Data Sheets (SDSs) for printer toner, the primary routes of entry of toner powder are via direct contact and inhalation.[c] Chronic lung exposure can cause irritation and lung fibrosis. Toner is combustible, and the powder has explosive qualities. It should be kept away from heat and flame. Personal protective goggles, gloves, and mask (PPE) should be worn if toner spills. A HEPA filter should be used if vacuuming the material. The Occupational Safety and Health Administration (OSHA) has not set permissible exposure limits at this time.

Special Procedure Rooms

Certain procedures or outpatient treatments may indicate the need for rooms designed for a specific purpose, such as interventional radiology, endoscopy, or cystoscopy. These rooms are designed with equipment for performing the specific interventional procedures, including specialized radiologic and monitoring devices. An interventional radiologist, cardiologist, and several endoscopists should be consulted when planning these types of facilities.

Interventional Radiography Room

Endovascular stenting, balloon angioplasty, cardiac catheterization, and other interventions that require fluoroscopy can be performed in a room with fixed x-ray equipment and specialized radiographic beds (Fig. 10.15). The endovascular instrument table may be double the average length because the aortic guidewires and deployment devices are extremely long. Proximity to the OR is important in case of an emergency that necessitates an open procedure. Many interventional rooms have doors that open into the semirestricted area of the surgical services department. Some interventional rooms double as minimally invasive rooms.

Cardiac catheterization (angioplasty and stenting) may be performed within the surgical suite in a room equipped for fluoroscopy. Imaging screens are located near the head of the OR bed or on articulated arms directly across the OR bed to allow the surgeon and the team to visualize the coronary arteries during the procedure. Monitors, suction, oxygen, and cardiopulmonary resuscitation equipment are available in this room for each cardiac catheterization procedure. The team must be alert for emergency situations, such as a perforated coronary artery, and be prepared for an emergency thoracotomy or transfer to an OR for an open procedure.

Minimally Invasive Surgery Room

Some rooms are equipped specifically for laparoscopic procedures, with ceiling booms in four quadrants of the room for endoscopic light sources, camera boxes, insufflators, electrosurgical generators, and video monitors. A dedicated **minimally invasive surgery (MIS) procedure** room has all the equipment for puncture and natural orifice endoscopy located on a large cart or a ceiling-mounted boom. The use of booms in these rooms helps minimize the amount of equipment spread around the room.

Several video monitors are located around the room on articulated arms or on the booms for ergonomic viewing of the surgical field by the surgical team. These rooms should have the capability

[c]See www.ehso.com for details per each manufacturer. Not many studies have been done to date.

• **Fig. 10.15** Hybrid interventional OR has permanently installed imaging equipment.

of immediately converting to an open procedure in the event of an untoward event such as arterial or organ puncture.

Endoscopy Room

Many surgical suites have a designated class A size room in which natural orifice flexible or rigid **endoscopic procedures**, such as bronchoscopy, gastroscopy, sigmoidoscopy, or colonoscopy, are performed. Most are equipped for the use of lasers and electrosurgery. Some endoscopy rooms have x-ray and video capabilities. Equipment for natural orifice endoscopy is usually affixed to mobile carts so they can easily be transported to a regular OR for intraoperative bronchoscopy, gastroscopy, or colonoscopy added to a major surgical procedure.

Cystoscopy Room

A cystoscopy room (cysto room) may be available for a urologic examination or procedure. Ideally, the room should be a class A or class B size located in the restricted area of the OR. Waste fluids are collected in special canisters or waste management suction devices and are disposed of like other biologically contaminated fluids. Older cystoscopy rooms may be equipped with special floor drains for the disposal of fluids during the procedure. The drain cover must be removable for cleaning. Modern styles have eliminated this drain for infection control reasons.

A cystoscopy room is also equipped with x-ray and fluoroscopy machines because many procedures require the use of IV or ureteral contrast media to visualize the kidneys, ureters, and bladder. Radiographic digital screens should be adjacent to the OR bed, and view boxes should accommodate a minimum of four still films simultaneously. Imaging screens are located in the room, either free-standing or mounted on articulated arms, to allow the urologist to visualize the urologic structures during fluoroscopy. Some urologists use ultrasonic equipment, lasers, and electrosurgery to perform minimally invasive procedures.

• **Fig. 10.16** Cesarean delivery room. (Courtesy Michael S. Clement, MD.)

A portable cystoscopy cart should be available for dispatch from the cystoscopy room when a procedure in the main OR requires placement of ureteral catheters, stents, or a cystoscopic examination. The cart should be equipped with a light source, sterile camera, video monitor, sterile cystoscopes (0 and 30 degrees) and light cord, bridges and sheaths, an assortment of ureteral catheters in pairs, Foley catheters, urinary drainage bags, and lubricant.

Cesarean Delivery Room

Most facilities that have obstetric departments have a self-contained OR within the delivery suite (Fig. 10.16). This is a restricted room with an attached substerile room and scrub sink area. The purpose of this room is to provide equipment and supplies in support of a surgical birth of the baby through the mother's abdomen (cesarean section) instead of a vaginal birth.

A few differences of the cesarean delivery room include resuscitation supplies and equipment for the newborn and a specialized warming bed that can be used to transport the baby to the special care nursery.

Construction or Renovation of the Surgical Suite

Considerations for Planning and Design

The planning and design of the new perioperative environment generally entails both renovation and new construction. Most facilities cannot shut down for the construction process and must continue with patient care services. Adequate planning and projection of needs during the process take some of the stress out of running the department around construction obstacles.

The AIA Guidelines require a preconstruction risk analysis in a consultative format. The Infection Control Risk Assessment (ICRA) is determined, with all parties offering multidisciplinary input about features such as water temperature between 105° F (40.6° C) and 120° F (48.9° C), electric safety, ventilation air changes, and containing potential contamination. Box 10.1 describes additional preconstruction assessment factors to consider.

Goals to strive for include (1) timing of construction phases, (2) precision of work done, and (3) staying within the budget. Generating a concurrent plan for maintaining patient flow and

• BOX 10.1 Preconstruction/Neoconstruction Risk Assessment Questions

Infection Control Issues

- Are walls and doors adequately sealed against particulates?
- Are potential sites of vermin entry sealed?
- Is ductwork free from material transferred from unclean areas?
- Are waterlines secured and leak free?
- Is a designated trash collection path identified?
- Is the environmental services need established?

Safety Concerns

- Are rerouted entrances and exits clearly marked? Will patient traffic change?
- Are fire alert mechanisms in place? Is a fire walk-through necessary?
- Is life-saving equipment in an accessible location? Any Code Blue changes necessary?
- Is a backup power source immediately available?
- Is a backup water supply immediately available?
- Will other departments be directly affected?
- Is the project boss immediately available to halt the work crew in the event of a critical event or emergency?

expanding/renovating the department requires a multidisciplinary team, which may include the following members:

- Department director, nurse manager, and senior perioperative nursing personnel
- Physicians (surgeon, anesthesiologist, pathologist)
- Infection control, risk management, and environmental services personnel
- Maintenance and biomedical personnel
- Project manager (may be in-house personnel or a consultant), architect, equipment vendor, and purchasing personnel; a collaboration between the architect and equipment vendor can generate three-dimensional drawings that can offer a preview of the area
- Communications and information technology personnel (e.g., computers, telephone, intercom, emergency call)
- Support services (e.g., laboratory, radiology, pharmacy) personnel
- City or municipality planning personnel
- Interior decorator

No one particular construction or renovation plan suits all hospitals or surgical centers; each plan is individually designed to meet projected specific future needs. Visiting other hospitals where building and reconstruction have taken place is beneficial. Ask about the good and bad points.

The number of ORs, storage areas, and immediate perioperative patient care areas required depends on the following:

- Number, type, and length of the surgical procedures to be performed. This determines the class of OR size to build.
- Type and distribution by specialties of the surgical staff and equipment for each. Some specialties may use the same room most of the time and use mounted equipment such as booms, microscopes, imaging equipment, and endoscopy.
- Proportion of elective inpatient and emergency surgical procedures to ambulatory patient and minimally invasive procedures.
- Scheduling policies related to the number of hours per day and days per week the suite will be in use and staffing needs.
- Systems and procedures established for the efficient flow of patients, personnel, and supplies.
- Consideration of volume changes and need for future expansion capabilities.
- Technology to be implemented and plans for potential technology to be developed.
- Safety of staff, patients, and other personnel during construction or renovation.
- Infection control procedures.

Principles in Construction or Renovation Planning

The universal problem of environmental control to prevent wound infection exerts a great influence on the design of the surgical suite and the plans for construction or renovation. Surgical suites older than 20 years do not have the capability of supporting newer technology with renovation for space and technologic, HVAC, and electrical capabilities.

Architects, administrators, and surgical suite designers follow several concepts in planning the physical layout and construction of a surgical suite, as follows:

1. Strategic planning
   a. Avoid as much inconvenience to facility personnel as possible.
   b. Include facility personnel in the planning phase as much as possible.
   c. Expedite completion as fast as possible without compromising safety of patients, staff, and construction personnel.
   d. Keep costs down by planning ahead. Do not substitute cheap materials for durable materials. They only cost more to replace later. Always follow manufacturer and blueprint specifications.
   e. Plan the project in steps, or phases, completing each area before starting the next. After each phase, have a group of committee members walk through to evaluate the work and the effectiveness of the design.
   f. Minimize the ordering of supplies for patient use to only those items needed for immediate procedures. Inventory storage is an issue as the project unfolds.
   g. Resolve replacement issues for current equipment in use. Sometimes it is financially better to buy units in a lot than to replace one at a time. Deals can be made regarding pricing when planning equipment for the new rooms. It is better to install equipment from scratch than to add later at an added construction/installation cost.
   h. Plan for the closing of rooms without too much disruption if they are to be updated.
   i. Determine the balance of fixed equipment versus mobile equipment for use in several rooms.
   j. Determine the need for dedicated rooms, such as for endoscopy, cystoscopy, orthopedic, minimally invasive procedures, interventional radiology, and cardiac procedures.
2. Plans for problems or emergencies
   a. Power, communications, medical gases, vacuum system, waste gas scavenger, air-handlers, water, and sewage cannot be interrupted. A plan should be in place to counter any accidental cutting of lines by construction personnel. *Legionella* has grown in standing water lines during phases of construction. *Aspergillosis* spores have been isolated and transmitted to patients.
   b. Plan for capability of construction work stoppage at a moment's notice if requested by a surgeon during a critical phase of surgery.

3. Exclusion of contamination from outside the suite with sensible traffic patterns to and from the suite
   a. A sealed barrier must be in place between working ORs and the portion of the suite under construction. Wood or drywall panels as temporary walls sealed over all edges with duct tape can keep dust and fungal spores from entering the suite. Plastic sheeting is not sturdy and can be easily punctured.
   b. Negative pressure must be maintained in halls with exhaust filtered to the outside of the building.
   c. Traffic patterns must be unobstructed for debris removal. Asbestos may be present and will require special handling of all materials removed. Toileting and hand-cleansing areas must be available to construction workers.
   d. Traffic patterns must be unobstructed for bringing in construction supplies and materials. Walk-off sticky mats can be placed on the floors at entrances and exits to attract particulate matter from the shoes of the workers. The sticky mats have tear-off sheets that can be removed as they become soiled, revealing a fresh sticky mat.
4. Separation of clean areas from contaminated areas within the suite during the building phase
   a. Patient traffic should be separated from construction traffic.
   b. Clean supplies are transferred in an area separate from construction supplies.
   c. Biologic decontamination and processing areas remain functional at all times.
5. Noise control
   a. Noise pollution should be kept at a minimum when surgical procedures are in process or the general patient population in the hospital is sleeping.
   b. Vibrations from powered equipment and jackhammers can disrupt microscopic or other procedures.

Physical plant design and construction/renovation planning of a surgical suite should include detailed consideration for the activities of patients, caregivers, and environmental maintenance.

Ambulatory Surgery Centers and Alternative Surgical Locations

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Compare the differences between hospital-based services and ambulatory surgery centers.
- Distinguish between activities in fixed and mobile surgery locations.
- Describe key elements of human versus veterinary surgery.

KEY TERMS AND DEFINITIONS

Ambulatory care Care delivered to a patient who is not confined to bed or in need of formal admission to a facility for a prolonged period.

Deployment A term that refers to sending one or more active duty soldiers forward into an area where medical war support is needed.

DEPMEDS A system of mobile military hospital components that are assembled and dismantled close to the location of military activity.

Monitoring Clinical observation of a patient's condition through continuous interpretation of vital signs, activities, and responses.

PAT center Area of a facility designated for patient assessment and preprocedural examination.

Telehealth A term used for the activities of health care with the use of computers, mobile health applications, live video conferencing, monitoring systems, and electronic records. All aspects of health can be covered, such as health information, digital records, provider contact, medical care, and education.

Ambulatory Surgical Setting

Ambulatory surgery can be defined as surgical patient care performed with general, regional, or local anesthesia without overnight hospitalization. Some ambulatory surgery centers (ASCs) offer diagnostic testing and radiologic examinations, such as mammography.

The following are organizations specifically for professional ambulatory surgical nurses:

- American Society of PeriAnesthesia Nurses (ASPAN); www.aspan.org
- American Academy of Ambulatory Care Nurses (AAACN); www.aaacn.org
- Association of periOperative Registered Nurses (AORN); www.aorn.org

AORN has established a specialty assembly for nurses who practice in the ambulatory setting. A chairperson and council are selected by the assembly membership to serve 3-year terms. AORN's website has an Ambulatory Surgery Center Solutions Guide for ASC leaders. It contains information on infection prevention, specific details for ambulatory facility practice, information on sterilization, nursing education modules, an administrator course, and a career center at www.aorn.org.

Ambulatory Surgery Programs

Various terms are used to describe **ambulatory care** facilities, including *outpatient surgery, same-day surgical unit, day surgery,* and *ambulatory surgery center.* Conceptually, an ambulatory facility has the following:

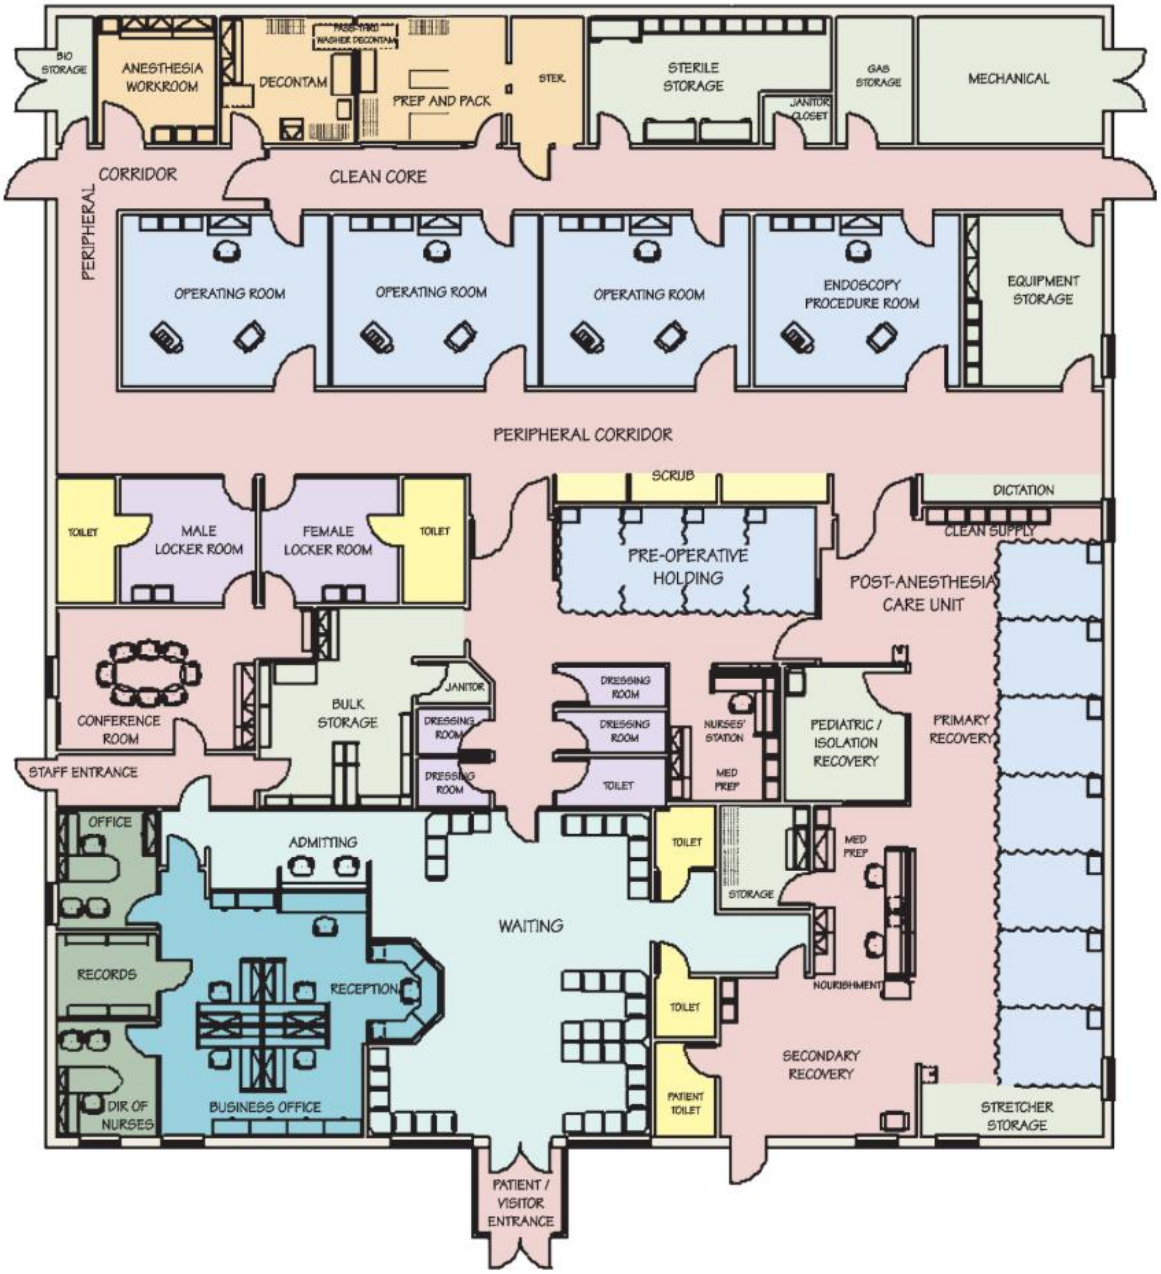
- Preprocedural testing and assessment area (**PAT center**)
- Admitting area
- Changing and dressing room with lockers and toilets
- Preoperative holding/preparation area
- Operating room (OR)
- Postanesthesia care unit (PACU) or access to a PACU
- Family waiting room

The decor of the ambulatory facility should be pleasing to enhance relaxation of the patient and family. Recliners are commonly available for postprocedure recovery. Many facilities have televisions and reading material and offer beverages for waiting family members. Figure 11.1 depicts a sample floor plan that shows the various areas within an ASC. Priority patient parking areas should be conveniently located near the entrance to the facility, with parking spaces for disabled patients located nearest the entrance.

Many hospital-based ASCs offer valet parking. The convenience of dropping off and picking up patients should be accommodated in the design of the facility. Studies have shown that this is a point of patient satisfaction. Space requirements for parking areas are determined by the numbers and types of surgical procedures to be performed.

The location of an ASC may vary. The Federated Ambulatory Surgery Association (FASA) indicates that a true ASC is not dependent on the main hospital and is physically independent in services, such as ORs, postprocedure care, and central service. ASCs are not designed to take emergency patients and typically employ fewer than 20 employees. Examples of outpatient surgery departments attached to hospitals include the following:

- *Hospital-based dedicated unit.* Patients come to a self-contained unit that is located within or attached to the hospital but physically separate from the inpatient OR suite.
- *Hospital-based integrated unit.* Ambulatory patients share the same OR suite and other hospital facilities with inpatients. The preoperative admission and holding area is shared. Ambulatory patients usually return to the same admission area for discharge after the procedure.



• **FIG. 11.1** Schematic of ambulatory surgery floor plan. (Reprinted with permission Herman Miller, Inc.)

- *Office-based center.* Patients come to a physician's office that is equipped for surgery. Many private surgeons, dermatologists, periodontists, and podiatrists perform surgical procedures in their offices with a local anesthetic. This office-based center may accommodate one or more surgeons in the same specialty, or it may be a multiphysician, interdisciplinary clinic. Although these are not always attached to a hospital, they are not considered an ASC by FASA.

Examples of ASCs by the definition of FASA are the following:

- *Hospital-affiliated satellite surgery center.* Patients come to an ASC that is owned and operated by a larger facility but geographically separate from it.
- *Freestanding ASC.* Patients come to a completely independent facility. Many of these facilities are owned and operated by physicians.

Accreditation of Ambulatory Facilities

The ASC should comply with standards set by the Accreditation Association for Ambulatory Health Care (AAAHC; www.aaahc.org), The Joint Commission (TJC; www.jointcommission.org), the American Association for the Accreditation of Ambulatory Surgery Facilities (AAAASF; www.aaaasf.org), the Ambulatory Surgery Center Association (www.ascassociation.org/home), and the American Osteopathic Association (AOA; www.osteopathic.org). These five patient advocacy and consumer groups advise patients to select facilities carefully and to look for accreditation and credentialing by professional and governmental agencies. The ASC should be certified by the Centers for Medicare & Medicaid Services (CMS). The AAAHC is one organization that is authorized by the CMS to conduct surveys of health care facilities for compliance with the standards.

The 2019 updates for Ambulatory Care and Office-Based Surgery National Patient Safety Goals (www.jointcommission.org) include the following:

- *Improve the accuracy of patient identification:* Use a minimum of two patient identifiers (name and date of birth) when administering pharmacologic agents or blood, taking blood samples or specimens, or providing any treatments or procedures.
- *Improve communications among caregivers:* All verbal orders or results should be read back to the person delivering the information. Standardize a list of all abbreviations, acronyms, and symbols that are not to be used within the organization. Improve the timeliness of information exchange between the reporter and receiver regarding test results and values. Standardize the hand-over report of patient care to qualified personnel between phases of care.
- *Improve medication safety:* Standardize the numbers and concentrations of drugs within the facility, identify sound-alike/look-alike medications and limit their use to prevent error, and label all containers and delivery devices with the name and concentration of the drug. Discard any unlabeled medication containers. Medications should be verified by two individuals. Visual identification of the original container and confirmation with verbal read back.
- *Determine the patient's medication history and be sure there are no potential drug interactions during the course of care:* Take care with patients who routinely take blood-thinning medications. Provide adequate education concerning postoperative home-going drugs by providing drug name, dose, frequency, route, and contact information in case of reaction.
- *Reduce the risk for health care–related infections:* Comply with Centers for Disease Control and Prevention (CDC) recommendations for hand hygiene. All deaths or permanent injuries associated with health care–related infection are treated as sentinel events and reported to the accrediting agency.
- *Reduce the risk for surgical fires:* Staff education should include spark, fuel, and ignition sources, including oxygen concentration under drapes and fumes from alcohol prep solutions, as a source of surgical fire.
- *Prevent mistakes in surgery:* The surgeon must mark the surgical site. A "time out" is performed to confirm the correct patient, procedure, supplies, implants, and pertinent health information (i.e., allergies) with the team. Include the patient in the confirmation as possible.
- *Implement Revised Pain Assessment and Management Standards (2019):* This revision requires education for employees and patients, prescribing requirements for narcotics and opioid monitoring, treatment, and resources. This revision is the result of the opioid crisis in an effort to reduce patient dependency.

ASCs should be licensed by the state wherein they are established. Requirements for licensure are similar to those for accreditation. Inspection visits are scheduled on a routine basis. Ambulatory centers are highly regulated by governmental agencies. Medicare and Medicaid certification is required for reimbursement. Accreditation and credentialing of an ambulatory facility can be attained by, but is not limited to, the following:

- Compliance with structural standards
- Establishment of policies and procedures that support competent standards of care
- Appropriate credentialing of personnel
- Emergency preparedness
- Appropriateness of procedures performed at the facility

According to statistics compiled by the CDC, approximately two thirds of all surgical procedures performed are done on an ambulatory or outpatient basis safely and without complications. Some smaller facilities limit the use of ambulatory surgery to procedures that can be performed with local or regional block anesthetics. Facilities with PACU capability allow surgeons to perform procedures with the patient under general anesthesia.

Although procedures performed in an ambulatory care facility are usually of short duration (15 to 90 minutes), the appropriate selection and evaluation of patients are essential. Patient care and anesthesia management also are crucial factors in the experience of the ambulatory surgical patient.

Some facilities are prohibited from performing complicated laparoscopy because of the risk for injury to the patient. More ASCs are doing bariatric, total joint replacement, and palliative care procedures. (More information can be found at the FASA website at http://www.ascassociation.org/home.)

Patient Selection for Ambulatory Surgery

After a surgical procedure, patients may prefer to recuperate at home rather than in the hospital. These patients may be candidates for ambulatory surgery, depending on the nature and extent of the surgical procedure and on the patient's ability to follow instructions or to receive adequate care at home. Consideration is

given to the duration and complexity of the surgical procedure, the risks of anesthesia, and the probability of postoperative complications.

Patients are carefully screened before being considered safe candidates for ambulatory surgery. The following are some of the criteria considered:

1. General health status. Acceptable patients are in class I, II, or stable III of the physical status classification of the American Society of Anesthesiologists (ASA). Patients are evaluated physically and emotionally to determine the possibility of complications during or after the surgical procedure.

   CMS regulations require three separate health assessments before a patient is placed on the OR bed. The three assessments include:

   a. A complete medical history and physical examination (H&P) no earlier than 30 days before the intended surgical procedure. The H&P must be redone if 30 days have passed.
   b. A physical assessment on arrival at the surgery center to validate that no changes have occurred since the H&P was performed. Care is taken when discussing private information in the ASC cubicles. Other patients can overhear conversation through the divider curtains.
   c. A preanesthesia evaluation to assess the safety of administration of anesthesia before the patient enters the OR.
2. Results of preoperative tests. Patients may have tests on admission the morning of the surgical procedure, but preferably these tests are performed before the scheduled surgery date so the results can be evaluated. This prevents cancellation on the day of surgery if test results are unsatisfactory. Test results are documented in the medical record before the patient is brought to the OR. Preoperative tests may include the following:
   a. Complete blood count (CBC) and urinalysis (usually included in basic laboratory tests)
   b. Pregnancy test, unless patient previously had a hysterectomy or oophorectomy
   c. Multichemistry profile for patients at higher risk
   d. Chest x-ray (may be required if clinically indicated)
   e. Electrocardiogram (may be required before general anesthesia for patients older than 35 years)
3. Willingness and psychologic acceptance by patient and family. The patient should be willing and able to recuperate at home. Some patients lack adequate home care and may need other arrangements.

Each patient is individually assessed. Provision is made for competent care at home by either an agency or the patient's family. Compliance with preoperative and postoperative instructions by the patient and the availability of a responsible adult support person are essential. Other factors to consider when screening a patient for possible ambulatory surgery include the following:

- *Recovery period:* The surgeon should anticipate minimal or no postoperative complications. Patients in whom a prolonged period of nausea and vomiting is anticipated or in whom pain will not be relieved with oral analgesics are not ideal candidates for ambulatory surgery.
- *Reimbursement sources:* Most third-party payers prefer less costly ambulatory surgery whenever a procedure can be safely performed in this setting. Patient safety and quality of care depend on patient screening and support systems.

PROS/CONS

Selecting an Ambulatory Surgery Center (ASC)

Pros

- Can the surgical procedure be done safely without complications?
- Accredited surgical centers offer convenience for preoperative testing, parking, and easy access.
- Accreditation requires the facility to follow set standards, performance measures, and site visits for compliance.
- Same day surgery allows the patient to recover at home.
- Wait times may be shorter because a schedule is followed without interruption of emergencies.
- Reduced infection rates. Orthopedic surgery centers are becoming popular because the patient does not have exposure to hospital-acquired infections.
- Patients may be able to shop around for procedure prices and reduce out of pocket expenses.
- Medicare patients can download the "What's Covered" application on Google Play or the Apple store to see which procedures are covered.

Cons

- Patients with high risk factors or certain ages may not qualify to have a procedure at an ASC.
- Complex procedures or procedures with risk for complications cannot be performed at an ASC.
- If an emergency occurs, the patient must be transferred to the nearest hospital.
- No overnight stay. Some facilities may offer a 23-hour stay.
- Some insurance companies will not cover certain outpatient facilities.
- Some patients may be transferred to a rehabilitation facility for recovery.

Preoperative Patient Care

Written instructions for both preoperative and postoperative care are given to the patient by the surgeon during an office visit or by the nurse during a preadmission visit to the ambulatory care facility. These instructions describe the admission, preoperative, intraoperative, recovery, and discharge procedures, and they should be written in a language the patient can understand.

For the protection of both the surgeon and the facility, the patient should sign for receipt of these instructions and should sign that informed consent has been given to the surgeon for the intended surgical procedure. Instructions should include the following:

1. Preoperative instructions
   a. Make an appointment for preadmission assessment and testing.
   b. Take nothing by mouth (NPO) after midnight (or other specified hour) before admission unless ordered to do so by the surgeon. This includes medications, unless ordered.
   c. Perform any necessary physical preparation such as bathing with antimicrobial soap as ordered.

d. Arrive at the facility by ____ AM/PM. (Time depends on the scheduled time for the surgical procedure. A minimal wait at the facility helps reduce preoperative anxiety. Patients are usually admitted at least 1 hour before the scheduled time of their surgical procedure. Figure 11.2 shows an ambulatory preoperative holding area.)
e. Notify the surgeon immediately of a change in physical condition, such as a cold or fever.
f. Wear loose and comfortable clothing, leave jewelry (including face, tongue, and body piercings) and valuables at home, and remove makeup and nail polish. (This may include the removal of acrylic fingernails for some procedures if affixing the pulse oximeter to another location, such as the toe, is not an option.)

2. Postoperative instructions
a. Arrange for a responsible adult support person to take you home. (After some procedures, the patient may not be permitted to drive or leave unattended.)
b. Do not ingest alcoholic beverages, drive a car, cook, or operate machinery for 24 hours if a sedative or general anesthetic has been administered.
c. Delay important decision making until full recovery is attained.
d. Take medications only as prescribed and maintain as regular a diet as tolerated.
e. Shower or bathe daily unless instructed otherwise. This helps relieve muscle tension and discomfort and keeps the wound clean.
f. Call the surgeon if postoperative problems arise.
g. Report to the nearest emergency department if your condition deteriorates.
h. Keep follow-up appointment with the surgeon.

The patient should be reminded that the postoperative information will be reinforced and possibly updated at the time of discharge. The patient's level of understanding of the preoperative instructions and planned procedure is assessed with a telephone call from the perioperative nurse to the patient the day before surgery; at this time, the scheduled date and arrival time are also verified. Patients should be reassured that they will be given a set of written instructions before discharge from the facility. The nurse should document patient instructions and responses in the record.

Intraoperative Patient Care

Intraoperatively, the same precautions are observed by all team members as for any surgical procedure. These include strict adherence to the principles of aseptic and sterile techniques and other OR routines.

Preoperative Holding

Patients arriving for surgical procedures are held in this area until the appropriate operating room is ready.

Patients will change into hospital attire in dressing cubicles before entering the preoperative holding area. An area should be available to store patients' clothing and personal belongings.

This area also may be called preanesthesia as patients may be given medications or intravenous fluids under close observation of the nursing staff.

A nurses control station and medication preparation area are often an integral part of this area.

Movable Modular Casework Applications

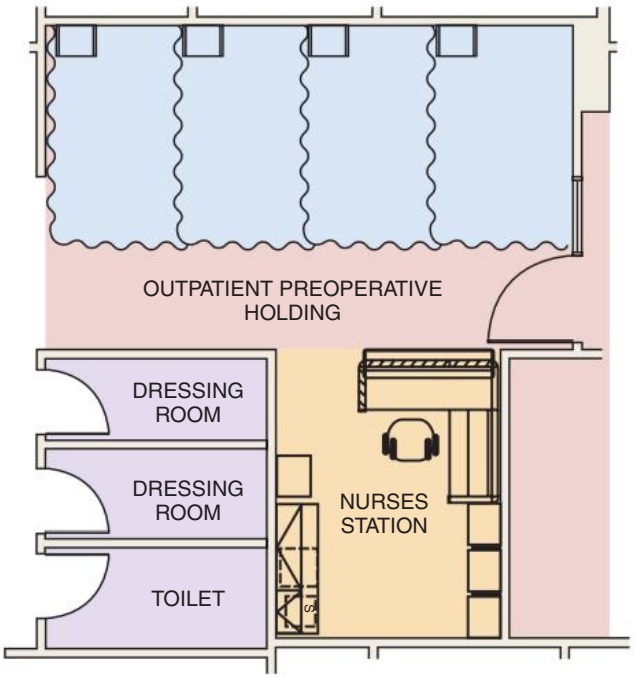
A preoperative holding area can be planned using movable modular casework and may include

- Small workstation.
- Locker to hold patient care supplies.
- L cart, procedure/supply cart, or rail-hung C-frame storage unit placed near each stretcher.
- Procedure/supply carts.
- Extra-deep modular shelving units.
- Sink unit.
- Med prep area.

Plan View of a Preoperative Holding Area

A preoperative holding area will range in size from 350 to 800 square feet.

8 linear feet work surface
6 linear feet overhead storage
40 filing inches
1 locker for medications
1 locker for IVs
2 lockers for supplies
1 C-frame storage unit per bed
504 square feet



• **FIG. 11.2** Preoperative holding area. This area is used for patients before surgery and can be used after surgery. If a local anesthetic has been used, the patient returns directly from the OR. If more complex anesthesia is used, the patient returns here after postanesthesia care unit discharge. (Reprinted with permission Herman Miller, Inc.)

Consideration for patient privacy and avoidance of embarrassment are essential. The general layout of the OR is similar to that of larger facilities but on a smaller scale (Fig. 11.3).

The careful selection of patients, preoperative evaluation, and instructions helps prevent complications from the anesthetic. Premedication, if given, is minimal. The surgical procedure should be less than 90 minutes in duration for general anesthesia and less than 3 hours for regional block. Local anesthesia or a regional block is preferable if appropriate. Spinal anesthesia is seldom used.

Cardiopulmonary resuscitation (CPR) equipment and nurses certified in CPR at a minimal level of basic cardiac life support (BCLS) should be available during the procedure (certification in advanced cardiac life support [ACLS] is preferred). Perioperative nurses who specialize in the care of pediatric patients should have certification in pediatric advanced life support (PALS).

Patients who undergo general anesthesia or moderate sedation are scheduled for surgery early in the day to allow for a maximum recovery time. Rapidly dissipating agents are administered, and various combinations of agents and drugs are used. Drugs associated with prolonged recovery are avoided unless there is a specific indication for their use. Doses of intravenous (IV) agents, such as narcotics and barbiturates, may be reduced to avoid delayed emergence.

Technologic **monitoring**, including bispectral analysis (BIS monitoring), allows the anesthesia provider to administer minimal amounts of an agent based on the patient's level of consciousness and sensorium. Anesthetic techniques should provide adequate depth of anesthesia but with minimal cardiopulmonary changes and side effects. Indications for endotracheal intubation are the same as for inpatients.

Scrub Area

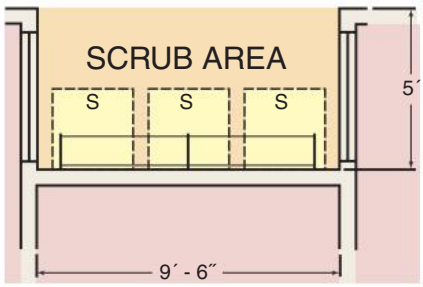
Scrub areas are placed strategically outside operating rooms. Surgical scrub sinks are generally ceramic or stainless steel with foot or knee controls. It is helpful to place shelves above the sink to hold scrub brushes and masks.

Movable Modular Casework Applications

Depending on the design of the scrub area, scrub brushes and masks can be housed in modular shelving hung on rail, on wall strips above the sinks, or in rail-hung C frame storage units with drawers beside the sinks.

Plan View of a Scrub Area

8 linear feet overhead storage (2 feet per sink)
50 square feet



A

Operating Room

An operating room is the area where surgical procedures are performed under strict sterile techniques.

For sanitization purposes, operating rooms should contain little or no built-in casework. Supplies and equipment are moved in and out as needed. Rather than using wall strips, horizontally mounted rail with rail-hung components are appropriate for hanging work surfaces for documenting/charting. Rail-hung shelves or CST units are suitable for overhead storage.

Plan View of an Operating Room

An operating room will range in size from 300 to 450 square feet.

- 4 linear feet work surface
- 4 linear feet overhead storage
- 3 lockers for supplies
- 1 L cart
- 1 anesthesia cart case carts as required

336 square feet

Movable Modular Casework Applications

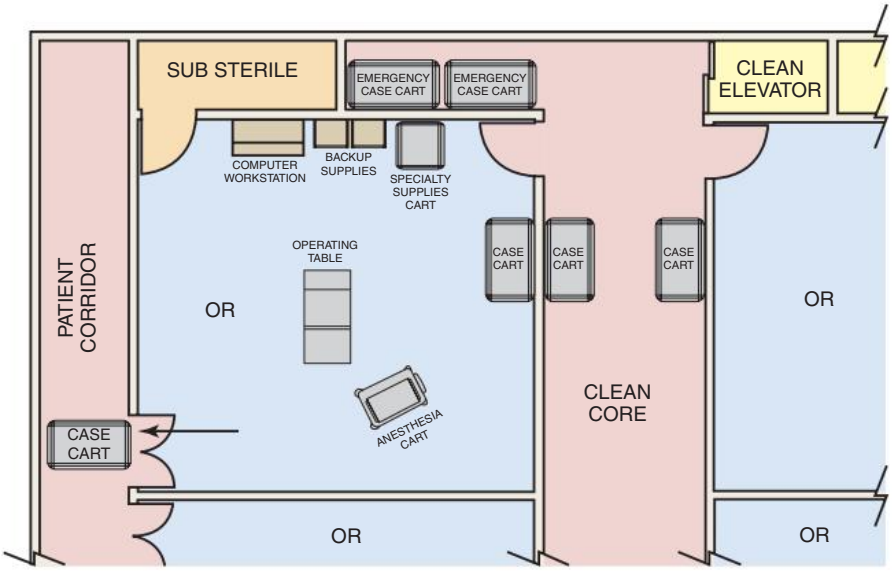
An operating room can be planned using movable modular casework and may include

L carts or procedure/supply carts used for
- Anesthesia supplies and equipment.
- Suction and cautery equipment.
- Monitoring equipment.
- Prep and dressing.

Stainless steel case carts, which can also be used as a back table.

Lockers used for
- General supply storage.
- Backup supplies.
- Specialty procedure carts.

Process tables used as
- Administrative/computer workstations.
- Back table for instruments.



B

• **FIG. 11.3** **A,** Scrub area. **B,** OR layout. (Reprinted with permission Herman Miller, Inc.)

The patient who is undergoing local anesthesia is monitored continuously for any reaction to the medications or change in physiologic status. If an anesthesia provider is not in attendance, a qualified perioperative nurse should be assigned to monitor the patient for behavioral and physiologic changes. This nurse should have a basic knowledge of the function and use of monitoring equipment and should not be assigned other duties while monitoring the patient's condition.

The monitoring perioperative nurse measures and records the patient's vital signs before the injection of a local or regional block anesthetic or analgesic and every 15 minutes thereafter; monitors physiologic status according to written policy and procedure; and institutes emergency measures if an adverse reaction occurs.

The perioperative nurse should be responsible for interpreting, identifying, and reporting abnormal readings to the surgeon. Additional functions of this nurse may include starting oxygen, administering IV therapy, and giving medications when clinically indicated. The perioperative nurse should have periodic competency reviews for the departmental files. These may be examined by accreditation officials during a site visit. Suggested noninvasive intraoperative monitoring methods for patients undergoing local anesthesia are listed in Box 11.1. Each OR must have a cardiac monitor, pulse oximeter, blood pressure apparatus, and oxygen delivery equipment. Each OR should have immediate access to a crash cart in the case of an emergency.

The policies and procedures for monitoring patients undergoing local anesthesia should include patient risk criteria, the type of monitoring to be used, documentation of vital signs and medications administered, and interventions within the scope of nursing practice. All pertinent data and therapy are documented according to the policies of the facility.

The awake and alert patient needs to receive physical and emotional comfort throughout the surgical procedure. The field of vision may be small while the patient is draped, and tactile and other stimuli come as a surprise if the patient is not forewarned. The patient should be told what is about to occur (e.g., "You will feel a needle sting"), what to expect (e.g., "You will have a burning sensation"), and what is expected of him or her (e.g., "Tell us if you feel pain"). The patient's questions should be answered truthfully and realistically. He or she should be reassured that appropriate amounts of the anesthetic will be administered as needed.

Conversation by team members should be appropriate and kept to a minimum. The use of an intercom system should be avoided. Hand signals between the surgeon and scrub person are more useful than a verbal request for instruments. However, the surgeon may request a No. 10 or 15 rather than a knife, or a Mayo or Metz rather than scissors. Strange noises and smells should be explained to the patient (e.g., the sound of suction to remove an irrigating solution; the sound of the electrosurgical unit [ESU] and odor of ESU plume).

Background music of the patient's choice may help to relax and distract him or her. Headsets are one option for this purpose and help block out other noises. Although headsets can distract the patient from the ambient room noise, they can also distract the patient from following necessary directions during the procedure; therefore cautious use is suggested.

Traffic in and out of the room should be kept to a minimum. A sign should be placed on the outside of the door to indicate the type of anesthesia being used (e.g., "Patient awake, local anesthesia").

• BOX 11.1 Noninvasive Monitoring Equipment Used for Patients under Local Anesthesia

- Electrocardiograph
- Pulse oximeter
- Blood pressure apparatus

Postoperative Patient Care

Patients who have received a local anesthetic are returned to the ambulatory unit for a brief assessment and discharge. Patients who have undergone general anesthesia or moderate sedation or who need postoperative pain management are taken to the PACU for stabilization and observation (Fig. 11.4). Medications may be given IV in small dosages; oral medications may cause nausea and vomiting that may prolong the length of stay. Routine orders may be established by policy for these analgesics and antiemetics.

Consciousness, rational behavior, and ambulation do not imply full recovery. Blood pressure and pulse rate may return to the normal range while residual myocardial depression continues. Patients may lapse back into sleep or drowsiness as the drugs used for general anesthesia are metabolized. Patients are under observation at all times in the PACU. Although the Aldrete Scoring System (Table 11.1) is commonly used for establishing postoperative discharge criteria, this method should not be used to replace patient assessment data in determining suitability for discharge.

A hospital short-stay unit may provide postoperative care for observation and pain control for up to a 23-hour stay. When all discharge criteria are met, patients are discharged on written order of the anesthesia provider or surgeon according to policy. Discharge is contingent on the patient's generalized condition. Vital signs are measured and compared with baseline, and the condition of the surgical site is documented before the patient leaves the premises. Patients who have questionable vital signs or an unstable physiology should be seen by a physician before discharge.

Patients are not allowed to drive home if a general or regional anesthetic has been administered. The patient should leave the facility via an appropriate mode of transportation and accompanied by a responsible adult. Select patients who have undergone local anesthesia without sedation may be permitted to drive home if an order is written by the surgeon. The means of the patient's discharge, regardless of transportation, should be documented.

Patient education is an essential element of ambulatory surgical care. Written discharge instructions are verbally reviewed with the patient and a responsible adult. The perioperative nurse should document how the patient or the representative signified understanding of the instruction. Some patients can verbalize or perform a return demonstration as confirmation.

The patient is instructed when to arrange for a follow-up visit with the surgeon. Appropriate phone numbers for the surgeon, ambulatory center, and emergency help should be listed on the discharge instruction sheet. If problems occur after discharge, the patient is encouraged to contact the surgeon or surgeon's designee.

Recovery Centers

Freestanding recovery care centers have been developed to accommodate a 24-hour to 48-hour uncomplicated postanesthesia recovery period. Although they occur infrequently, the most common reasons for admission to a freestanding recovery care

Postanesthesia Care Unit (PACU/Recovery Room)

This area is adjacent to the operating room. Patients are brought to this area after surgery to recover from anesthesia and regain stable vital signs. After the patients are stable, they are moved to secondary recovery before being discharged.

The space is usually in an open area with patients seperated with cubicle curtains. Those patients who need to be isolated are kept in a seperate isolation recovery room. The isolation room also can be used for pediatric patients.

The layout of this space usually includes a nurse control station with a medication preparation area, a physicians' dictation area, an area for supplies and equipment, hand-washing sinks, and a patient toilet.

Plan View of a Postanesthesia Care Unit

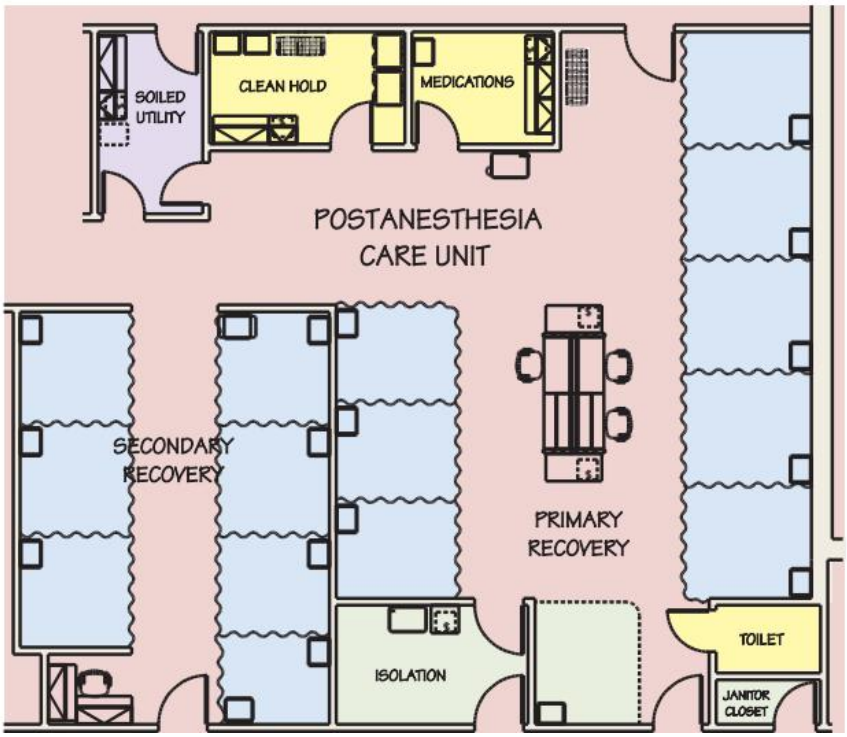
A PACU will range in size from 2000 to 4000 square feet.

26 linear feet work surfacce
18 linear feet overhead storage
80 filing inches
8 lockers for supplies
1 locker for medications
1 L cart for supplies
1 l cart for isolation cart
1 emergency cart
1 C-frame storage unit per bed dictation area
2126 square feet

Movable Modular Casework Applications

Movable modular casework components appropriate for use in the PACU include

- Nurses control station.
- L cart or rail-hung C-frame storage units with drawers for supplies for each patient.
- Lockers for linen and medical supplies.
- Cantilevered sink units.
- Dictation area.



• **FIG. 11.4** Postanesthesia care unit. (Reprinted with permission Herman Miller, Inc.)

center or hospital after ambulatory surgery are pain, nausea and vomiting, urinary retention, and concern for wound integrity. Several types of homelike or hotel-like facilities provide care for up to 72 hours after surgery. For select ambulatory surgery patients, arrangements for postoperative care can be made with a private home health agency.

Interfacility Transfer Management

If complications develop (e.g., adverse reactions to an anesthetic or cardiac changes), the patient may need to be admitted to a hospital for intensive care monitoring. Therefore freestanding ASCs and office-based centers need to have a patient transfer/admission agreement with a nearby hospital. Accredited facilities have guidelines and policies for patient emergency transfers. Surgeons may have admitting privileges at the nearest hospital. The team in the room should notify the nurse in charge and arrange for transport. Smaller facilities use the emergency number 911 to request emergency medical services (EMS) personnel for the physical transport of the patient to the hospital.

The doorways of office-based practices should be wide enough to accommodate the EMS stretcher. A registered nurse (RN) may be designated to travel with the patient. The plans for emergency transfer of a patient should be reviewed with the entire staff on a routine basis.

Accrediting bodies require the ASC staff to have drills on patient emergency management, such as malignant hyperthermia, cardiac arrest, or other crisis event. [1,2] Emergency supplies and equipment must be immediately available and tested on a regular schedule.

Follow-Up Phone Calls and Technology

Most complications occur within the first 48 hours after surgery. Therefore an RN should call to check on the patient's progress and to reiterate postoperative instructions the next day or, at most, within 2 days of discharge. The nurse reminds the patient to keep the follow-up appointment with the surgeon. Some facilities ask several survey questions for quality improvement during this call. Other forms of communication are used to communicate with patients after surgery such as text messaging, medical applications, **telehealth**, and e-mail.

Patients who plan to return to work within 1 or 2 days after surgery may be asked to phone, text message, or e-mail the nurse themselves because they may not be home when the nurse makes routine calls during the day. Patient satisfaction can be surveyed with technology methods of postoperative contact.

TABLE 11.1 Aldrete Postanesthesia Scoring System

			Admission	15 min	30 min	45 min	60 min
Activity	Able to move voluntarily on command	4 Extremities	2	2	2	2	2
		2 Extremities	1	1	1	1	1
		0 Extremities	0	0	0	0	0
Respiration	Able to breathe deeply, cough freely		2	2	2	2	2
	Dyspnea or limited breathing		1	1	1	1	1
	Apnea		0	0	0	0	0
Circulation	BP + 20 of preanesthesia level		2	2	2	2	2
	BP + 20-50 of preanesthesia level		1	1	1	1	1
	BP + 50 of preanesthesia level		0	0	0	0	0
Consciousness	Fully awake		2	2	2	2	2
	Arousable on calling		1	1	1	1	1
	Not responding		0	0	0	0	0
O_2 saturation	Able to maintain O_2 saturation >92% on room air		2	2	2	2	2
	Needs O_2 inhalation to maintain O_2 saturation >90%		1	1	1	1	1
	O_2 saturation <90% even with O_2 supplementation		0	0	0	0	0

BP, Blood pressure.

PROS/CONS

Follow-Up Communication

Pros

- Follow-up communication after surgery or hospital discharge is usually done within 48 hours. The patient may have a choice of communication method.
- A telephone call from a specially trained health care provider discusses patient progress and complaints, confirms discharge and medication instructions, and confirms physician follow-up appointments.
- Follow-up telephone calls reduce hospital readmissions by recognizing lack of patient knowledge and preventing medical problems.
- Telephone calls to postoperative patients have proved to be cost saving to the health care facility.
- Patient satisfaction was higher when follow-up telephone calls or messaging was done.
- Some surgeons give out a personal cell phone number to receive text messages if problems arise from patients.
- Medical applications are being used to have patients answer questions at a convenient time about symptoms. An immediate call can be made to the patient if symptoms are concerning. Educational material also can be put onto the app.
- For patients who live far from a health care facility, telehealth can be utilized to video chat with the patient. The surgeon can see the incision, and the patient saves a trip to the office. Some insurance companies are now paying for telehealth.
- Many younger patients like to use technology because it is fast, user friendly, and can provide a personal response from the nurse or surgeon.

Cons

- Failure to follow up with patients after surgery or hospital discharge increased hospital readmission rates.
- Hospital readmission within 30 days is attributed to poor communication and education.
- Hospital readmission or health problems are common and costly to the health care system.
- Patients were less likely to follow discharge instructions and follow up with their physician without a follow-up telephone call or other form of communication.
- If a computer system or Internet connection is lost, communication can be obstructed.

Documentation of Ambulatory Procedures

The development, implementation, and evaluation of the plan of care should be documented in the patient's medical record. Documentation should include, but is not limited to, the following:

1. Preoperative care
   a. Preanesthetic evaluation by the anesthesia provider if a general, regional, or local anesthetic with sedation is to be given
   b. Nursing assessment data, nursing diagnoses, expected outcomes, plan of care, and preoperative teaching by the perioperative nurse
   c. Medical history and physical examination
   d. Laboratory reports and results of other tests
   e. Informed consent for the surgical procedure
2. Intraoperative care
   a. Anesthetic and medications administered
   b. Vital signs and intraoperative monitoring data
   c. Intraoperative implementation of the plan of care
   d. Surgical procedure note by the surgeon
   e. Wound classification at the end of the procedure
   f. Any unexpected outcomes
3. Postoperative care
   a. Postanesthesia care, including monitoring of patient responses and medications
   b. Discharge instructions, including follow-up appointment with the surgeon and signs and symptoms of potential complications that require immediate medical attention
   c. Radiology, pathology, and any other medical reports
   d. Physical and psychologic status at the time of discharge
   e. Attainment of expected outcomes
   f. Mode of transport from the facility and destination, including relationship to the accompanying support person
4. Remote postoperative care
   a. Follow-up phone call or confirmed use of technology method within 24 to 48 hours to assess the patient's progress
   b. Follow-up phone call or communication within 6 weeks to assess the patient's satisfaction with outcomes and services (for continuous quality improvement data)
   c. Patient follow-up with the surgeon

Most patients who undergo ambulatory surgery are satisfied with their care. Studies have shown that if further surgery is indicated, most patients choose to have the new procedure performed in an ambulatory setting.[3] Fewer incidents of postoperative complications have been documented, as have lower costs of treatment for the patient. Preoperative teaching is beneficial in helping patients attain the expected outcomes. Careful patient evaluation and planning can make the ambulatory surgery a successful and positive experience for the patient, family, significant others, and caregivers.

Alternative Sites Where Surgery Is Performed

Mobile Army Military Hospital

Military medical personnel can be categorized as active duty or reserves.[4] Several branches of military service personnel operate hospitals in the time of war. Colonel Michael Ellis DeBakey, MD (1908–2008), was integral in the initial design of the Mobile Army Surgical Hospital (MASH) and received the Legion of Merit Award in the early 1940s. This section discusses the Army Nurse Corps and the activities associated with mobilization of a mobile surgical hospital in the second millennium. (Additional information can be found online at www.olive-drab.com.)

Active duty personnel can be stationed in their homeland or abroad for a particular tour of duty. Wherever they are located, there are medical facilities for the care and health maintenance of the troops in times of peace and of war. In a war zone, these military hospitals care for injured civilians as well.[5] Nurses and other supporting personnel provide care according to the same standards followed by health care personnel located in main hospitals in civilian locations. Nurses and other medical support personnel are deployed to the duty area in the same manner regardless of active duty or reservist status. Many surgical personnel employed by civilian hospitals are members of reserve units and could be called for active duty. The civilian surgical knowledge and skill are valuable attributes when caring for battlefield casualties.[4]

Reservists who are called to active duty for any augmentation or supporting role first go through mobilization activities to prepare for **deployment**. During the mobilization period, which can be several days or weeks, the soldiers are prepared for the specific area where they will be stationed for active duty. Activities include creating family care plans, immunization updates, physical examination, overview of geographic location, briefing on local native customs and language, and military-specific roles. Family care plan considerations are finalized by providing support for dependents and confirming childcare arrangements for single parents. During the Persian Gulf War, 16,337 single parents were called to active duty.

Nursing and medical support personnel are considered soldiers and train with weapons and bioprotective gear (i.e., gas masks, hazmat attire [mission-oriented protective posture, or MOPP gear]). Field grade officers and chief nurses wear a side arm pistol (e.g., 9-mm Beretta) and carry three clips of 15 rounds at all times in defense of the mobile hospital and its patients. The ammunition is loaded into clips, but not inserted into the pistol unless under imminent threat. Weapon chambers are always cleared before entering the medical facility. Only security troops' weapons remain loaded at all times. Additional weapons (M16 rifles) are stored in a centralized location for personnel to use in case of an attack.

All personnel are responsible for erecting the hospital and support structures for the deployment period (Fig. 11.5). Teams specially trained in setting up mobile medical facilities construct patient care wards, intensive care units, emergency triage tentage, supply areas, and ORs.[4] Additional service structures, such as soldier sleeping quarters, dining tent (mess tent), laboratory, radiology, and pharmacy units, are set up as well. All services and structures are self-supporting, such as electricity, water supply, sanitation, laundry, showers, food service, and communications.

Deployable Medical Systems

Deployable medical systems (**DEPMEDS**), developed in the 1980s, are essentially mobile hospital units (Fig. 11.6). One type, the combat support hospital (CSH), consists of special tents, known as *TEMPER tents,* measuring 64 × 20 ft, which are designed to be used in all climates (Fig. 11.7). They are used in combination with large rooms destined to be ORs or laboratories fashioned from fold-out aluminum box rooms referred to as International Standards Operations containers (ISOs; Fig. 11.8).

• **FIG. 11.5** **A,** Hospital being moved into position. **B,** Hospital under construction. **C,** Teamwork setup.

• **FIG. 11.6** Aerial view.

The ISOs and tentage are transported to the site by helicopters or large trucks. All personnel are specially trained to erect the DEPMEDS facility. Fort McCoy in Wisconsin is a training center where most of the training takes place.

Some of the ISOs open out to create a protected environment double or triple its compacted size. ISOs are used to create environments for laboratory, radiology, pharmacy, sterile processing, and ORs. TEMPER tents are used to house patients and auxiliary work areas. Some DEPMEDS facilities can house up to 1000 hospital beds. Chemically protected types of ISOs and TEMPERs are used in areas where nuclear, chemical, or biologic terrorism threat exists.

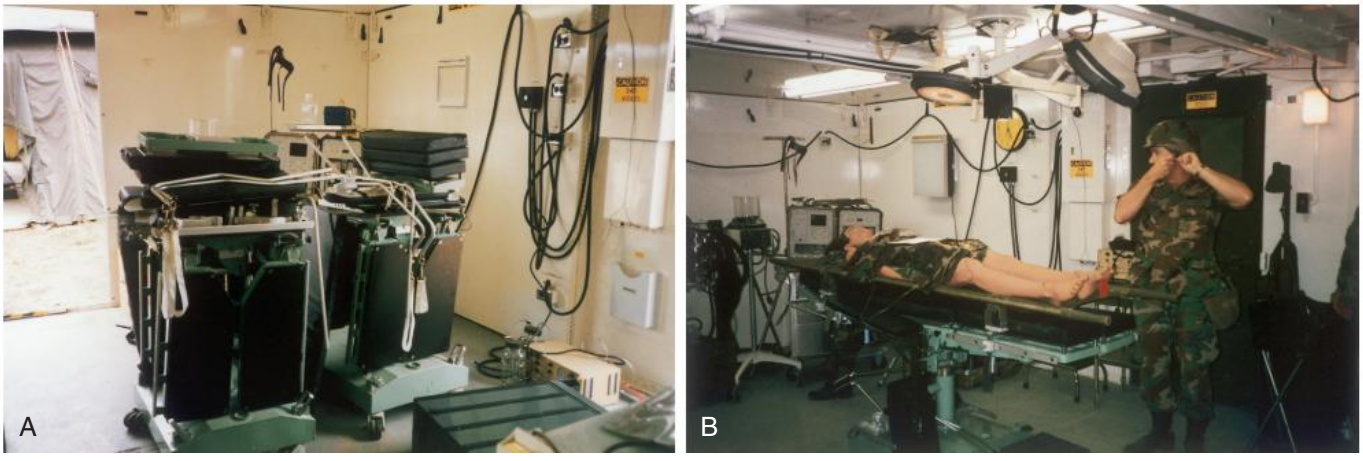
The OR ISO is designed to provide a surgical setting for two patients at once with two OR beds (Fig. 11.9). In severe situations, two surgical teams can work in the same room simultaneously. Each half of the ISO has complete OR usage with two independent anesthesia stations placed in opposite ends of the structure.

Passages made of canvas, referred to as *vestibules,* connect the TEMPER tents and ISOs to form the working environment of the hospital in a series of connecting hallways complete with flooring and climate control (heating and air conditioning) for all weather (Fig. 11.10). The completed structure is reasonably comfortable and efficient.

The grounds on which the mobile DEPMEDS hospital is built are surveyed and cleared of hazards. Some dangers to look for are unexploded landmines, poisonous plants and animals, disease-carrying insects, and human-made booby traps. Snipers are always a threat until the perimeter is secure. A specialized administrative team inspects the grounds and marks off each site for the layout to the exact inch. If the team miscalculates the plan, the TEMPERs and the ISOs do not line up correctly when the connecting vestibules are attached.

• **FIG. 11.7** **A,** TEMPER tent frame. **B,** TEMPER tent setup for patient care area.

• **FIG. 11.8** **A,** Fold-out ISO with door open. **B,** Completed ISO setup from outside.



• **FIG. 11.9** **A,** Duplicate sets for the OR ISO. **B,** One side of OR ISO.

The integrity of each structure is inspected daily for stability in all types of weather. Desert areas are subject to sand storms. Rain water and mud can cause dramatic shifts. The team checks the ISOs daily for any shift in balance with a level device. Delicate equipment (e.g., scanners) do not work correctly on uneven ground. Jacks on the corners of the ISOs are used to shift the baseline to balance the unit.

In a hostile environment, the functionality of the hospital depends on the maintenance of the physical plant. Security patrols continually monitor the perimeter of the area and diligently protect the hospital from sabotage by the enemy. Power generators and water supplies are prime targets for disabling the effectiveness of the mobile hospital's mission. The constant threat of chemical and biologic weapons is also a consideration. All personnel carry

• **FIG. 11.10** Vestibule connects ISO and TEMPER.

TABLE 11.2 Patient Classification with Tags for Mass Casualty

Color Tag	Definition	Explanation
Green	Minimal care needed; ambulatory	Minor injuries. Return to duty as soon as possible
Yellow	Need urgent care, but can be delayed; not ambulatory	Not in immediate life threat
Red	Need immediate care; in critical condition and treatment may save life	Cannot be delayed
Black	Expectant or expired; unconscious and no available treatment can save life	Nonresponsive, but all available measures for comfort are given until all vital signs cease

a protective mask in a holder attached at the belt. The personnel are trained to respond to a warning (e.g., the sound of banging metal against metal) by donning the mask and providing protection for the patients. The personnel of the hospital must be prepared to dismantle the hospital and move to a new location on short notice.

Patient care in the mobile hospital is based on returning the soldier to duty as soon as possible. Studies have shown that soldiers who are separated from their units for prolonged periods because of war-inflicted injury suffer increased duration of traumatic stress.[4] A wounded soldier who can be saved with available resources is triaged and treated according to the type of injury or injuries incurred. After stabilization, the wounded can be evacuated to a larger hospital away from the war zone.

Surgery in a Mobile Hospital Setting

Injured soldiers who can be treated with a surgical procedure are taken to a presurgical holding area, where their conditions are stabilized for surgery. The surgical procedures are performed by two separate teams who maintain individual sterile fields for both patients. Although the OR ISO is designed to accommodate two surgical procedures at the same time, great care is given to maintain sterile and aseptic techniques.

Postoperatively, the patients are taken to the postsurgical recovery area. The ISO is cleaned and set up for two more patients. The OR must be prepared at all times. The instrumentation is taken to an adjoining tent or processing ISO for cleaning and sterilization to prepare for subsequent surgical procedures. The processing area is referred to as the *central materials service* (CMS).

Each type of injury is carefully evaluated in a mass casualty scenario. This activity is used in civilian areas when terrorist attacks take place in nonmilitarized zones. Each patient is triaged according the amount of care needed. If chemical, biologic, or radiation contamination has been used in the attack, the patient is taken to a decontamination area before going to the patient care area. Clothing and personal effects are removed. Clothing is discarded appropriately, but personal effects (i.e., jewelry) are bagged and marked for decontamination at a later time. The patients are tagged with colored tags to indicate where they will be taken within the hospital according to the type of injury (Table 11.2). The decontamination team is specially trained for this task. They also decontaminate the area and dispose of contaminated materials before the next patient is brought in to the area for processing. Deceased contaminated personnel must be decontaminated before delivery to the morgue.

Wounded soldiers or other personnel who need extraordinary surgical procedures and are not likely to survive are transferred to an expectant ward, where they receive comfort measures until they expire. Expectant patients are protected from the view of other patients. This is extremely stressful to the nursing and medical staff because in the civilian sector resources are frequently expended in the care of expectant patients, regardless of survivability. In a CSH environment, standard operating procedures mandate the type of care given to patients who are treated onsite, patients who are shipped out, and those who are beyond treatment. Some examples of expectant categories include open head wound with exposed brain in an unconscious-unresponsive patient, radiation exposure greater than 500 RADS and signs of advanced radiation sickness, or totally absent pulses and no spontaneous breathing with airway support.

Consideration is given to the injured enemy prisoners of war (EPW). A separate hospital facility is set up to accommodate EPW care. Security is complex, and additional training is required to manage patient care. Interpreters should be available. EPW are allocated resources according to need per the Geneva Convention.

Service animals, such as mine-sniffing dogs, may need surgical treatment. A separate surgical tent is set up for their care. Instrumentation and other sterile supplies are processed separately from items used in human care. A separate sterilizer may be set up for the sterilization of instruments used in animal surgery.

The living quarters of the mobile hospital personnel consist mainly of tents capable of housing 20 or more people. During field training exercises, smaller two-person tents are used to conserve space and expedite setup. Personal belongings are limited to what can be packed into two duffel bags and carried by one person. Equipment, such as protective masks, pistol belts, Kevlar helmets, and other survival gear, leaves little room for personal belongings. Uniformity in attire is part of the unity of the group. Individuality is not stressed. The standard clothing worn by all army personnel is referred to as an *all climate uniform* (ACU). Helmets are worn at all times when not in the confines of the hospital.

The work day is 12 hours long. Every soldier is expected to perform the manual labor necessary to keep the hospital running 24 hours. Physical preparedness includes remaining strong through proper exercise and diet. A regular routine of workouts

and running keeps the soldiers in condition. Periodic physical testing (sit-ups, push-ups, and running 2 miles) is performed to assess each soldier's readiness status. The intensity of the testing is determined by age and sex. Each person is required to be qualified in weapons use according to rank. Although hospital attacks are not common because of perimeter guards, the need to be prepared to protect the hospital is always foremost in the minds of all medical personnel.

Stress of combat is unavoidable. Although nurses, technologists, and physicians are healers, not warriors, they suffer the same levels of combat stress as fighting soldiers. The personnel are exposed to horrific injuries not commonly seen in civilian hospitals. The treatment for a nurse or other caregiver suffering from posttraumatic stress disorder (PTSD) is the same as that for a combat soldier. After a war, caregivers with PTSD may experience intense intrusive thoughts, such as flashbacks or nightmares, and may have many personal issues to resolve. Psychologic counseling is usually indicated. Specific categories of military caregivers are designated for the psychologic care and well-being of military personnel. Support groups are available when discharged from duty.

Much preparation goes into the readiness for war. Medical personnel learn the same soldiering skills as the fighting force in combination with remaining current in health care knowledge.

Veterinary Surgical Facilities

Animals have been the companions of humans since the beginning of time. They serve as a physical source of medication, food, and other by-products that we encounter every day. Service animals have a special place in our society because they are used to protect humans from harmful substances and items with their keen sense of smell; they serve as part of search and rescue teams, guides, and transportation; and also serve as diagnosticians by sensing seizures and sniffing cancer cells. Specialized facilities, such as veterinary clinics, provide health services to this unique segment of society. Animal health insurance is becoming a popular concept for animal health care.

Scrub personnel are sometimes employed in a facility where investigational procedures are performed on animals or employed by veterinary clinics for the treatment of domestic animals. This specialized role requires knowledge in sterile and aseptic techniques; instrumentation; and modifications of positioning, prepping, and draping according to the size and body habitus of the veterinary patient.

The setting for performance of surgical procedures on animals should be treated with the same sterile and aseptic techniques as used for human surgery. The outcomes directly reflect the care given by the absence of infection and freedom from other untoward injury. Microbial carriage of an animal undergoing a surgical procedure can be minimized by containment of contaminated fur, fins, and feathers with adequate cleansing and draping practices. Precautions are taken for personnel with sensitivities to animal dander. Antiseptic preparations can reduce the microbial load of the skin in the same way they render human skin surgically clean.

Instrumentation is decontaminated and sterilized with the same methods as implements used in human care. Some hospitals have animal laboratories and clinics for research purposes within a separate section of the facility. Care is taken to isolate and process animal care instrumentation and supplies in a location that does not intermix with instruments and supplies intended for surgical procedures on humans. The risk for inadvertent transmission of infectious material, such as prions, between species is significantly increased when instrumentation used for susceptible animals is mixed with instrumentation used for other animals.

The physical plant is similar to ORs used for humans with the exception of specialized beds and positioning devices for extremely large animals, such as horses, or for small animals, such as birds or rodents. Postanesthesia care areas for large standing animals, such as horses, should have padded walls and floors and minimal equipment to prevent an animal's self-inflicted injury.

Institutional animal care is accredited by the Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC). Policies and procedures are specifically designed to meet the needs of animals in laboratory settings. Funding and grants for research commonly include provisions for the care and use of animal subjects. Humane treatment is stressed. Documentation of housing, bedding, feeding, and watering is required as part of the accreditation process.

Regulation of hazardous materials and infection control is required for the safety of human handlers and the welfare of the animals in their care. Waste disposal and sanitation is monitored. Animals involved in investigational studies are tagged for identification and sometimes quarantined as part of the study.

12
Care of the Perioperative Environment

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Describe how a room is prepared for the first case of the day.
- Describe how a room is cleaned and prepared between patients.
- Describe how a room is terminally cleaned at the end of the day.
- Discuss environmental responsibility.

KEY TERMS AND DEFINITIONS

Between-case cleanup Cleaning that takes place at the end of one case to prepare the environment for the next case of the day. Also referred to as turnover.

Case cart system Computerized method of selecting and delivering instrument sets and supplies to the perioperative environment. Some models include provision for the return of instruments and contaminated items to the appropriate decontamination area.

Contamination Potentially pathogenic material that must be contained.

Custom packs Prepackaged disposable supplies standardized and assembled into packages and sterilized by the manufacturer or distributor according to specific instructions and requests by a particular service at a facility.

Decontamination Cleaning reusable items with an approved sporicidal disinfectant to render the item safe for handling.

Fomite Inanimate objects that can harbor and transmit infectious material.

Iatrogenic Condition that results during or from the process of treatment or care that has unfavorable results.

Terminal cleaning Thorough cleaning and disinfection of the perioperative environment at the end of daily use.

Turnover Cleaning and preparation of the OR between cases for the next patient's arrival. Areas are cleaned according to level of need.

Guidelines for Cleanliness in the Surgical Environment

AORN (The Association of periOperative Registered Nurses) has established guidelines and recommended practices for cleaning and maintaining optimal cleanliness in the perioperative environment. The recommendations include but are not limited to the following:

1. All patients are entitled to a clean environment for their surgical procedures.
2. Any **contamination** encountered during a surgical procedure should be contained and confined. Cleaning starts at the cleanest area and works toward the dirtiest area and works from the top down.
3. **Between-case cleanup** should reestablish the cleanest environment possible for the next patient.
4. Procedure rooms, processing areas, and utility areas should be cleaned daily.
5. A schedule should be in place for routine cleaning of all areas and equipment in the surgical department.
6. All environmental sanitation processes should be defined by a multidisciplinary team and supported by facility policy and procedure. [1,2]

Establishing the Surgical Environment

The duties of the scrub person and circulating nurse are many and varied as they prepare for the arrival of the patient in the OR. They are responsible for the cleanliness of the environment preoperatively, intraoperatively, and postoperatively so that the potential for contamination of the patient is kept to a minimum. They prepare the room and maintain the sterile field, work within it, and then break it down for **terminal cleaning** at the end of the day. These activities are performed in specific steps to minimize the risk for infection and maximize the use of time and supplies. Standardization is in the best interest of the patient and the personnel performing the cleanup.

Preliminary Preparations

Preliminary preparations of the operating room (OR) are completed by the circulating nurse and scrub person before each patient enters the OR. Assistance is provided by educated environmental service personnel. It is a cooperative effort. Clean, organized surroundings are part of total patient care.

A visual inspection of the room and its contents should be performed by the team before bringing in supplies for a case. Keep in mind that the human eye cannot see microscopic contamination. The environmental sanitation activities described in this chapter are for the benefit of the patient's protection in the spirit of surgical conscience and should not be taken for granted as an unnecessary inconvenience for the staff. Preparation for the start of the day requires making sure the room is as clean as it can be.[2]

Basic room contents should include the OR bed, anesthesia machine and supplies, electrosurgical unit (ESU), instrument table, prep table, Mayo stand, suction apparatus, receptacles for biohazard and regular trash, and a linen hamper for reusable woven fabrics (Fig. 12.1). Other tables and equipment are added as needed. According to the Centers for Disease Control and Prevention (CDC), anything brought into the room for the procedure must be wiped down with an Environmental Protection Agency (EPA) registered intermediate sporicidal disinfectant before put into use by the team.[1]

Before the First Surgical Procedure of the Day

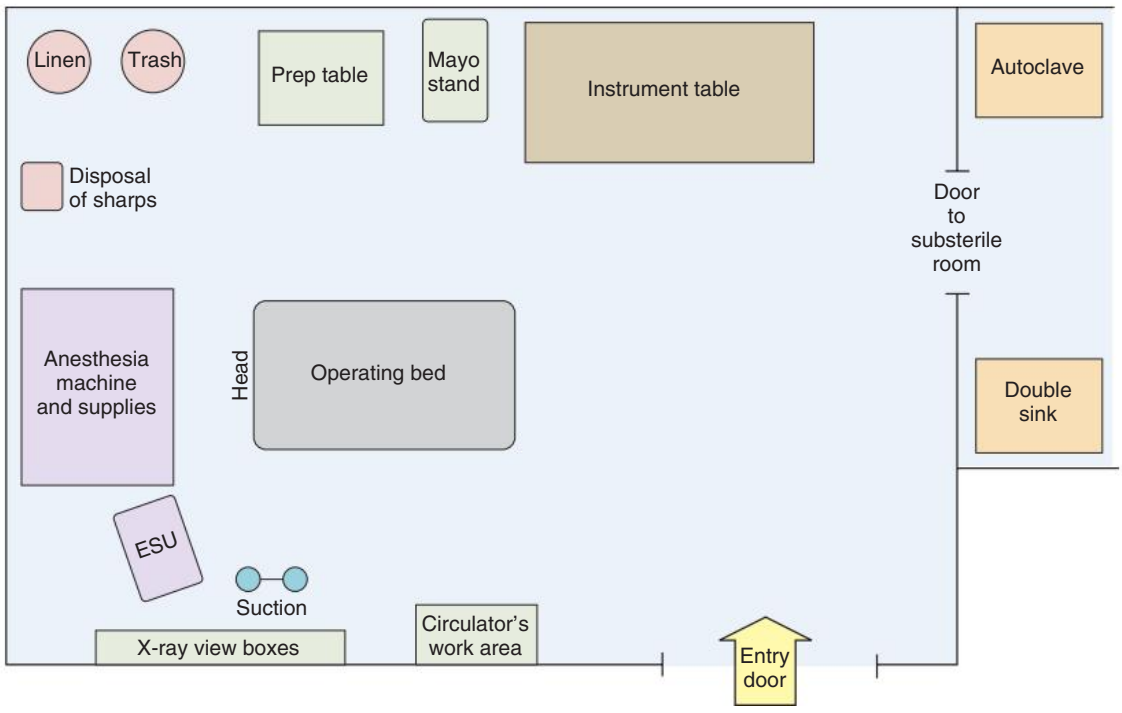
The following housekeeping duties should be done before bringing sterile surgical supplies into the room for the first case of the day:

1. Remove unnecessary tables and equipment from the room. Arrange the appropriate furniture in an organized manner away from the traffic pattern. Some head and neck procedures require the OR bed to be oriented in a sideways direction to provide working space for the team. The anesthesia provider might be positioned at the patient's side.
2. Damp-dust from the top down (with a facility-approved sporicidal disinfectant solution and lint-free cloth) the overhead operating light, articulated arms, furniture, flat surfaces, and all portable or mounted equipment.[2] Avoid dry-dusting because this sets dust aloft. Start at higher surfaces and work down to lower levels because dust may fall from higher areas. "High touch" areas such as knobs, handles, and keyboards must be cleaned after every patient.
3. Damp-dust the tops and rims of the sterilizer and/or washer-sterilizer and the countertops in the substerile room adjacent to the OR.
4. Visually inspect the room for dirt and debris. The floor may need to be damp-mopped.

Room Turnover Between Patients

Physical facilities influence the flow of supplies and equipment after the surgical procedure. However, basic principles of aseptic technique dictate the procedures to be performed immediately after a surgical procedure is completed and prepare the OR for the next patient. Every patient has the right to the same degree of safety in the environment. In addition, personnel working in surgical services should be protected.

Personnel cleaning the room between patients should wear personal protective equipment (PPE) appropriate for the cleaning task. Gloves worn for cleaning should be durable in the presence of cleaning agents. Vinyl gloves are not reliable and may not protect the wearer from environmental contamination in the presence of degradation caused by cleaning agents.



• **FIG. 12.1** Layout of basic OR and substerile room. The traffic pattern from the doors should not interfere with the setup of the sterile tables or the transfer of the patient to the OR bed.

PROS/CONS

Damp Dusting

Pros

- Cleaning the OR is a collaborative effort between the environmental services personnel and the OR staff.
- Specific cleaning procedures and schedules should be in place to keep room contaminants to a minimum and provide the patient with a clean, safe environment.
- Environmental services personnel are responsible for the cleaning of the OR after the last procedure of the day. Terminal cleaning is done with high-level disinfectants.
- All hospital cleaning chemicals are registered and rated by the Environmental Protection Agency (EPA). They are rated from high-level disinfectants to low-level disinfectants.
- Health care providers should be educated on the correct procedure of damp dusting and which chemicals are accepted for use, how to safely use them on equipment and surfaces, and personal protective equipment (PPE) requirements.
- Keeping the OR clean is the responsibility of every staff member. The OR should be inspected for cleanliness before any surgical equipment is brought into the room.
- The process of damp dusting should take place before the first procedure of the day. All horizontal surfaces such as surgical lights, furniture, booms, tables, and beds are wiped with a damp cloth starting from top to bottom.
- The purpose of damp dusting is to remove any dust that has settled on surfaces after terminally cleaning and disinfection have taken place.
- Dust can become airborne and eventually settle on surfaces. Dust is known to contain particles from numerous sources such as skin, bacteria, mold, fibers from supplies, insect parts, and many more contaminants.
- Damp dusting is done with low-linting cloths moistened with an EPA-approved hospital-grade disinfectant. The damp cloth prevents the dust from becoming airborne, which could contaminate supplies or a surgical wound.
- Surfaces that were damp dusted with a hospital-grade cleaner and allowed to dry retained the ability to kill microorganisms that came into contact with the surface.
- All chemicals used in the perioperative setting must have a Safety Data Sheet (SDS) available containing all information about the chemical and steps to take if exposure occurs.
- Any chemical removed from its original container must be labeled with the chemical name, expiration date, and concentration.

Cons

- Some health care providers do not think it is their responsibility to do any cleaning because specific staff is hired at their facility to do the job. They may skip the damp dusting process.
- Areas that are not easily reached such as OR surgical lights are commonly skipped and disperse dust particles when moved during a surgical procedure exposing the patient to microorganisms.
- Some ambulatory facilities depend on the OR staff to do all the cleaning between cases. Staff may be rushed to complete cases and may skip the damp dusting process and do a poor job of cleaning the OR between cases.
- Damp dusting is not performed to disinfect surfaces when tap water is used.
- Environmental cleaning chemicals should not be used from a spray bottle; this method can aerosolize the dust and cleaning solution.
- Many health care workers do not wear PPE while performing the damp dusting process which exposes them to any dust or chemical aerosolized particles.
- Alcohol should not be used as a damp dust cleaner because it is does not remove soil and it is not registered by the EPA for that purpose. Alcohol is a fire hazard.
- Lack of knowledge about the damp dust process and purpose puts patients and employees at risk for contamination from microorganisms that were once airborne.

3. Armellino D, Dowling O, Newman S, et al: Remote video auditing to verify OR cleaning: a quality improvement project, *AORN J* 108(6): 634–642, 2018.

Some patients have known pathogenic microorganisms; others have unknown infectious organisms. Therefore every patient should be considered a potential contaminant in the environment. Cleanup procedures should be rigidly followed to contain and confine contamination, known or unknown. Some examples of conditions that require special consideration are the following:

1. Patients with known respiratory-borne disease (i.e., rubeola, varicella, tuberculosis) may deposit microorganisms in the environment. They should be wearing a high-efficiency particulate air (HEPA) mask during transit and in the room as much as possible. In addition to routine environmental **decontamination** after they leave the room, the air exchanges should be 99% complete before the next patient is brought into the room. This may take 20 to 30 minutes on a 15 to 20-air change per hour cycle. Staff should wear appropriate filtration masks during room cleaning.
2. Patients with known endospore-forming bacterial contamination (i.e., *Clostridia* or *Bacillus*) may deposit bacterial endospores in the environment on inanimate objects, known as **fomites**. These endospores have been shown to survive in the environment for 5 months and have been cultured in ORs 40 days after the patient has used the room. AORN recommended practices state that an approved sporicidal disinfectant should be used for cleaning the environment.
3. Patients with known or suspected transmissible spongiform encephalopathies such as Creutzfeldt-Jakob disease (CJD) and new variant CJD may deposit prions in the environment. Prions are proteins found in neurologic tissue and fluids that cause fatal neurodegenerative diseases in humans and animals.[3] **Iatrogenic** introduction of prion disease can happen if the patient is exposed to the protein during the surgical procedure by instrumentation or the environment. Prions are nonliving proteins that persist on surfaces and require special cleaning solutions. Disposable equipment, instruments, linens, and supplies should be used in the presence of known or suspected prion diseases. All environmental surfaces should be covered with disposable impervious material during the surgical procedure.[2]

The routine cleanup procedure can be accomplished expeditiously by the circulating nurse and scrub person working

cooperatively. While the circulating nurse secures the outer layer of dressing and prepares the patient for transport from the OR, the scrub person begins to dismantle the sterile field before removing gown and gloves.

All instruments, supplies, and equipment should be decontaminated, disinfected, terminally sterilized, or contained for disposal as appropriate before being handled by other personnel.

After a patient leaves the room, the immediate environment is cleaned with an approved sporicidal disinfectant and all surfaces are dried. Room cleanup between patients is directed at the prevention of cross-contamination. The cycle of contamination is from patient to environment and from environment to OR personnel and subsequent patients.[1]

Exposure to infectious waste is a hazard to everyone who encounters it. After each surgical procedure the environment should be made safe for the next patient to follow in that room. Institutional policies and procedures for routine room cleanup should be designed to minimize the OR team's exposure to contamination during the cleaning process.

Room Turnover Activities by the Scrub Person

The patient should be thought of as the center, or focal point. The surrounding sterile field and all areas that have come in contact with blood or body fluids are considered contaminated. The primary principles of cleaning procedures are to confine and contain contamination and physically remove microorganisms as quickly as possible.

Do not contaminate the table or Mayo stand until the patient has actually left the room if there is a question of patient stability, especially during trauma, cardiac, vascular, and neurologic procedures. Remain sterile until the patient leaves the room.

When the patient leaves the room, the sterile field is broken down by the scrub person, who remains protected with the gown, gloves, a mask, protective eyewear, and a cap during the dismantling procedure. Contaminated instruments, basins, and other reusable items are collected by the scrub person and placed in the case cart for decontamination, packaging, and sterilization in the processing department.

The following are activities/responsibilities of the scrub person at the end of the case:

1. Push the Mayo stand and instrument table away from the OR bed as soon as the dressing is applied and the drapes are removed. Roll drapes off the patient from head to foot to prevent airborne contamination; do not pull them off.
2. Check drapes for towel clips, instruments, and other items. Be sure that no equipment is discarded with disposable drapes or sent to the laundry.
   Disposable drapes are placed in a red biohazard container for disposal. Soiled drapes, whether disposable or reusable, should be handled as little as possible and with minimum agitation to prevent gross microbial contamination of air by dispersal of lint and debris.
3. Discard soiled sponges, other biologically contaminated waste, and disposable items in red biohazard containers. Discard unused sponges, nonwoven drapes, and other disposable waste into the main trash.
4. Dispose of sharp items safely. Special care should be taken in handling all knife blades, trocars, sharp instruments such as hooks or rakes, burrs and bits, surgical needles, and needles used for injection or aspiration. Remove the tip from the ESU handle (pencil). A self-closing adhesive pad or box designed for this purpose is the safest device to use. A safe disposal procedure should be implemented and sustained. Place these items in an appropriate rigid, puncture-resistant container for safe disposal to prevent injury and potential risk for contamination.
   The primary cause of accidental cuts and punctures to personnel, both inside and outside the OR, is disposal of surgical sharps at the end of the surgical procedure. Adherence to standardized systems designed specifically for safe handling and disposal of sharps prevents virtually all accidental cuts, punctures, and lacerations. Unused suture packets are discarded.
5. Basins and trays too large for the case cart are put into plastic bags for transport to the decontamination area. The Mayo tray may be included at some facilities. Place these on the lower shelf of the case cart. Some cases require a second cart for dirty instrumentation.
6. The instruments are opened completely and placed into the wire mesh basket with all box locks spread apart. Blood, tissue, bone, and any other gross debris are removed from instruments during the case as much as possible. All instruments, used and unused, must be decontaminated, terminally sterilized, or undergo high-level disinfection (as appropriate) before they are processed for reuse. Instruments should be presoaked and/or prerinsed before processing in a washer-sterilizer or decontaminator. Some facilities have the scrub person spray enzymatic foam over the instruments to start the cleaning process.
   Any biologic material remaining on instruments is more difficult to remove if left to dry or after the instruments have been heat-sterilized because the material becomes baked on them. The biologic debris inhibits sterilization and disinfection processes.
   a. Remove knife blades from handles using a heavy hemostat; never use fingers. Using a needle holder can cause the jaws of the instrument to become misaligned. Point the blade toward the table and away from the field and other people in the area so that if it breaks or slips it will not fly across the room.
   b. Unloaded scalpel handles and other instruments with sharp tips or edges, such as scissors, should be placed in a container separate from the other instruments so they can be easily identified by the processing personnel.
   Do not put knife handles in an instrument tray with blades left on them. Other instruments designed for replaceable cutting blades, such as dermatomes, should have blades removed and discarded; thereafter the device may be handled with other instruments.
   Place reusable surgical needles, either on a needle rack or loose, into a perforated stainless steel box to be decontaminated and sterilized with the instruments.
7. Dispose of solutions and suction bottle contents according to facility policy. The facility must follow all state and federal regulations for disposal of contaminated fluids.[2] If a flush hopper is used, it should go into a sanitary sewer system. Wear PPE to protect from splashes. Some facilities have closed-system liquid waste disposal units that empty suction canisters and decontaminate the contents. Disposable suction units simplify disposal. Commercial substances can be added to liquid in the disposable canister to solidify or gel contents for solid waste disposal.
8. The scrub person removes gown and gloves before taking the case cart to the processing area. The gown is removed first

before removing gloves. The circulating nurse unfastens neck and back closures. Protect arms and scrub clothes from the contaminated outside of the gown. The gown is turned inside out as it is removed to prevent contamination of the scrub suit. Discard the gown in a laundry hamper if it is reusable or in a trash receptacle if it is disposable.

To remove gloves, use a glove-to-glove and then skin-to-skin technique to protect the hands from the contaminated outside of gloves. Turn gloves inside out as they are removed to contain the biologic contamination, and then discard them into a trash receptacle. Wash hands after removing gloves. Clean examination gloves are worn to transport the table to the processing area. Wash hands after removing gloves.

9. Instruments should be placed in leakproof containers. Contaminated items should be placed in labeled or color-coded containers for easy identification. The case cart should be totally enclosed or covered in plastic before taking it to the decontamination and processing area. Fresh examination gloves are worn when transporting the case cart.

Room Turnover Activities by the Team

After the patient leaves, the environmental service personnel should be available to perform room cleaning. Regardless of which member of the team performs them, specific functions should be performed to complete the between-case room cleanup. The following personnel and areas are considered contaminated during and after the surgical procedure:

- Members of the sterile team, until they have discarded their gowns, gloves, caps, masks, and shoe covers. These items remain in the contaminated area; scrub clothes are changed if they are wet or contaminated.
- All furniture, equipment, and the floor within and around the perimeter of the sterile field. If accidental spillage has occurred in other parts of the room, these areas are also considered contaminated.
- All anesthesia equipment.
- Stretchers used to transport patients and patient moving devices. These should be cleaned after each patient use.

Clean examination gloves are worn to complete the room cleanup. Decontamination of the environment includes the following tasks starting at the highest point and working down:

- *Overhead operating light.* Wipe overhead lights with a clean cloth that has been wetted with sporicidal disinfectant solution specifically intended to prevent clouding of the surface that can cause dullness and glare. Lights and overhead tracks become contaminated quickly and present a possible hazard from fallout of dust particles onto sterile surfaces or into wounds during surgical procedures.
- *Furniture.* Wash horizontal surfaces of all tables and equipment, including the anesthesia machine, with a sporicidal disinfectant. Apply disinfectant from a squeeze-bottle dispenser, and wipe with a clean cloth or a disposable wipe that is changed frequently. Spray bottles can cause particles to become aerosolized and should be avoided.[2]

All surfaces of mattress, pads, and screw connections of the OR bed are included. Safety straps should be cleaned between patients. Velcro straps can be laundered according to the manufacturer's recommendations. Mobile furniture can be pushed through sporicidal disinfectant solution used for floor care to clean casters. Excess strands of loose suture should be removed from the wheels.

Knobs, machine controls, keyboards, cabinet handles, and other frequently touched surfaces must be cleaned with sporicidal disinfectant between patients.[2]

- *Anesthesia equipment.* Most masks and anesthesia tubing are disposable. Any reusable anesthesia masks and tubing are cleaned and sterilized between patient uses. Reusable equipment is processed according to the manufacturer's recommendations. Some items can be steam or chemically sterilized.
- *Laryngoscope blades and handles* should be disassembled, thoroughly decontaminated, and disinfected. Any parts that can tolerate a sterilization process should be terminally sterilized.
- *Noncritical items,* such as blood pressure cuffs, should be cleaned with an approved sporicidal disinfectant between patient uses.
- *Laundry.* After all cleaning procedures have been completed, discard cleaning cloths or put into a laundry bag if they are not disposable. When all reusable woven fabric items, used and unused, have been placed inside the laundry bag, close it securely. To help protect laundry personnel, an alginate bag that dissolves in hot water may be used as the primary laundry bag or as a liner within a cloth bag. Transport reusable woven fabrics soiled with blood or body fluids in leakproof bags.
- *Trash.* Collect all trash in plastic or impervious bags, including disposable drapes and kick bucket and wastebasket liners. Bags should be sturdy to resist bursting or tearing during transport. Trash is separated into biohazardous waste, noninfectious trash, and recyclable items. Separate receptacles for each type of trash should be available. Disposition of potentially infectious waste must comply with local, state, and/or federal leakproof regulations for contamination control measures. Use appropriately labeled and color-coded bags for infectious waste, and use puncture-resistant containers for sharps.
- *Floors.* Clean a perimeter of 3 to 4 ft in circumference of the surgical field between cases. This perimeter expands from the clean area to dirty area—in the direction of visible soilage. Hot water may hasten the biocidal/sporicidal action of the disinfectant agent but may also soften tile adhesive. Floors are always considered contaminated. Standing platforms (step stools) are considered part of the floor and should be cleaned between cases. Sticky or tacky mats with adhesive surfaces are not recommended because they have not proved to reduce the contaminants on OR shoes. They may be used in areas of new construction where workers come in and out of areas from the outside.
- *Mops.* Clean mops are used with fresh EPA-registered sporicidal disinfectant solution. The floor is flooded with fresh detergent-disinfectant solution. A clean mop is used to apply solution and used to take up solution beginning in the cleanest area and working toward the dirtiest areas. After one-time use, remove mop heads and place in a laundry hamper with other contaminated reusable woven fabrics. Mop handles should be cleaned with disinfectant after use and stored in the housekeeping storage area until they are needed again. Use clean mops and sporicidal disinfectant solution for each cleanup procedure.
- Wet vacs can be used to clean the OR flooring. The wet vac unit should be cleaned and disinfected between uses.
- *Walls.* If walls are splashed with blood or organic debris during the surgical procedure, wash those areas. Otherwise, walls are not considered contaminated and need not be washed between surgical procedures.

Cart System Cleanup

All contaminated reusable instruments and basins are put on or inside the case cart. The cart is covered or closed and taken to the central decontamination area outside surgical services for cleanup. The case cart with contaminated supplies should be removed from surgical services via the outer corridor if this is the design of the suite. If dumbwaiters or elevators are used, a separate one is provided for contaminated carts. Even when the cart is covered, the person returning the cart to the processing area must wear examination gloves.

The instrument processing personnel will unload the contaminated cart in the workroom. The instruments will be managed in the following manner:

1. The instrument-washing tray is loaded with heavy instruments in the bottom. All hinged instruments are fully opened to expose maximum surface area, including box locks. Instruments designed to be disassembled are taken apart. The instruments are spaced apart to prevent contact of sharp edges or points with other instruments. Small basins and solution cups are inverted in a tray. Concave surfaces are turned down.
2. Glass syringes, medicine glasses, and other glassware, including those used by the anesthesia provider, are placed in a separate tray. Reusable syringe plungers are removed from the barrels.
3. Detergent-disinfectant solution is suctioned through the lumen of reusable suction tips. The lumen is difficult to clean if biologic debris dries. Disposable suction tips and tubing are recommended.
4. The cart is designed to go through an automatic steam cart washer or a manual power wash for terminal decontamination after it is emptied and before it is restocked with clean and sterile supplies.

Getting the Room Ready for the Next Patient

The cleaning procedures described provide adequate decontamination and terminal sterilization after any surgical procedure. With a well-coordinated team, minimal **turnover** time between surgical procedures can be accomplished. In an average time of 10 to 15 minutes, the room will be ready for the next patient. The turnover time includes cleaning up after one procedure and setting up for the next procedure. Additional equipment brought into the room for the next patient should be damp-dusted with sporicidal disinfectant before entering the OR where sterile supplies are opened.

Individual Patient Setups

Each patient has a right to individual supplies prepared just for him or her. Sterile supplies should not be opened until they are ready to be used. **Case cart systems** and the use of **custom packs** eliminate the need for preparing the sterile field several hours ahead of the patient's arrival. The scrub person, working with an efficient circulating nurse, should have time to set up the instrument table immediately before each surgical procedure. There is no arbitrary life span of a setup table once it is open and prepared as a sterile field for a patient. Sterility is event related, not time related. The sterile table must be under in-room surveillance at all times.

Unless it is under constant surveillance, sterility of any setup cannot be guaranteed. If a scheduled surgical procedure is delayed and a sterile setup has not been contaminated by the patient's presence in the room, the setup may remain open, under surveillance by someone in the room, with the doors closed. The setup should be used as close to the time of preparation as possible.

If a patient is taken into the OR and for some reason the surgical procedure is canceled before the procedure has begun, the tables are torn down and the room cleaned as if the surgical procedure had taken place. The setup is considered potentially contaminated and may not be saved for another patient. Disposable items may be useful for the clinical educator in the department during orientation and education sessions.

Daily Terminal Cleaning

In the Operating Room

At completion of the day's schedule, each OR, whether or not it was used that day, should be terminally cleaned. Additional and more rigorous cleaning is done in all areas already discussed for cleanup between surgical procedures. At the end of the day's schedule, the following routine should be followed:

- Ceiling- and wall-mounted fixtures and tracks are cleaned on all surfaces.
- Furniture is thoroughly scrubbed, using mechanical friction in addition to chemical disinfection. Special attention to high-use items such as computer keyboards, telephones, intercom buttons, and cabinet handles is important.
- Casters and wheels should be cleaned and kept free of suture ends and debris.
- Equipment, such as ESUs and lasers, should be cleaned with care so as not to saturate surfaces to the degree that disinfectant solution runs into the mechanism, causing malfunction and requiring repairs.
- Kick buckets, laundry hamper frames, and other waste receptacles are decontaminated and disinfected.
- Floors are thoroughly wet-mopped with a clean mophead and sporicidal disinfectant solution. A wet vac may be used.
- Walls and ceilings should be checked for soil spots and cleaned as necessary.
- Cabinets and doors should be cleaned, especially around handles or push plates, where contamination is common. Clean all knobs, machine controls, and keyboards.
- Air intake grilles, ducts, and filter covers should be cleaned.
  - Some facilities use automated ultraviolet-C (UV-C) band lighting to disinfect surfaces. The UV-C light deactivates the DNA in bacteria to prevent replication within 30 to 60 minutes.[4]
  - Some facilities use hydrogen peroxide misting systems as an adjunct to routine terminal cleaning practices.[2] The vapor is effective against multidrug resistant bacteria and endospores.

Outside the Operating Room

- Countertops and sinks in the substerile room are cleaned. The outer surface of the sterilizer, including the top is washed.
- Scrub sinks and spray heads on faucets undergo thorough cleaning daily. A mild abrasive on sinks removes the oily film residue left by scrub antiseptics. Spray heads, faucet aerators, or sprinklers should be removed and disassembled, if possible, for thorough cleaning and sterilization of parts. Tap water is not sterile and can deposit microorganisms on the skin. Contaminated faucet aerators and sprinklers can transfer

accumulated organisms directly to hands or items washed under them. Scrub sinks should not be used for routine cleaning purposes or disposal of waste solutions.
- Soap dispensers should be disassembled, cleaned, and terminally sterilized, if possible, before they are refilled with antiseptic solution. These dispensers can become reservoirs for microorganisms.
- Walls around scrub sinks should receive daily attention. Spray and splash from scrubbing cause buildup of antiseptic soap film around the sink. This film should be removed daily.
- Transportation and storage carts need to be cleaned, with specific attention given to wheels and casters.
- Cleaning equipment must be disassembled, cleaned, and dried before storage.

Weekly or Monthly Cleaning

A weekly or monthly cleaning routine is set up, in addition to the daily cleaning schedule, by the director of environmental/housekeeping services and the OR manager. Any routines for housekeeping are based on the physical construction of the department. However, if specific schedules are not established, some areas could be inadvertently missed. Areas to be considered are the following:
- *Walls.* Walls should be cleaned when they become visibly soiled. If they are painted or tiled with wide porous grouting, these factors should be considered in planning cleaning routines. Washing walls in the OR and throughout the suite once a week is reasonable, but less frequent time intervals for cleaning may be acceptable if spot disinfection is performed on a daily basis. This requires adequate continuous supervision.
- *Ceilings.* Ceilings may require regular special cleaning techniques because of mounted tracks, air diffusers, and lighting fixtures. Specialized ceiling mounts for microscopes and booms for suspended equipment should be included in this plan. The types of fixtures are considered in planning cleaning routines.
- *Floors.* Floors throughout surgical services should be machine-scrubbed periodically to remove accumulated deposits and films. Rounded corners and edges facilitate cleaning.
- *Air-conditioning grilles.* The exterior of air-conditioning grilles should be vacuumed at least weekly. Additional cleaning is necessary when filters are checked and changed. Debris can be discharged into the room when the filter is changed. In-room air handlers are positive pressure. The filters should be changed on an off-shift or on the weekend. The room should be terminally cleaned after changing the filters.
- *Storage shelves.* Storage cabinets have been replaced in many OR suites by portable storage carts or pass-through shelving to a sterile core. Storage areas should be cleaned at least weekly or more often, if necessary, to control accumulation of dust, especially in sterile storage areas.
- *Sterilizers.* All types of sterilizers should be cleaned regularly and tested as recommended by the manufacturer.
- *Transfer zones.* Walls, ceilings, floors, air-conditioning grilles, lockers, cabinets, and furniture should be cleaned on a regular schedule.

Greening of the OR: Environmental Responsibility

Many surgical supplies are recyclable. Recycling reduces not only air pollution and the amount of waste in landfills but also the amount of virgin resources consumed. Paper wrappers and many plastic items that are noninfectious, nonregulated trash can and should be recycled. Recycling in the OR should be an integral part of the overall recycling and sustainment program of the health care facility. Consideration of recycling potential can be part of the evaluation process in selecting products. OR personnel should be taught how to recycle and what items are disposable or reusable. A definition of the different waste products should be defined as follows[5]:

Clinical waste. Waste contaminated with blood, bodily fluids, or pharmaceuticals is placed in biohazard bags. These bags or containers are usually red.

Recycled items. Noncontaminated wrappers, plastic, paper, packaging from sterile items are placed in regular trash bags for recycling.

Reusable instruments. Reusable instruments should be placed in a labeled container and sent to the proper destination for reprocessing.

OR personnel should also think about the energy cost to run the facility. Energy efficient plans should be in place to turn off lights and equipment when not in use.

The OR team should not use more consumable product than necessary. Overfilling prep basins with antiseptic solution and then disposing of it in the sanitary sewer exposes the environment to risk for resistant microorganisms and pollution. The Green Guide for Health Care is one organization that gives ideas on how to reduce waste in the health care setting.[5]

Potential Sources of Injury to the Caregiver and the Patient

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Identify potential environmental sources of injury to patients and personnel in the perioperative environment.
- Discuss the prevention of injury through proper testing and use of equipment in the operating room.
- Discuss the importance of fire and disaster drills.

KEY TERMS AND DEFINITIONS

Anaphylaxis An acute, life-threatening physical condition resulting from exposure to an allergen that affects two or more organ systems (i.e., respiratory and cardiovascular); fatal if untreated promptly.

Ergonomics The study of people's efficiency in their working environment. It is concerned with how people arrange and design equipment to maximize productivity and reduce fatigue and injury.

Fire triangle Three conditions, when in combination, cause a fire. Fuel—Ignition—Oxidation. Practicing safety at the sterile field can prevent a fire.

Ionizing radiation Sufficient radiant energy to yield ions from the disintegration of the nuclei of unstable or radioactive elements. This radiation occurs naturally from cosmic rays, and these ions disrupt the electronic balance of atoms. Synthetic x-rays and nuclear power are capable of modifying molecules within body cells as they pass through tissue. They can be mutagenic (i.e., cause mutations of DNA) in somatic body cells, predisposing a person to cancer, and in germ cells, predisposing a person to spontaneous abortion or congenital malformations.

Nonionizing radiation Radiant energy that does not produce ions but can produce hyperthermic conditions that are harmful to the skin and eyes. With the possible exception of ultraviolet rays, wavelengths from the electromagnetic spectrum do not alter DNA in body cells.

Urticaria A rash resulting from exposure to an allergen or other irritant. Urticaria is also known as hives and can appear as itchy, erythematous wheals.

Environmental Hazards

The perioperative environment poses many hazards for both patients and personnel. The potential for physical injury from electric shock, burns, fire, explosion, exposure to bloodborne pathogens, and inhalation of toxic substances is ever present. Therefore it is important that staff have knowledge of the hazards involved in equipment use, the causes of accidental injury, and the sources of health risks. Faulty equipment or improper usage increases the hazards of potential risk factors. The health care facility should be made as safe as possible.

Potential hazards should be identified and safe practices established. The facility's risk management personnel are charged with the responsibility of tracking issues of safety and potential injury. The recommendations that arise from these data are established to guide personnel in corrective actions. Patients and caregivers are never completely free from risks, but the risks can be minimized.

Safety refers to conditions that will not cause injury or harm to the employee, the patient, and other people in the health care facility. Safety goes hand in hand with knowledge, skill, and competency. Some equipment, such as lasers, x-ray equipment, and chemical sterilizers, can cause long-range injury if personnel are lax in safety and protective practices. The education and training of personnel are essential to create an awareness of the potential

hazards. No one should be permitted to use equipment until properly instructed in its correct use and care.

Each caregiver should seek instruction when needed and follow the safety and control measures established by facility policies and procedures. Failure to use equipment and devices safely places both the caregiver and the patient at risk for injury.

Competency in using equipment should be tested periodically because technology changes frequently and the knowledge and skill associated with one piece of equipment may not apply to a newer model. In some instances the technology may become safer, but this is not always the case.

Classification of Hazards

Injuries can be caused by faulty equipment, using equipment improperly, exposing oneself or others to toxic or irritating agents, or coming into contact with harmful agents. Hazards in the operating room (OR) environment can be classified as follows:

- ***Physical,*** including back injury, falls, noise pollution, irradiation, electricity, and fire[a]
- ***Chemical***, including anesthetic gases, toxic fumes from gases and liquids, cytotoxic drugs, and cleaning agents[a]
- ***Biologic,*** including the patient (as a host for, or source of, pathogenic microorganisms), infectious waste, cuts or needlestick injuries, surgical plume, and latex sensitivity[a]

Regulation of Hazards

Standards, guidelines, and recommended practices have been developed by many professional associations, such as AORN (the Association of periOperative Registered Nurses), and governmental agencies, such as the Department of Health and Human Services (DHHS). The policies and procedures of the health care facility should be developed and enforced in compliance with local, state, and federal regulations. Others include, but are not limited to, the following agencies:

- The American Conference of Governmental Industrial Hygienists (ACGIH; www.acgih.org) sets standards for threshold limits for exposure to toxic materials.
- The American National Standards Institute (ANSI; www.ansi.org) sets standards to limit exposure to devices that emit light or sound, such as lasers, ultraviolet light, and nonionizing radiation.
- The National Fire Protection Association (NFPA; www.nfpa.org) sets standards for electrical codes and fire safety.
- The Joint Commission (TJC; www.jointcommission.org) sets standards of patient care for accreditation.
- The Centers for Disease Control and Prevention (CDC; www.cdc.gov) sets standards for infection control.
- The National Institute for Occupational Safety and Health (NIOSH; www.cdc.gov) sets standards for ventilation systems and environmental protection in the workplace.
- The Environmental Protection Agency (EPA; www.epa.gov) sets standards for the disposal of infectious and hazardous waste.
- The U.S. Food and Drug Administration (FDA; www.fda.gov) sets standards and controls for the use of drugs, biologics, devices, and chemicals in patient care.
- The Center for Devices and Radiologic Health (CDRH; www.fda.gov) sets standards for the management and monitoring of radiation in patient care.
- The National Patient Safety Foundation (NPSF; www.npsf.org) sets goals for patient safety in health care organizations.

In 1970 the Occupational Safety and Health Administration (OSHA) was created within the U.S. Department of Labor. Initially OSHA adopted preexisting federal and national consensus standards and guidelines for environmental, patient, and personnel safety. Since its inception, OSHA has issued new standards and amended others, such as permissible exposure limits (PELs) to various occupational health and safety hazards. OSHA is authorized by law to enforce its standards, which may require employers to measure and monitor exposure to toxic or harmful agents, notify employees of overexposure and provide medical consultation or care, and maintain records of corrective actions. OSHA inspects health care facilities for compliance with standards. (More information can be found at www.osha.gov.)

The CDC oversees the activities of NIOSH. The research branch of NIOSH is the National Occupational Research Agenda (NORA).

Physical Hazards and Safeguards

The architectural design of the perioperative environment affects its overall efficiency and productivity. The physical facility is designed to control traffic patterns, decrease contamination, facilitate the handling of equipment and supplies, and provide a comfortable working environment.

Environment Factors

Several factors contribute to providing a safe, comfortable working environment: temperature control, ventilation, lighting, color, and noise. Temperature control should provide physical comfort, 68° F to 75° F (20° C to 24° C) (i.e., it should not be too warm or too cool).

The heating, ventilation, and air conditioning (HVAC) system in the OR usually evacuates odors fairly quickly by exchanging air 20 times per hour, with four exchanges of fresh air. The ventilating system should help remove toxic fumes and anesthetic gas waste that is not picked up by the scavenger system on the anesthesia machine. Perfume and other odors can cause headaches, nausea, or respiratory congestion in people with sensitivities to smells. Heavy perfume can also have an annoying, lingering effect; therefore people in the perioperative environment should avoid wearing it.

Lighting should be adequate, but excessive glare causes fatigue. Illumination is the product of the light and the reflectance of the target. A bright, highly polished mirror finish on an instrument tends to reflect light and can restrict vision. Satin or dull-finished instruments eliminate glare and lessen eyestrain. These instruments are made with varying degrees of dullness depending on the manufacturer. Lightly tinted or polarized eyewear may save sterile team members from visual fatigue but should not distort the color of tissues. For drapes and walls, soft, cool colors, especially blues and greens, are less reflective than white. Drapes with blue, gray, or green tones help reduce the contrast between most tissues and the surrounding field.

Environmental design is specific to ventilation, lighting, color, and auditory effects. Some facilities have piped-in music in waiting areas. Music can be stimulating for personnel and relaxing for patients who are awaiting surgery or undergoing a surgical procedure under local anesthesia. The selection of music should be appropriate for the intended listener. Music with a low volume, moderate rhythm, and bright tone can motivate muscular activity and increase levels of efficiency of OR personnel. However, this

[a]NIOSH publishes ergonomic safety information, chemical hazards, and strategies for health care workers online at www.cdc.gov.

type of music would not be conducive to relaxation for the patient who is awaiting surgery. On the other hand, music can be a distraction and an annoyance, especially for the anesthesia provider, who may depend on auscultation when monitoring the patient. Music should be turned off at the request of the patient, surgeon, or anesthesia provider.

Extreme noise from drills, fan motors in equipment, and other sources can be annoying and potentially dangerous to patients and personnel. The noise can become intense enough to increase blood pressure and provoke peripheral vasoconstriction, dilation of the pupils, and other subtle physiologic effects. It also can interfere with necessary communication and thereby provoke irritation. The EPA recommends that noise levels in hospitals not exceed 45 decibels during daytime hours.

The OR should be as quiet as possible except for the essential sounds of communication among team members directly concerned with the patient's care. Excessive noise and distractions in communication are directly linked to medical errors and patient death.[1] Nurses have an obligation for patient safety; noise and unnecessary tasks must be discontinued during critical situations and communication. Any necessary talking should be done in a low voice. Counts or requests for supplies should be done quietly or by hand signals. Conversation unrelated to the surgical procedure is out of place. Even during the deep stages of anesthesia, a patient may perceive and remember noise that occurs during the surgical procedure. This phenomenon is referred to as anesthesia awareness.

If a regional or local anesthetic is used, the patient can hear the conversation. Because patients interpret anything they hear in terms of themselves, all words should be guarded.

Major sources of noise in the OR involve paper, gloves, objects wheeled across the floor, instruments striking one another, monitors, and high-pitched power instruments, including suction. The scrub person should keep in mind the sources and the effects of this noise. The clattering of instruments should be avoided. Except while in actual use, suction tubing can be clamped or kinked to minimize noise. Paper wrappings should not be crushed. Monitors with necessary audible signals should be placed as far away from the patient's ears as possible; continuous monitor beeps also can distract the surgeon and anesthesia provider but should never be turned off. The circulating nurse should keep the doors to the OR closed to shut out the noise of the corridors, water running in the scrub room, or the sterilizer operating in the substerile room. Aside from blocking noise, the doors should remain shut to maintain the proper functioning of the air-handling system in the OR.

Working in a pleasantly quiet environment is less fatiguing, produces fewer psychological and physiologic adverse effects and allows for greater efficiency on behalf of the patient.

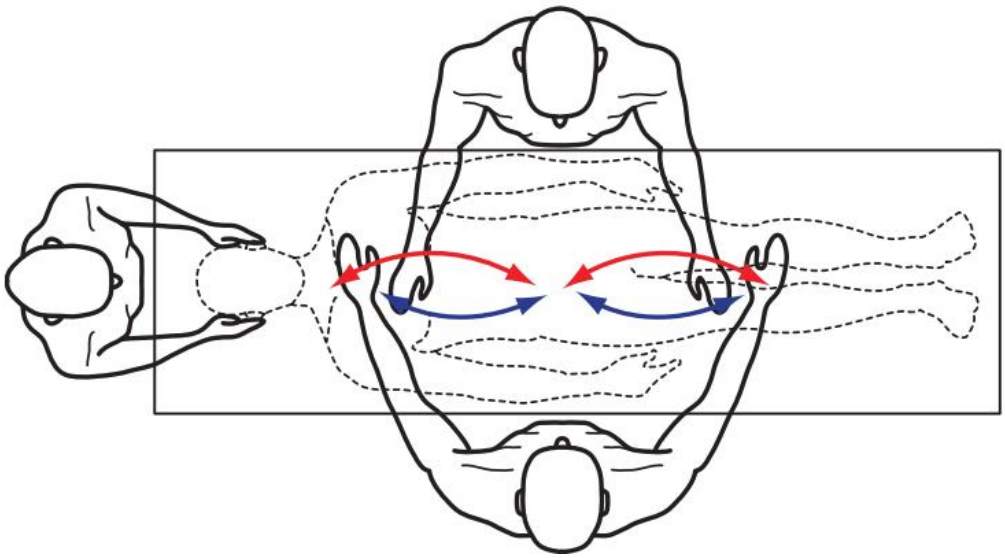
Body Mechanics

Backache is a leading cause of work-related lost time, second only to upper respiratory tract infections. Standing for prolonged periods, often in an awkward position, is a common cause of low back pain. Tiring body motions or an awkward or strained body posture should be avoided. Weight bearing on only one foot causes additional strain. When the feet are placed together while standing, constant muscular effort is required by the thigh muscles to maintain an erect posture. In contrast, when the feet are apart the ligaments of the hips and knees support the body with less effort. Therefore maintaining a wide stance, with knees periodically slightly flexed while standing at the OR bed for prolonged periods will be less fatiguing for the scrub person.

While in a location to observe both the surgical procedure and the instrument table, the circulating nurse can stand with the upper and lower extremities in a resting position. In this standing position the arms are clasped behind the back and the feet are in a wide stance.

Shoes should be considered for comfort and safety. Soft canvas or leather athletic shoes that tie or secure with Velcro provide adequate, nonskid support for the foot. OSHA requires all OR personnel to wear impervious closed-in shoes. If running is required during an emergency, these shoes will be more secure than clog varieties with open backs. Soft shoes do not afford protection from dropped items.

The OR bed is adjusted to the best working height for the tallest person on the sterile team. The reach potential of the entire team should be considered when planning where each individual team member will stand (Fig. 13.1). Team members should be able to stand erect with their arms comfortably relaxed from the shoulders, without stooping, and they should not need to raise



• **Fig. 13.1** Work motion of each sterile team member should be ergonomically safe and comfortable.

their hands above the level of their elbows for the majority of their work motions. Standing platforms (stepstools, referred to as *steps*) may be needed to elevate the scrub person and/or the assistant to a feasible working height. These platforms should be long enough and wide enough to allow a wide stance. A shorter surgeon can stand on steps to allow the team to have the OR bed at a comfortable working height.

Correct posture while in the sitting position is equally important. The back is strongest when it is straight. When seated, team members should sit far back in the chair or on the stool with the body straight from hips to neck. They should lean forward from the hips, not the shoulders or waist. This position puts the least strain on muscles, ligaments, and internal organs. Before and after the surgical procedure the circulating nurse and scrub person(s) should rest in a sitting position between long periods of standing. If work is done in a sitting position, the stool or chair should be adjusted to the correct height for the working surface. Sterile persons should not change the height of the sterile field by sitting while dressed in sterile attire.

First assistants may develop carpal tunnel syndrome as a result of holding retractors in one position for prolonged periods. Carpal tunnel syndrome is a form of repetitive stress injury caused by tenosynovitis that places pressure on the median nerve of the hand. Consequently, the thumb, index, and ring fingers tingle and feel swollen. Self-retaining retractors help relieve some of this strain.

Sprains and strains are common injuries sustained to the back, arms, or shoulders as a result of lifting patients or moving equipment. The following principles of body mechanics should be observed to minimize physical injury:[2]

- While maintaining a straight back, keep the body as close as possible to the person or equipment to be lifted or moved.
- Lift with the large muscle groups of the legs and abdominal muscles, not the back.
- Bend the knees to get body weight under the load, and then straighten the legs to lift with the heels flat on the floor.
- Lift with a slow, even motion, keeping pressure off the lumbar (lower back) area.
- Push, do not pull, stretchers, tables, and heavy equipment on wheels or casters.
- Use large body muscles to maneuver the base of portable equipment such as laser equipment or microscopes.
- If standing for prolonged periods, stand in a wide stance with the heels apart so the ligaments of the hips and knees can support the body without effort.
- Distribute weight evenly on both feet, but shift the body occasionally during prolonged periods of standing. Do not stiffen the legs at the knee. A slight flex at the knees is less stressful.
- Sit with the back straight from the hips to the neck, and lean forward from the hips.
- Align the head and neck with the body when standing or sitting, maintaining the lumbar curve.
- Change position, stretch, or walk around occasionally if possible.
- Pivot the entire body to avoid twisting at the waist.
- Bend forward with hip flexion and hand support.
- Avoid overhead reaching or overstretching; keep materials in the chest-to-knee range if possible; use steps as appropriate.

A lifting frame, sliding board, air mattress, or Davis roller helps relieve the potential strain of moving unconscious or obese patients (Fig. 13.2). A clean draw sheet must always be used to protect the patient from contact with the moving device. A minimum of four persons is required to move an unconscious patient. If one caregiver attempts to move these patients alone, it can cause injury to the patient or the caregiver. Assistance is also needed to position patients on the OR bed. Physical therapy department personnel or the occupational health director can be a resource for teaching the patient care staff the proper techniques for lifting, bending, reaching, and pivoting.

PROS/CONS

Body Mechanics

Pros

- Body mechanics plays a major role in the perioperative workplace. The perioperative setting is a physically demanding area in which there is a high risk for musculoskeletal injuries.
- The perioperative setting requires staff to push, pull, and lift patients, heavy equipment, and supplies.
- The National Institute for Occupational Safety and Health (NIOSH) offers a Musculoskeletal Health Program to improve workplace efficiency and prevent musculoskeletal injuries.
- **Ergonomics** is the study of people's efficiency in their working environment. It is concerned with how people arrange and design equipment to maximize productivity and reduce fatigue and injury.
- OSHA has a General Duty Clause that employers must provide a safe working environment for all personnel, patients, and visitors. It offers guidelines for safety and training programs for employees.
- AORN offers a Safe Patient Handling Tool Kit. It recognizes seven high-risk activities uniquely acquired from working in the perioperative setting. These tools include Lateral Transfer from Stretcher To and From the OR Bed, Positioning and Repositioning the Patient on the OR Bed, Lifting and Prepping Head and Limbs, Prolonged Standing, Retraction, Lifting and Carrying Supplies and Equipment, and Pushing and Pulling Equipment on Wheels.
- The Ergonomic Tools give recommendations on how to safely complete each task and the rationale for each. It also incorporates the NIOSH lifting equation, which recommends how much weight an individual can lift and still be considered safe. It also explains the proper lift technique: lift with the legs, bend the knees, get under the object, and lift slowly and evenly.
- Assistive devices are available, such as a Davis Roller or air-assisted mattresses for obese patients to move from a stretcher, instead of manual labor.
- Posture while standing or sitting is fundamental in preventing injury because the back is stronger in a straight position.
- OR equipment should be in good working condition to reduce the force necessary to push or pull.
- Perioperative education on body mechanics has been shown to reduce the amount of lost time from work-related injuries.

Cons

- The perioperative setting requires staff to lift patients, heavy equipment, and supplies. These actions also require pushing and pulling movements that can put staff at risk for injury.
- Many health care workers leave the profession due to high physical demand and occupational injury such as back injuries and muscular pains and strains. Back injuries are one of the most common injuries among health care workers.
- Lifting and moving patients can cause injury to workers if they do not use assistive devices or the correct amount of people necessary to properly move a patient.

Continued

PROS/CONS—cont'd

Body Mechanics

- Lifting limbs during skin prep can cause a sprain or strain to a worker if the weight of the limb is too heavy or held for a longer period of time.
- Standing in one position for a long period of time is common and can cause fatigue and pain. Standing on both feet with a wider stance may help relieve some fatigue.
- Standing or holding retractors in awkward positions may result in poor posture thus causing fatigue, back pain, neck pain, or carpal tunnel syndrome. The height of the OR bed should be at a safe working level to prevent awkward positions.
- If one person cannot safely move equipment, then staff help should be available when necessary.
- Lack of knowledge about proper body mechanics is the leading cause of work-related injuries.

• **Fig. 13.2** Four surgical personnel using a patient roller correctly to move the patient from one surface to another.

• **Fig. 13.3** Radiation warning sign.

Ionizing Radiation

Radiation cannot be seen or felt. **Ionizing radiation** produces positively and negatively charged particles that can change the electrical charge of some atoms and molecules in cells. These changes can alter enzymes, proteins, cell membranes, and genetic material. This can cause the death of cancer cells when radiation is used in therapeutic doses; however, exposure to radiation also can cause cancer, cataracts, bone marrow injury, burns, tissue necrosis, genetic mutations, spontaneous abortion, and congenital anomalies. When radiation is in use, warning signs should be prominently displayed (Fig. 13.3).

Perioperative patient care personnel may assist with invasive x-rays. If personnel are unprotected, they are exposed to scatter radiation from the patient during intraoperative and interventional procedures when x-rays are taken or fluoroscopes and image intensifiers are used. One study measured the exposure of anesthesia providers over a 6-month period in interventional suites and found that with proper protective attire the exposure gradient was below the permissible levels. Team members are also exposed during the implantation or removal of radioactive elements. Patients exposed to radioactivity for therapeutic purposes or by accident may emit radiation.

Intraoperative x-rays may be taken during, but are not limited to, procedures, urologic examinations, biliary tree visualization, angiography, or orthopedic bone alignment procedures. The sterile team should be wearing lead protective garments under the sterile gown or should step behind a lead screen when the image is made. The x-ray cassette (if one is used) may need to be draped or encased in a sterile cover, and the surgical incision may need to be protected with a sterile drape to prevent contamination by the x-ray machine. When a C-arm image intensifier is used, a large, specialized, sterile, clear plastic tubular drape is slid over the entire machine (Fig. 13.4).

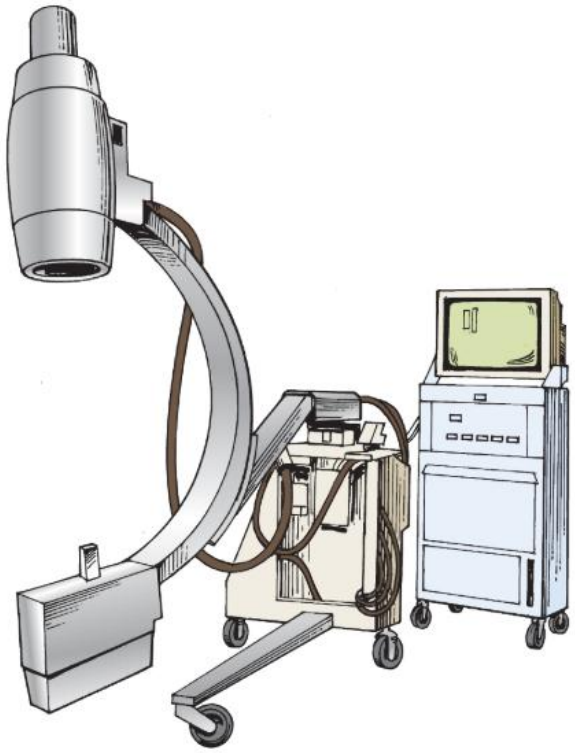
The effect of radiation is directly related to the amount and length of time of exposure. Exposure is cumulative, and because there is an extended latency period, the effects may not be evident for years. Therefore constant vigilance for personal safety is essential to avoid excessive exposure to ionizing radiation. Protection implies understanding the basic terms and adhering to strict policies and procedures.

Safety Considerations in the Use of Ionizing Radiation

Because of the adverse and cumulative effects of ionizing radiation on body tissues, safety precautions are taken to protect patients and personnel from the potential hazards. Box 13.1 lists safe radiation exposure limits according to the area of the body. Monitoring badges must be worn if radiation devices are in use.

Patient Safety

A patient can be exposed to the primary beam of x-rays, the radioactivity of implants, and scatter radiation. Any exposure to radiation has biologic risks; therefore the exposure should be as



• **Fig. 13.4** C-arm keeps image intensifier and x-ray tube in alignment to amplify fluoroscopic optical image.

• BOX 13.1 Permissible Doses of Radiation as Established by the National Council on Radiation Protection and Measurements

Permissible doses of radiation are based on units of an equivalent dose quantity that express all radiations on a common scale for the purpose of calculating their biologic effects. The maximum permissible doses per year for occupationally exposed people older than 18 years of age varies by body parts:

- Whole body, including blood-forming organs, bone marrow, and gonads: 5 rem, 50 mSv
- Lenses of eyes: 15 rem, 150 mSv
- Other organs and tissues: 50 rem, 500 mSv
- Fetus in utero: 0.5 rem, 5 mSv; no more than 50 mR, 0.5 mSv in any 1 month of gestation during pregnancy
- Exposure should not exceed 100 mR, 1 mSv per week

low as possible. To reduce the amount of radiation exposure, the following precautions should be taken:

1. The fluoroscope should be turned off when not in use. The patient is continuously exposed to radiation during fluoroscopy. Keep in mind that the radiation emanates from the part of the C-arm that is under the OR bed.
2. Every effort should be made to reconcile an incorrect sponge, sharps, or instrument count. An x-ray should be made only as a last resort to locate a missing item.
3. Body areas should be shielded from scatter radiation or the focused beam whenever possible. A lead shield can be positioned between the patient and radiation source if it will not interfere with the sterile field or visualization for the x-ray study. The shield is placed before the patient is draped. A shadow shield connected to the x-ray tube may be a preferable alternative if a lead shield cannot be used.
   a. Lymphatic tissue, the thyroid gland, and the bone marrow of the sternum are especially sensitive to radiation. Therefore a thyroid/sternal shield should be used during x-rays or fluoroscopy of the head, upper extremities, and chest.
   b. To protect the testes or ovaries, a gonad shield should be used during x-rays or fluoroscopy of the hips and thighs.
   c. A lead shield always should be used to protect the fetus of a pregnant patient. Even low levels of scatter radiation may be harmful to the fetus. Therefore x-rays of the abdomen and pelvis are avoided as possible, especially during the first trimester.

Intraoperative documentation should include the anatomic location of the direct x-rays or fluoroscopy, the types and locations of radioactive implants, and shielding measures to protect the patient from scatter radiation. The FDA and AORN have a list of facility requirements that must be followed for personnel safety in the perioperative setting.[3,4] Safety requirements include the following:

- The amount of radiation used should be as low as reasonably achievable (ALARA).
- A safety program must be in place run by an experienced radiation expert or physicist.
- Personnel training programs must include proper wearing of protective devices such as lead aprons, dosimeter placement, thyroid shields, eye protection, and protective measures for patients.
- Documentation for patients includes the type of radiation and protection measures.
- Any radioactive tissue, bodily fluids, or radiation implants must be disposed of by a trained individual in the correct manner.
- According to the Centers for Medicare & Medicaid Services, equipment must be checked regularly and run by trained individuals.
- Safety program must pass annual safety inspections.

Personnel Safety

Safety precautions should be taken to protect team members from the potential hazards of ionizing radiation. Three vital factors must always be remembered: time, distance, and shielding.

Time

Overexposure and unnecessary exposure should be avoided in everyone, and especially in those of childbearing age. Changes may occur in the reproductive cells as a result of radiation, leading to potential genetic defects. The following precautions should be used to limit the length of exposure to radiation:

- Patient care personnel should rotate assignments on procedures that involve radiation.
- Staff members may request relief from exposure during pregnancy. If this is not possible, a pregnant staff member should leave the room or be adequately shielded when x-rays are made or fluoroscopy is used.
- Radiation from an x-ray tube, fluoroscope, and image intensifier is present only as long as the machine is energized. These machines should be turned off when not in use.
- Radioactive elements should remain in lead-lined containers until ready for implantation. Trained personnel should handle the radioactive elements as quickly as possible and always with special forceps. A careful accounting of how many items are present and used should be made.
- A patient who has received radioactive substances for diagnostic studies may emit up to 2 milliroentgens (mR)/hr. If possible, the surgical procedure should be delayed for at least 24 hours after the test.

- Personnel should limit the time spent in proximity to a patient who has had a diagnostic study with or an implantation of radioactive elements until disintegration reaches a low level.
- Body tissues and fluids removed from patients with radioactive emissions should be contained quickly.[3]

Distance

Automatic or manual collimators, which confine the x-ray beam to the precise size of the image or fluoroscopic screen, are required for all equipment. Most image intensifiers have a lead shield as part of the installation. A single-frame computerized recording device incorporated into the fluoroscopy system also helps reduce exposure. Fluoroscopy produces more scatter radiation than do direct x-ray beams. Personnel should distance themselves as far as possible from the source of radiation, as demonstrated by the following procedures:

- Unsterile team members who can safely do so should leave the room or stand behind lead shields during each single x-ray.
- Inanimate holding devices should be used to maintain the position of the x-ray and patient.
- Sterile team members and others who cannot leave the room should stand 6 ft (2 m) or more from the patient, if possible, and out of the direct beam during exposure. Team members should remember the inverse square law of distance: double the distance equals one-fourth the intensity.
- If possible, team members should stand behind or at a right angle to the beam on the side of the patient where the beam enters, not exits.
- Lateral or oblique x-ray increases scatter radiation. Positioning the beam in a plane vertical to the pelvis or thighs helps reduce scatter. For supine and upright x-rays, the beam should be directed at the floor or walls.

Shielding

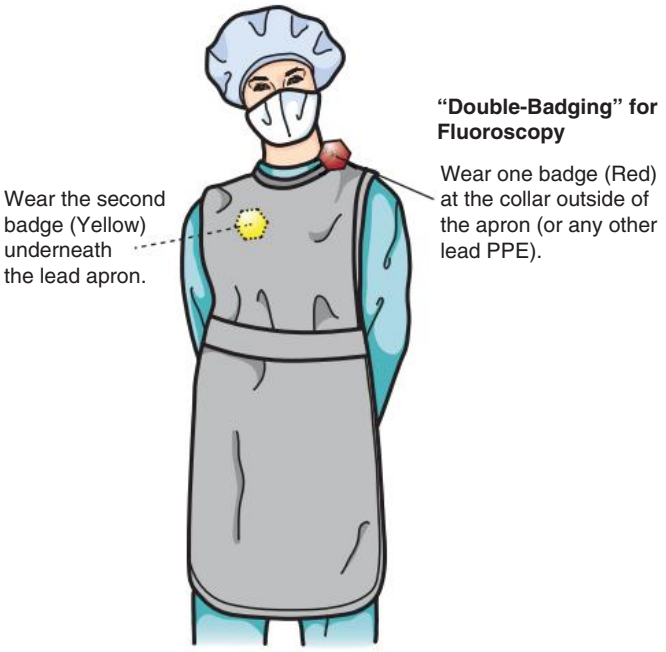
Lead that is at least 0.5 mm thick offers the most effective protection against gamma rays and x-rays to halt and absorb radiation scatter. Alpha and beta particles do not require shielding. The following guidelines for shielding should be observed:

1. The walls of rooms with fixed radiation equipment are usually lined with lead. Gamma rays can penetrate lead to a depth of 12 inches (30.5 cm). X-rays can be stopped with lead or thick concrete.
2. Portable lead screens should be available.
   a. Sterile team members and others who cannot leave the room should stand behind a lead screen while x-rays are taken or the patient is exposed to intraoperative radiation therapy. The screen(s) should be positioned behind a portable machine.
   b. When a lateral exposure is taken, the screen should be positioned behind the x-ray cassette to absorb rays that penetrate through or scatter from the cassette.
   c. People preparing radioactive implants that emit gamma rays should do so from behind a lead screen that is up to 12 inches (30.5 cm) thick. A sterile drape can be put over the screen so the scrub person or other sterile team member can stand behind the screen and reach around it.
3. Sterile and unsterile team members should wear intact lead aprons (Fig. 13.5).
   a. The lead apron is worn under the sterile gown. Lead aprons that bear the total weight from the shoulders can cause fatigue and back strain. Lead protective attire can be worn like a vest and skirt to distribute the total lead weight.
   b. If the apron does not wrap around the body, team members should face the radiation source so the apron provides protection between the source and the body.

• **Fig. 13.5** Lead apron.

   c. To protect against beam and scatter radiation, team members should wear aprons during fluoroscopy and for lateral or oblique x-rays. Levels of scatter radiation are greater at lateral and oblique angles, and exposure time is prolonged during fluoroscopy.
   d. Lead aprons should be hung or laid flat when not in use. They should not be folded. Folding can crack the lead, making the shield ineffective. The aprons should be examined under x-rays periodically to determine intactness. A policy should be in place concerning lead apron testing.
4. Lead-impregnated rubber gloves can attenuate (reduce the intensity of) rays by 15% to 25%.
   a. Sterile team members should wear sterile gloves over lead-impregnated gloves when the hands will be in direct exposure (e.g., during fluoroscopy), when injecting radioactive dyes or elements, and while handling radioactive implants.
   b. If it is necessary to hold a cassette in position for a single x-ray exposure, lead gloves should be worn.
   c. Lead gloves may be supplied sterile or sterilized by the appropriate method for reuse. The rubber should allow adequate aeration to avoid skin irritation of the wearer. Latex-sensitive individuals should wear latex-free gloves under the rubber lead gloves.
5. Lead thyroid/sternal collars or shields should be worn during fluoroscopy and exposure to oblique-angle x-rays. Personnel within 6 ft (2 m) of the radiation source, including the anesthesia provider, risk exposure of the head and neck (Fig. 13.6).
6. Leaded glasses may be worn to protect the eyes from cataract formation during fluoroscopy.

• **Fig. 13.6** Lead thyroid shield.



• **Fig. 13.7** Placement of radiation dosimeter monitors.

Lead shields should be tested routinely by the radiology department every 6 months and whenever damage is suspected. Defects may not be visually detected.

Monitoring Radiation Exposure

All personnel exposed to ionizing radiation with any frequency or during prolonged procedures should wear a monitoring device. The purpose of the device is to measure the total rems of accumulated exposure. Therefore the monitor is worn only by the person to whom it is issued and at all times of exposure for the designated period. Exposure data on the monitor are recorded for each individual either monthly or weekly, depending on the type of monitor.

Film badges (dosimeters) are the most widely used monitors. These monitors contain small pieces of photographic film that are sensitive to different types of radiation: beta rays, gamma rays, and x-rays. Thermoluminescent badges and pocket dosimeters also are available. When only a single monitor is used, it is worn outside the lead apron along the neckline.

Two dosimeters may be worn. One monitor should be worn external to the lead apron at the level of the neck to measure exposure of the head and neck, especially during fluoroscopy. The second monitor should be worn on the scrub suit under the lead apron to measure exposure of the whole body and gonads (Fig. 13.7). A double monitoring system validates the effectiveness of the lead apron when exposed to ionizing radiation.

Nonionizing Radiation

Radiant energy in the form of heat and/or light is emitted from radiowaves, microwaves, televisions, computers, radiant warmers, and light sources. For example, overhead lights in the OR produce heat. Fiberoptic light cables are cool, but the light transmitted is intense and can produce heat. Radiation from these sources is nonionizing (with the exception of ultraviolet lights, which can produce radiant energy in wavelengths and intensity sufficient to alter DNA in cells, burn tissue, and damage the eyes). **Nonionizing radiation** does not accumulate in the body and therefore does not require monitoring. Nonionizing radiation per se is not hazardous when properly controlled.

• **Fig. 13.8** Laser warning sign.

Lasers, one form of nonionizing radiation, concentrate very-high-energy light beams within a small circumference to produce intense heat. (*Laser* is an acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation.) Laser equipment should be used in accordance with established regulatory standards and guidelines and the manufacturer's instructions for laser safety. Lasers can vaporize, cut, or coagulate tissues directly exposed to the beams. They can cause thermal burns from indirect exposure.

Fire, explosion, eye and skin exposure, and laser plume (smoke) also are potential hazards for patients and personnel. Eyewear of the correct optical density is required, and reflective surfaces should be covered. Safety measures should be taken. A laser warning sign is prominently displayed outside the door where a laser is in use (Fig. 13.8). Correct eyewear should be available outside the door in case authorized personnel must enter the room when the laser is active. Lasers are described in more detail in Chapter 20.

PROS/CONS

Eyewear: Does It Need To Be Worn at All Times?

Pros

- Eyewear is part of the personal protective equipment (PPE) required by the Occupational Safety and Health Administration (OSHA) according to their Bloodborne Pathogens Standard. Eyewear must be provided by the facility to protect the mucous membranes of the eyes.
- Eyewear is necessary to protect the wearer against chemical, mechanical, radiologic, environmental, and biologic hazards and irritants. Liquid and chemical hazards can be from splashes, splatter, vapor, mist, fumes, dust, and airborne particles. Contaminated eyewear should be decontaminated or replaced with a clean pair. X-ray personnel can wear eye protection made of leaded glass.
- All employees should be trained about PPE. Eyewear is provided by the facility because it must meet certain standards to provide adequate protection. If employees would like to purchase their own eyewear, it must pass the facility standards and be cleaned after each use.
- Eyewear comes in a variety of styles such as disposable goggles, glasses with side shields, face shields, antifog goggles, surgical masks with attached visors, laser eyewear, and full-face respirators. All eyewear must be wide enough to protect the eyes in front as well as have side shields to protect from splashes entering at the side of the face. Some procedures require specific eyewear for protection.
- Eyewear should be put on and secured before performing the surgical scrub and worn throughout the procedure and during cleanup. It should be worn when handling dirty instruments or during patient care if there is a risk for coming into contact with bodily fluids. Goggles provide the best circumferential protection.
- Protective eyewear is specifically manufactured for use with lasers. Each laser has protective eyewear with specific optical density lenses. They prevent the energy or wavelength from reaching the lens or retina of the eye. Eyes are vulnerable to injury from scattered, reflected, or diffused laser beams.
- The eyes of the patient also must be protected with eyewear that prevents exposure from all angles. The direction of the hazard differs because the patient is lying down. Moist eye pads secured over the patient's eyes can be used during general anesthesia.
- Signs must be placed on the outside of the surgical suite warning other staff members that a laser is in use, and special eyewear is to be donned before entering the room. Specific eyewear should be available outside the door for personnel who may need to enter the room during a procedure in progress.
- Eyewear with small digital video cameras are now being used as educational tools. The glasses are lightweight, wrap around the sides of the face for protection, and are cable free. They contain a battery and a secure digital (SD) card.

Cons

- Many health care workers do not wear eye protection at all. They forget to put it on or think they are not at risk for contamination.
- Any health care worker who does not follow the policy for wearing eyewear may receive a verbal or written warning. OSHA or other regulatory agencies may conduct an unannounced visit. The facility could be fined for each breach by a government agency if they are not enforcing mandatory policies.
- Many health care workers do not put on eyewear while scrubbing, setting up a sterile table, prepping a patient, intubating or extubating a patient, cleaning up after a procedure, cleaning a room, and washing their hands after the procedure. All of these are examples of activities that put them at risk for eye contamination.
- Personal spectacles are not a substitute for proper eyewear. Even if side shields are applied to spectacles, it may not provide protection from splashes. Health care workers may wear their spectacles under a full face shield.
- Many health care workers do not wear the appropriate type of eyewear for the procedure. For example, if a health care worker is doing an orthopedic procedure, a full face shield or large goggles should be worn to prevent splatter from power equipment or irrigation devices.

Magnetic Resonance Imaging

The first human testing of magnetic imaging took place in 1977 and took more than 5 hours to accomplish. Today this technology is a diagnostic and interventional standard. Some larger facilities have interventional suites with high-tech surgical equipment for real-time magnetic imaging during a surgical procedure that creates three-dimensional maps of the patient's body with radiowaves. Noise from the magnetic resonance imaging (MRI) machine is shielded from the patient's ears by earplugs or headphones.[5]

Patients with implanted stainless steel clips and other components, such as older style pacemakers, can suffer injury in the presence of MRI. Implanted clips may be attached to intracranial vessels or other structures that could be injured if exposed to extreme magnetic forces. Patients with retained ferromagnetic bullet fragments or armor-piercing munitions (i.e., victims of a crime or a suspected perpetrator) are at risk. These bullet-type or shrapnel materials may be present in hospitalized military or law enforcement personnel from previous duty-related injuries. A careful history must be taken before MRI testing. [5,6]

Patients with stimulator leads are at risk because the metal in the leads will become superheated, causing tissue injury. Examples of implanted stimulators include pacer wires, spinal or neurologic stimulators, and internal defibrillator wires. Patients with extreme black ferrous tattooing may experience burns. Many radiologists used to refuse MRI to patients with tattoo eyeliner. The U.S. Food and Drug Administration (FDA) does not regulate tattoo ink or the practices of permanent make-up. [4,6] If a doctor recommends an MRI, precautions such as cold compresses or ice packs can be applied to the area of concern.

No magnetic metal object can be used within the MRI environment. Items have been pulled from caregivers' pockets, including scissors. Instrument tables, intravenous (IV) poles, oxygen tanks, instrumentation, and OR furniture cannot be composed of any magnetic substance. Titanium or plastic is commonly used in this environment because it is inert and nonmagnetic. Patients may be asked to change into facility attire because some personal clothing can contain metal such as buttons.

The floor of the hybrid MRI OR is marked with safe distance positions referred to a *gauss lines.* Special equipment, such as

anesthesia machines, can be positioned outside the gauss line marked "5-G."[5] A sudden shutdown for an emergency cut-off of the magnet causes a release of helium into the OR, which can be harmful to personnel. Safety precautions include having oxygen masks available for all persons in the room in case of an emergency shutdown of the MRI. The emergency shut-off panel (referred to as the *quench button*) is in the control booth of the MRI suite.[5]

Electricity

The appropriate use of electronic devices is a prime concern of health care providers and industry personnel who seek safer patient care. Underlying this concern is the rapidly expanding use of electronic equipment. The marketing and safety standards of medical electronic devices used in the perioperative environment are federally regulated. The standards and practices recommended by the Association for the Advancement of Medical Instrumentation (AAMI) are helpful to both manufacturers and users. Standards set by TJC also should be met for facility accreditation. Inadequately trained personnel or the malfunctioning of devices such as electrosurgical units (ESUs), defibrillators, and x-ray machines are responsible for the fatalities and near-fatalities that occur.

Parameters of Electricity

Electricity is the flow of electrons along a path. It consists of three basic parameters: voltage, resistance, and current.

Voltage

Voltage forces electrons to move through material in one direction and causes current to flow. It is measured in volts. The greater the number of volts, the more direct the path of the current.

Resistance

Resistance is the measurement of opposition to the flow of electrons through material. It is measured in ohms. Electricity flows easily through conductors (e.g., metals, carbon, water); flow is minimized by insulators (e.g., rubber, plastic, glass) that prevent the flow of electricity. The resistance of the human body is more comparable to a conductor than an insulator.

Current

Current is the rate of flow of electrons through a conductor. It is measured in amperes—the number of electrons passing a given point each second. Current flow is proportional to voltage and inversely proportional to resistance. Current may be one of the following two types:

1. Direct current (DC), as from a battery. This is a low-voltage current.
2. Alternating current (AC), as from a 110 or 220-volt line. This type of current has an alternating directional flow. AC is considered low voltage, but it is three times more powerful than low-voltage DC.

Grounding

The grounding of all electrical equipment is essential for safety and prevention of stray current leakage. Grounding systems are designed to discharge any harmful electricity directly to the ground without including the patient in the circuit. This prevents the inadvertent passage of electric current through the patient, thereby preventing shock or burn.

ESUs are grounded. When using a monopolar ESU a return electrode or dispersive electrode is positioned on the patient to disperse the electrical energy and return it to the generator. The pad itself is not a ground, but a path for the current to return back to the machine. ESUs are described in more detail in Chapter 20.

Electrical power is supplied through two wires—hot and neutral—that transmit current to the three-wire outlets in the building. The third wire is the ground wire. When the cord from an electrical device is plugged into an outlet, the hot and neutral wires deliver the current. The ground wire is attached to a copper pipe that is driven into the ground at the point where power enters the building. An electrical connection to the ground provides a means for current to flow through the ground wire (or any other conductive surface) to the ground rather than going to the neutral wire. The copper ground wire is used to prevent the metal housings of electrical equipment from becoming electrically "hot." The ground wire within the three-wire power plug and cord connects the equipment (instrument) housing to the ground contact in the receptacle (wall outlet). This provides a constantly available return path for current to the electrical source.

When an instrument is grounded, leakage current returns through the ground wire to earth, causing no damage. However, if the ground path is absent or broken, leakage current will seek another path to ground. For example, if the insulation on wires is defective (e.g., broken or frayed cords or plugs), some current will leak or flow to other nearby conductors, such as the equipment housing. The same is true of endoscopic instrumentation with fractured insulation. The current will pass into the patient's tissues, causing an inadvertent injury.

Equipotential Grounding System

Current flows between points only when a voltage difference exists between them. Therefore electric shock can be minimized by eliminating voltage differences. One system designed to do this is the equipotential grounding system, which maintains an equal potential or voltage between all conductive surfaces near the patient. To achieve equipotential grounding, all exposed conductive surfaces within 6 ft (2 m) of the patient are electrically connected to a single point that is itself connected by a copper conductor to the ground tie point at the electrical distribution center serving the area. Consequently, all exposed metal surfaces are electrically tied together and to the ground.

Isolation Power System

Isolated power systems are used in hazardous locations such as ORs. An isolation transformer isolates the OR electrical circuits from grounded circuits in the power mains. Thus the isolated circuit does not include the ground in its pathway; the current seeks to flow only from one isolated line to the other. As a result, accidental grounding of people in contact with the hot wire does not cause current to flow through the individual.

A line isolation monitor checks the degree of isolation maintained by an isolated power system by continually measuring the resistance and capacitance between the two isolated lines and the ground. This measurement is called the hazard index. The monitor, a wall-mounted meter, has an alarm that is activated at the 2-milliampere (mA) level. This warning system indicates when inadvertent grounding of isolated circuits has occurred and alerts personnel to a dangerous situation. Because grounding can take place only when faulty equipment is plugged into ungrounded circuits, maximum safety is afforded by use of the isolation transformer. Ungrounded circuits fed through isolation transformers

are required in OR and obstetric suites. Permanently installed overhead OR lights and receptacles in anesthetizing locations should be supplied by ungrounded electrical circuits.

The following steps should be taken in the event that the line isolation monitor alarm is activated during a surgical procedure:

1. Unplug the last piece of electrical equipment that was plugged into the power system.
2. Continue to unplug all equipment in the OR to identify the faulty equipment. A battery-operated backup system may be needed.
3. Close the OR until a biomedical engineer can check for current leakage.

Electric Shock

Electrocution occurs when an individual becomes the component that closes a circuit through which a lethal current may flow. Lethal levels may be attained by currents through the intact body via the skin or by currents applied directly to the heart. Electric shock occurs when a current is large enough to stimulate the nervous system or large muscle masses (e.g., when the body becomes the connecting link between two points of an electrical system that are at different potentials).

The physiologic effect of shock may range from a mere tingling sensation to tissue necrosis, ventricular fibrillation, or death. This effect is an electrical response of sensory cells, nerves, or muscles to electrical stimuli that originate either intrinsically (within the body) or extrinsically (outside the body). The severity of shock depends on the magnitude of the current flow and the path taken through the body. There are two types of shock: macroshock and microshock[7]:

1. *Macroshock.* Macroshock occurs when current flows through a relatively large surface of skin. It usually results from inadvertent contact with moderately high voltage sources, expressed in milliamperes (1/1000 ampere). A current intensity of 1 to 5 mA through the chest can cause severe burn at the point of contact. If the cardiac conduction system is involved, a current intensity of 50 to 100 mA through the chest can cause ventricular fibrillation because the heartbeat is electrically controlled.

   Macroshock occurs through the trunk of the body, with the current following many paths; each path carries a fraction of the current. It may or may not be harmful, depending on how much current flows through a susceptible heart along its path. Common sources of macroshock are electrical wiring failures that allow skin contact with a live wire or surface at full voltage. The victim, instrument, or surface should never be touched with bare hands in a case of shock. The power supply should be disconnected, or an insulating material should be used to push the victim away from the source of electricity.
2. *Microshock.* Microshock occurs when current is applied to a very small contact area of skin. The development of medical techniques that permit the application of electrical impulses directly to the heart muscle has raised awareness of the extreme danger of microshock to an electrically sensitive patient. Cardiac microshock is a potential hazard of indwelling catheters filled with conductive fluid, probes inserted into the great vessels, and electrodes implanted around the heart. These devices multiply the potential for electrocution because they can be conductors of electricity.

The external portion of a cardiac catheter generally consists of two parts: an inner conductor(s) of wires or conductive fluid and an outer insulating sheath. When there is a highly conductive pathway from outside the body to the great vessels and heart, small electric currents may cause ventricular fibrillation and cardiac arrest. When a shock has an internal route to the heart, it takes only one thousandth as much electricity to be fatal as when the shock is transmitted through the surface of the skin. Microshock occurs only if current from an exterior source flows through the cardiac catheter or conductor. Conductive intravascular catheters that disperse current at skin level diminish the risk for microshock. The most important precaution is to protect the exposed end of the cardiac conductor from contact with conductive surfaces, including the body. Rubber or plastic gloves should always be worn when handling the external end of a cardiac catheter or conductor.

Safeguards

Although the value of electronic devices is unquestionable, their use must not be allowed to cause electric shock or electrocution. Cardiac fibrillation and arrest may occur if a patient encounters an excess of accumulated small currents while connected to the ground through implanted electronic devices or by contact with other grounded objects, such as electrocardiograph (ECG) leads. Faulty electrical equipment may cause a short circuit or electric shock or can cause severe sparks that may be a source of ignition. The following safeguards should be used when working with electrical equipment:[8]

- Particular care should be used when operating high-voltage equipment such as x-ray machines, ESUs, lasers, and electronic monitoring devices. These machines should be checked for frayed or broken power cords, properly functioning power switches, and grounding.
- Power cables should not be stretched taut or across traffic lanes.
- Liquids should never be placed on an electrical unit. A spill could cause an internal short circuit.
- Electrosurgical and laser units may interfere with the operation of other equipment. Therefore they should be located on the operator's side of the table and as far as possible from the monitoring equipment. Preferably these units are plugged into separate circuits to avoid overloading power lines. They should not be plugged into extension cords.
- Equipment should be properly grounded to prevent small extraneous current leaks.
- Machines should be turned off when plugging or unplugging them from the power receptacle and when attaching cords to the machine.
- Power cords should be unplugged by pulling on the plugs, never the cords; this prevents breakage of wires.
- All electrical equipment, including a surgeon's personal property, should be inspected by the biomedical engineering department before its initial use. Every piece must meet Underwriters Laboratory (UL) standards or other electrical safety requirements. All equipment should be inspected, preferably monthly but at least quarterly, and verified as safe for use. Equipment should be used according to the manufacturer's instructions.

Electrical and Thermal Burns

Monitors and all high-powered equipment are hazardous. Electrical energy is converted into thermal energy, and therefore the electricity supplied by a defective system may cause burns. The amount of heat produced depends on current density, contact time, and tissue resistance. As little as 300 mA of current for

20 seconds can produce enough heat (113° F [45° C]) to burn intact skin. Current that is concentrated or has a high density at the point of contact can result in an electrical burn severe enough to require debridement.

ESUs generate high-frequency current. In these units current flows to an active electrode that is used to cut or coagulate tissue. The use of a dispersive electrode (also known as a return electrode or Bovie pad) protects the patient. This provides the high-frequency current present at the active electrode with a low-current density pathway back to the generator. This is not the same as a ground. Proper connections from the dispersive electrode to the patient and the unit are essential to prevent burns. Deep-tissue burns can occur at the site of a dispersive electrode if it does not have adequate surface contact with skin or body tissue. Burns also can occur at the site of rings, piercings, or other metal jewelry, ECG electrodes, or other low-resistance points from invasive monitor probes (e.g., temperature probes) if the current diverts to an alternative path.

Conductive surfaces should be capable of providing a return path for current other than through the OR bed or its attachments. If the return circuit of high-frequency equipment is faulty, the circuit may be completed through inadvertent contact with metal parts or attachments of the OR bed. If the pathway for the current is small, the current passing through the exposed area of skin contact will be relatively intense, causing a deep burn to the patient. For example, one such contact point may be the thigh touching the leg stirrup when the patient is in the lithotomy position.

Surface burns can occur when battery-operated equipment, such as a peripheral nerve stimulator, is used with external electrodes. Tetanic stimuli should be limited to 1 or 2 seconds. Handheld battery-operated cautery pencils can cause pinpoint burns when the tip remains hot after use. The heat from this tip can cause ignition to drapes or dry sponges.

Other potential sources of burns include malfunctioning controls on heat-generating devices that are in contact with the patient, such as radiofrequency diathermy or hypothermia/hyperthermia machines. Individual reactions to electrical hazards are influenced by factors such as the patient's nutritional state, the amount of body fat that acts as insulation, and the circulation in the body part in contact with the device.

Static Electricity

Static electricity consists of current of high voltage and low ampere. An electrostatic spark develops from friction and accumulates on physical objects. When two static-bearing objects come into contact, the one bearing the higher potential discharges to the one with the lower potential. Air is a nonconductor, but a high enough potential can overcome air resistance and jump the gap to a lower potential object. This causes an arc across air gaps, which are seen as spark(s) from the heat thus generated. These sparks can ignite flammable materials or gases.

Objects accumulate static in inverse proportion to their conductivity. A spark between two objects can occur only when an electrical path of good conductivity does not exist between them. Because earth has a zero potential, a charge is discharged to the ground if it is brought into contact with earth directly or indirectly through a conductor. The aim is to provide adequate channels for the dissipation of static. Moderate conductivity has a tendency for the gradual spread of charge over both objects so they come to the same potential. The generation of static electricity cannot be prevented absolutely because its intrinsic origins are present at every interface. For static electricity to be a source of ignition, the following situations must be present:

- An effective means of static generation
- A means of accumulating the separate charges and maintaining a suitable difference of electrical potential
- A discharge of energy adequate to make a spark in an ignitable mixture

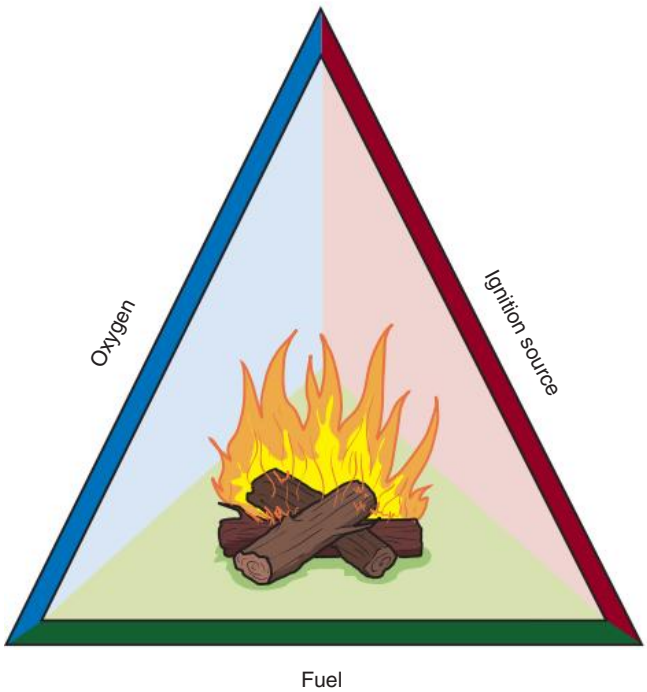
Fire and Explosion

Fire should be a matter of prime concern in the OR. Fires in an oxygen-enriched atmosphere (OEA) are fundamentally different in character from those occurring in a normal atmosphere. The fire severity potential should be regarded as serious, with the potential for extensive damage and endangerment to lives of patients and personnel. The presence of flammable and combustible liquids, vapors, and gases in an OEA can result in the ultrarapid combustion of surrounding materials with explosive violence (Fig. 13.9).

Anesthesia providers have discontinued the use of highly flammable anesthetic agents (e.g., cyclopropane, ether) in favor of halogenated agents. These noncombustible agents are mixed with medical air, oxygen, or nitrous oxide.

The literature reports an additional, unexpected potential source of a combustible material. Critically ill patients brought to the OR from an intensive care unit in beds with powered dynamic air mattresses are sometimes surgically treated in their bed while in the OR. The mattress is electrically powered to maintain an alternating pressure surface during the procedure. Occasionally, a tracheotomy or another invasive procedure is performed. The possibility of a puncture in the air mattress could release air under the drapes, causing a fire in the presence of a spark.[9]

Although oxygen and nitrous oxide are nonflammable gases, they do support and accelerate combustion.[10] A fire or explosion



• **Fig. 13.9** Fire triangle.

is the result of a combination of these factors, known as the **fire triangle**:

- ***Fuel:*** A flammable gas, vapor, or liquid (e.g., ethylene oxide, alcohol, ether, methane from the bowel, collodion). Dry sponges are flammable. Alcohol-based prep solutions can ignite if not permitted to dry before draping.
- ***Ignition:*** A source of ignition (e.g., laser, electrosurgery, fiberoptic light cord)
- ***Oxidizer:*** Oxygen (pure or in medical air with greater than 21% oxygen) or some other substance that provides oxygen, such as nitrous oxide gas or medical air. Oxygen can build up under the drapes and cause ignition when the cautery is used.

Safeguards

Standards of the NFPA and AAMI are evaluated by TJC to safeguard against fire and explosion in anesthetizing locations. Requirements are less stringent when only nonflammable inhalation agents are used. For example, nonconductive flooring and footwear are acceptable when a nonexplosive anesthetic is used. The factors that can cause fire should be controlled.

Flammable Agents

Spontaneous combustion can occur when flammable or combustible agents are exposed to an ignition source in the presence of oxygen. The following safeguards help prevent spontaneous combustion:

- Anesthesia machines, cylinders of compressed gas, and flammable liquid containers should be kept away from any source of heat and must not touch one another. A mixture of gases under high pressure is hazardous.
- Oil or grease is not used on oxygen valves or on parts of anesthesia machines. Oil or grease should not contact any cylinders, including those containing ethylene oxide, compressed air, or nitrogen.
- Flammable antiseptics containing alcohol and fat solvents are used with care for preoperative skin preparation before laser or electrosurgery. Vapors under drapes or pooled material on or around the skin can ignite if the prep solution is not completely dry before draping. Common pooling areas include the umbilicus and the sternal notch. The patient's hair should be coated with a water-soluble gel to decrease the risk for fire.
- Petroleum products used on the skin can ignite in the presence of an ESU or laser. Water-soluble jelly can be used to coat eyebrows and lashes to render them less likely to ignite.
- Bowel gases (methane) are flammable. The rectum should be packed with a moist radiopaque sponge before using an ESU or laser near the perineum.
- Other flammables include collodion, benzoin, paraffin, and white wax (bone wax).

Ignition Sources

The minimum ignition temperatures of combustible materials in an OEA are lower than in air.

The following list contains precautions to use when working with combustible materials:

1. Thermal devices and other heated objects can cause a fire or explosion.
   a. Precautions should be taken to prevent a laser beam, either directly or indirectly, igniting drapes, sponges, and gowns or melting an endotracheal tube. Place damp towels around the surgical site when using a carbon dioxide laser.
   b. Electrosurgical units should not be used on the neck, trachea, nasopharynx, and adjacent areas. Oxygen can cause a fire if the endotracheal tube is ignited or leaks into the field. Avoid using pieces of red rubber catheter as electrode insulation.
   c. Inadvertent activation of laser and ESUs should be avoided. When not in use, handpieces should be placed in a holder on the sterile field, not left loose. Handpieces are hot after activation. Laser units should be on standby or turned off as appropriate.
   d. Beams from fiberoptic light carriers should not be directed onto a drape. Heat can build up until sufficient to produce burning or smoldering.
   e. Lights and sources of heat should be kept at least 4 ft (more than 1 m) away from the anesthesia machine and cylinders.
   f. Heat-generating equipment, such as the operating microscope and the projection lamp for fiberoptic lighting, must not be completely enclosed. Heat can build up under the covering.
   g. The hypothermia/hyperthermia machine should be at least 3 ft (1 m) away from the anesthesia machine, and both should be adequately grounded.
   h. Only approved photographic lighting equipment with suitable enclosures can be used. Strobe lamps are preferred.
   i. High-speed burrs and drills create extreme heat and can cause ignition.
2. An electrostatic (incendiary) spark can be an ignition source.
   a. The relative humidity (weight of water vapor present) in the perioperative environment should be maintained between 50% and 60%. Moisture provides a relatively conductive medium, allowing static electricity to leak to earth as fast as it is generated. Sparks form more readily in low humidity.
   b. Explosion-proof electrical receptacles or locking Hubble plugs cannot be pulled apart accidentally. Grounding adapter plugs, multiple-outlet plugs, and extension cords are prohibited.
   c. Power cords should be rubber coated, and switches should be explosion-proof. Electrical equipment should be plugged into the power receptacle before the anesthetic is administered and before the power switch is turned on.
   d. Motion should be minimal in the area around the anesthesia equipment and the patient's head. Friction on the reservoir bag should be avoided. Team members should watch that drapes do not touch the bag or cover the anesthesia machine.
   e. Patients are covered with cotton blankets. Woolen or synthetic blankets are prone to producing static electricity.
   f. The hair of patients, personnel, and visitors is covered to avoid static discharge.
   g. Antistatic outer garments are worn. Hose and undergarments in close contact with the skin may be made of synthetic material.
   h. Antistatic liners in kick buckets are handled with caution.
   i. Metals should not make contact with a force sufficient to produce percussion sparks.
   j. Anesthesia is discontinued as soon as possible if the ground monitoring system indicates a warning. After completion of the surgical procedure the room is not used until the electrical defect is corrected.

Fire Safety

All health care facilities have fire warning and safety systems. Staff members should be familiar with the location and operation of

fire alarms and fire extinguishers as well as with evacuation routes and procedures. Fire drills should be scheduled routinely and be part of competency testing. Personnel should know the uses of fire extinguishers, be able to distinguish among the three main classes of them, and know how to operate them:

- *Class A* (pressurized water for combustibles such as paper, cloth, wood). A picture of a trashcan or campfire may be on the side. The "A" is imprinted within a triangle.
- *Class B* (carbon dioxide or dry chemical to smother flammable liquids, oil, gas). A picture of a gas can may be on the side. The "B" is imprinted inside a square. A number may precede the B. This number represents the distance in feet the spray will reach.
- *Class C* (halon [bromochlorodifluoromethane halogenated compressed gas] to smother an electrical or laser fire without leaving a residue on equipment). A picture of an electrical plug may appear on the side. The "C" is imprinted in a circle.

When a fire extinguisher is used, the mnemonic **PASS** may aid in remembering how to operate the device:

Pull the safety ring out of the handle.
Aim the nozzle.
Squeeze the handle.
Sweep the spray over the base of the fire.

If fire should occur in the OR during a surgical procedure, the first concern is for the safety of the patient and personnel. To prevent an explosion, the burning article is removed immediately from the proximity of the oxygen source and the anesthesia machine or outlet of piped-in gases. The fire on the field is smothered with wet towels, and burning drapes are removed from the patient. The shut-off valves for piped-in gases are turned off and electrical power cords are unplugged.

The mnemonic **RACE** may aid in preventing panic and should enable the team to act quickly in the event of fire anywhere within the perioperative environment:

Rescue anyone who is in immediate danger.
Activate the fire alarm.
Contain the fire if possible.
Evacuate the area. (Some facilities use the term *Extinguish.*)

The patient should be removed immediately from any danger, and the fire should be extinguished in the room, if possible. The anesthetized patient is evacuated on the OR bed to a distant location on the same floor. Lateral evacuation is when the team movement from the fire is creating a distance from danger on the same floor. Anesthesia personnel should be assisted with life-support equipment, such as breathing bags (Ambu bags) and tubing. Keep in mind that oxygen will support the fire.

Pack the surgical site with saline-moistened lap tapes, and cover with a sterile towel or drape. Although attempts are made to prevent infection, this is a secondary thought to the loss of life. All fires, no matter how small, must be reported to the facilities risk management department. Team members should refer to the departmental policy and procedure manual for evacuation and safety protocols specific to the facility.

Fires within the patient's body are usually small, but deadly. The most common type is an endotracheal fire. The cause is usually laser or ESU contact with a flammable endotracheal tube. In the event of an endotracheal fire, immediately withdraw the burning tube and pinch the nose and mouth shut to extinguish the fire (this removes the fuel and oxygen). Flush the airway with sterile saline if necessary, but have the suction immediately available. The anesthesia provider must immediately reintubate with a smaller, uncuffed tube and reoxygenate the patient. A cuffed tube would increase pressure on the damaged tissue.

Chemical Hazards and Safeguards

Health care providers are exposed to many hazardous chemicals daily. The hazards of these chemicals include irritation of the eyes or mucous membranes, contact dermatitis or burns, toxicity that causes renal or liver disease, and exposure to carcinogens or mutagens. These or other effects may be immediate, delayed, or chronic. Hazardous chemicals in the workplace are controlled by government regulations, such as those of OSHA and the EPA in the United States or those of the Control of Substances Hazardous to Health (COSHH) in Great Britain.

Chemicals should be labeled by the manufacturer with the identity of the agent(s) and appropriate warnings of hazards. The latter may be symbolic; that is, pictures added to words. Labels must not be removed or defaced. Employees should read the labels and understand procedures for safe handling and use. OSHA has incorporated right-to-know regulations in its standards. One part of this Hazard Communication Standard requires that employees have access to the material safety data sheet (SDS) supplied by the manufacturer for each hazardous chemical in the workplace. An SDS specifies the following information:

- Composition and common names of the chemical
- Chemical and physical properties
- Known acute and chronic health effects, such as carcinogenic, mutagenic, or allergenic
- Exposure limits
- Protective measures
- Antidote or first-aid measures

OSHA standards are legally enforceable. Although not legally enforceable, NIOSH and ACGIH recommendations for exposure limits to hazardous gases and vapors in ambient air should be adopted for the safety of personnel.

Anesthetic Gases

Air conditioning or ventilating systems help prevent pockets of anesthetic gases in the OR, although concentrations around the anesthesia machine and the patient's head may not be remarkably reduced. Substantial amounts of gases can escape during surgical procedures. The patient's exhalations also can pollute the air in the OR and the postanesthesia care unit (PACU). Heavy gas can accumulate and channel along the floor as far as 50 ft (15 m). Confining agents by using a closed carbon dioxide absorption technique tends to restrict gases from getting into airstreams.

Waste anesthetic gases are gases and vapors that escape from the anesthesia machine and its hoses and connections, from around the facemask on the patient, and from the patient's expirations. Although not conclusive, data indicate that personnel may incur health hazards if chronically exposed to waste anesthetic gas. Stress, long working hours, and other unknown related factors may contribute to this occupational risk. Possible health hazards include the risk for spontaneous abortion, congenital abnormalities in the offspring of male and female personnel, cancer, and hepatic and renal disease. Significant behavioral changes have been observed and include decreased perception, cognition, and manual dexterity. Personnel also may complain of fatigue or headache.

Studies of the retention of anesthetic agents in anesthesia providers after the administration of clinical anesthesia have demonstrated traces of gas in expired air for varying lengths of time—from 7 hours after nitrous oxide administration to 64 hours after halothane administration. It has been shown that high doses of nitrous oxide block the metabolism of vitamin B_{12}. Chronic exposure to trace levels of nitrous oxide may also lead to neurologic problems or neuropathy.

Because millions of inhalation anesthetics are administered annually, a substantial number of OR staff are occupationally exposed to these gases. OSHA enforces the NIOSH recommendations that room air not be contaminated by more than 0.5 parts per million (ppm) of halogenated agents per hour when used in combination with nitrous oxide or more than 2 ppm/hr when used alone. Nitrous oxide should be controlled to less than 25 ppm during an 8-hour time-weighted exposure.

The use of scavenging equipment and procedures is strongly recommended. Scavenging involves the removal of waste anesthetic gases, mainly by trapping them at the site of overflow on the breathing circuit; this is followed by disposal to the outside atmosphere, where the gases are safely diluted. The rate of removal of gases by the disposal system depends on the rate at which fresh air enters the OR and the patterns taken by air currents as they circulate through the room.

The proper use of vacuum scavenging equipment attached to the anesthesia machine can reduce exposure to trace concentrations of gas by 90% to 95%. Personnel exposure should be reduced to the lowest practicable limits by reducing waste gas to the most technically feasible level. Waste gas is vacuumed with a purple hose connected to the rear of the anesthesia machine. When setting up the room for the day, make sure that the hose is connected. A waste-gas control program to ensure the continuing purity of environmental air includes the following measures:

1. Good work practices of anesthesia providers. The major source of waste gas in the OR is the intentional outflow of gases from the anesthesia breathing system. The quantity of gases discharged varies depending on the type of breathing system, the gas flow rate, and gas concentration.
2. Use of a well-designed, well-maintained scavenging system. Inexpensive, practical, and effective exhaust systems are available. The gas evacuation system should be attached to every anesthesia machine and ventilator to scavenge excess gases directly into a vacuum line with a minimum flow rate of 440 ppm.
3. Use of proper anesthesia technique:
   a. Different techniques of administration result in different exposure levels. Some leakage is uncontrollable.
   b. All components of the breathing system should fit well. Masks should fit facial contours to ensure a good seal. An oral or nasal airway may reduce the escape of gas from around the mask.
   c. Liquid halogenated agents should not be spilled. The gas flow should not be turned on until the mask is in place or the patient is intubated and the endotracheal tube is connected to the breathing circuit.
   d. Masks, tubing, reservoir bags, and endotracheal tubes should be inspected after each cleaning for leaks, holes, and abnormalities. Disposable equipment is preferable to recycled equipment.
4. Proper maintenance of anesthesia equipment through the following measures:
   a. Daily routine checking of anesthesia machines for leaks. NIOSH recommends that the total leak rate of each machine not exceed 100 mL/min at 30 cm of water pressure. Leaks can be detected with a gas analyzer or bubble test.
   b. Periodic preventive maintenance of all machines and fittings by a manufacturer's representative every 6 months, with in-house monitoring at least quarterly.
5. Maintenance of a high flow rate of fresh air into the air conditioning system through engineering control procedures. A good ventilating system (preferably not a recirculating one) is also important in the PACU. The ventilation system should comply with the minimum requirements of 20 air changes per hour to minimize the risk to PACU personnel.
6. Use of an OR atmospheric monitoring program to record trace anesthetic levels and determine the effectiveness of the previous measures. Specialized monitoring equipment, such as an infrared analyzer, is the only way to detect leaks. Dosimeters are available for each individual to wear to indicate exposure.

Sterilizing Agents

The chemical agents used to sterilize heat-sensitive items can be toxic or can vaporize to emit noxious fumes that are irritating to the eyes and nasal passages, even at low levels of exposure.

Ethylene Oxide

Ethylene oxide (EO) is used in a gaseous form for sterilization and is a known mutagen and carcinogen. The residual products can be toxic if there is direct contact with the skin or the gas is inhaled. Exposure can cause dizziness, nausea, and vomiting. Ethylene glycol and ethylene chlorohydrin are by-products of a reaction with moisture, such as on the hands. All porous items sterilized with EO should be aerated to dissipate the gas. The PELs for EO are 5 ppm for a short-term exposure of 15 minutes and 1 ppm time-weighted average (TWA) over 8 hours.

Formaldehyde

Formaldehyde may be used in a gaseous or liquid form. The vapors are toxic to the respiratory tract. Formaldehyde is a potent allergen, mutagen, and carcinogen, and it can cause liver toxicity. The PEL is 1 ppm TWA (NIOSH recommendation) to 3 ppm TWA (OSHA standard) over 8 hours.

Glutaraldehyde

Glutaraldehyde is the least toxic of the three sterilizing agents, but the fumes from the liquid form may be irritating to the eyes, nose, and throat. Contact dermatitis and hives have been reported. The PEL is 0.2 ppm per exposure. Glutaraldehyde should be used only in a closed container and in a well-ventilated area. PPE should be worn. A dosimeter is available to determine the airborne concentration of fumes.

Disinfectants

Some of the disinfectants used to clean or decontaminate equipment and furniture can be irritating to the skin and eyes. Gloves and goggles should be worn when using these chemicals, and the agents should be used in proper dilution. The fumes from some agents can irritate the nasal passages. The following substances can cause gloves to degrade:

- Isopropyl alcohol
- Phenol
- Sodium hypochlorite

- Glutaraldehyde
- Hydrogen peroxide
- Quaternary amines
- Povidone iodine

More information on sterilizing agents can be found in Chapter 18.

Methyl Methacrylate

Commonly referred to as *bone cement,* polymethylmethacrylate (PMMA) is a mixture of liquid and powder polymers. Some brands are mixed with antibiotic powder, and it is important to double check patient allergies before use. It should be mixed at the sterile field just before use. The vapors released during mixing are irritating to the eyes and can damage gas-permeable contact lenses. The monomer vapors are also irritating to the respiratory tract, and they can cause drowsiness. The fumes are flammable. PMMA mixing devices with vacuum attachments are commercially available.

Patients may experience adverse reactions during or immediately after the placement of PMMA. The patient can become hypotensive within a few moments of use and continue a hypotensive state for up to 5 minutes. The FDA reports that some asystolic events have occurred. Continuous monitoring is critical for the well-being of the patient.

PMMA may be a mutagen, a carcinogen, or toxic to the liver. The liquid solvent can cause corneal burns if it splashes into the eyes. It also can diffuse through latex gloves to cause an allergic dermatitis; gloves that are impermeable to this solvent are available. Gloves should be changed after handling the doughy mixture. PMMA has an exothermic effect. A scavenging system should be used to collect the vapors during mixing and to exhaust it to the outside air or absorb it through activated charcoal. The PEL for methyl methacrylate has been established at 100 ppm TWA. PMMA is considered a hazardous waste and must be disposed of according to facility and government policies.

Drugs and Other Chemicals

Antineoplastic cytotoxic drugs used for chemotherapy can be hazardous, as can laser dyes and other pharmaceuticals. All chemical agents should be prepared and administered to minimize unnecessary exposures for both patients and personnel. Chemicals should be combined or mixed with diluents only when this is known to be a safe practice, as specified by the manufacturer.

Intraperitoneal chemotherapy can be administered in the OR during laparotomy. The surgeon can use the Coliseum technique in which the chemical is introduced via a Tenckhoff catheter and a roller pump with a heat exchanger set at 111.2° F (44° C). The solution remains in the patient's abdomen for 90 minutes. The surgeon, wearing two sets of sterile gloves, continually manipulates the intraabdominal organs to evenly distribute the heated chemical as it continually circulates through the cavity and is removed through several abdominal drains. The air is continually filtered through activated charcoal and a smoke evacuator to protect the OR environment from aerosolization of the drug.

Safe Handling of Cytotoxic Agents

Antineoplastic cytotoxic agents have carcinogenic and mutagenic properties, and most can cause local and/or allergic reactions. Personnel should avoid inadvertent direct contact with skin or eyes, inhalation, and ingestion during handling.

Written precautions and procedures for handling, preparing, administering, and disposing of cytotoxic agents should be followed. Basic guidelines for the use of cytotoxic agents include the following:

1. Protect self from skin and respiratory contact. Preferably, prepare agents under a vertical laminar flow hood. Whether or not a containment hood is available, wear thick gloves, a mask, eye protection, and a gown.
2. Wash hands after handling cytotoxic agents and all items that have been in contact with them, including those used for administration.
3. Place all cytotoxic waste in sealed leakproof bags or containers. Incineration is recommended for all materials used in preparing and administering cytotoxic agents.

Biologic Hazards and Safeguards

The transmission of infection and disease within the health care facility is a concern of both consumers and providers. Biologic hazards do exist in the environment, and every effort should be made by health care providers to protect their patients and themselves. Standard precautions are a necessity (i.e., treating all body fluids and materials as infectious). Employers must ensure that the appropriate protective equipment is available and that employees are trained to wear and use it.

Surfaces such as door handles and computer keyboards have been found to harbor active vancomycin-resistant *Enterococcus* (vancomycin-resistant *Enterococcus* [VRE]), methicillin-resistant *Staphylococcus aureus* (MRSA), and *Pseudomonas aeruginosa* for prolonged periods. Endospore-forming clostridia (i.e., *Clostridium difficile* [*C. diff*]) can persist for months.

Simple handwashing is becoming less effective in adequately removing these microorganisms. Antiseptic gel hand hygiene is recommended. Cleaning contaminated surfaces such as computer keyboards may be unreliable because these surfaces were not designed for exposure to disinfectant solutions. Some chemicals and solutions can damage the equipment. The surface of the keyboard can be covered with a plastic cover that is easier to clean.

Infectious Waste

Infectious medical waste is an environmental concern both within and outside the health care facility. The EPA defines infectious waste as waste-containing pathogens with enough virulence and quantity that exposure to them could result in an infectious disease in a susceptible host. The disposal of potentially infectious waste generated in health care facilities is regulated by governmental mandates. Although regulated medical waste refers to the portion of waste that has the potential to transmit infectious disease, a uniform definition of what constitutes regulated medical waste has not been universally adopted. Consider the following factors when deciding if something is infectious waste:

- The presence of pathogenic organisms in sufficient numbers to be capable of causing infection in living beings. Many microorganisms are incapable of causing infection.
- The presence of a portal of entry into a susceptible host. A cut, needlestick, puncture wound, or skin lesion provides a portal of entry, but not all living beings are susceptible hosts to infectious diseases.

These two factors permit the regulation of medical waste that poses a risk to public health and the environment and creates aesthetic concerns for the public. Potentially infectious waste is considered to be blood and blood products, pathologic waste, microbiologic waste, and contaminated sharps. This includes items contaminated by blood, such as sponges, drapes, gowns, and gloves. These items should be segregated from general waste, such as wrappers.

Infectious waste is placed in leakproof containers or bags strong enough to maintain integrity during transport. These bags should be closed and either labeled or color coded. For example, red bags may be used to indicate infectious waste. Needles and sharps should be put in puncture-resistant containers. If the outside of the container is contaminated, double-bagging is necessary for safe handling during transport to the disposal area. Waste can be steam sterilized or decontaminated with microwaves before compaction and disposal in a landfill, or it can be incinerated. Federal, state, and local regulations should be followed for disposal.

Biohazards

All patients are potential sources of infection. OSHA defines occupational exposure as reasonably anticipated skin, eye, mucous membrane, or parenteral contact with blood or other potentially infectious materials during the course of duty. This contact includes blood, tissues and organs, and all body fluids. Careful handling of and adequate protection from potentially contaminated equipment also are important. Personnel, such as radiologists who handle tissue as part of the diagnostic process, are at risk not only from biologic exposure, but from marker wires used in needle localization. Handwashing is a must after every patient contact or glove removal. Personal exposure should be a concern of all team members.

To be in compliance with OSHA standards, every health care facility must develop a written exposure control plan that includes procedures for evaluating an incident and determining when exposure has occurred. Engineering controls include safety devices or equipment designed to minimize or eliminate a biohazard. Likewise, restrictions or changes in work practices should ensure the safety of all patients and personnel in the environment. For example, food must not be stored in the same refrigerator as blood products or specimens. Eating, drinking, and applying lip balm are prohibited in areas where contact with blood or other potentially hazardous material is possible. Eating or drinking should never be allowed at any time in the OR during a surgical procedure.

Punctures and Needlesticks

A penetrating injury (e.g., needlestick, cut) or a splash (e.g., into the eye, onto mucous membranes) with fluid contaminated with blood or body fluids must not be ignored. Hepatitis, human immunodeficiency virus (HIV), and other bloodborne pathogens can be transmitted through breaks in the skin or contact with mucous membranes. The hepatitis B vaccine is recommended for all high-risk health care workers.

If exposure to blood or body fluid occurs, the following procedures should be performed:

1. Stop activity immediately and step back from the point of contamination. Remove glove.
2. Squeeze the skin around the needlestick or cut to expel blood and contaminants.
3. Cleanse the puncture site or flush the eye with cool water. Flush cut or puncture with alcohol or iodine preparation. Continue to squeeze blood until coagulation takes place.
4. Report the incident according to facility policy and procedure and seek medical attention promptly. Baseline blood may be drawn from the patient and injured person for determination of risk for transmission of disease. The patient should be informed.
5. Follow the particular protocol established by the facility for follow-up.

If a needlestick is involved, most facilities will draw a baseline blood sample from the patient and the injured caregiver. Periodic blood samples are drawn over a period of months to make sure results remain clear. Caregivers who have been contaminated by a high-risk patient or a patient known to have hepatitis B or to be positive for HIV should be prophylactically treated with the appropriate drugs and followed by the employee health department. Additional information about postexposure prophylaxis and guidelines for treatment can be found at www.cdc.gov.[b]

Surgical Plume

Plume (surgical smoke) is generated by the thermal destruction of tissue or bone. Bloodborne pathogens, mutagens, carcinogens, and other toxic substances can be aerosolized by lasers, electrosurgery, and powered surgical instruments.[10] Twenty air exchanges with four fresh, clean air duct filters, and positive room pressure help minimize buildup of plume in the OR atmosphere. Masks capable of filtering particles at least as small as 0.1 mm (high filtration) are recommended to prevent inhalation of plume particulate. Face shields, goggles, or eyeglasses with side shields should be worn to protect the eyes.

A smoke evacuator should be used to suction laser and electrosurgical plumes. The evacuator has a filtration system that incorporates a prefilter to trap particles, an ultralow penetrating air filter for particles in the 0.1-mm range, and a charcoal filter to absorb odor and hydrocarbons. The vacuum nozzle should be held close to the surgical site. Wall suction only filters 5 ft^3 per minute and is not recommended for large volumes of smoke evacuation. An inline filter is necessary to avoid clogging the department vacuum system.

OR personnel can change the filters in some evacuators, whereas others require maintenance by a biomedical technician. Filters are contaminated with biohazardous material and should be disposed of in the same manner as items contaminated with blood and body fluids. Complete PPE, such as gloves, masks, and protective eyewear, should be worn when changing filters because the connecting couplers have been contaminated with plume and the material may be released into the air when the connection is disengaged.[11]

Reproductive Hazards

Male Reproductive Health Implications

Chemical, radiologic, and physical exposures can cause abnormalities in sperm numbers, shapes, and motility. The reaction experienced by an individual will depend on the agent, duration of exposure, and other health status considerations. Chemicals such as ethylene varieties can accumulate in the epididymis,

[b]CDC website: Guidelines for HIV prophylaxis after occupational exposure.

seminal vesicles, or prostate, causing decreased sperm production and decreased ability to fertilize an ovum.

Some chemicals can affect a man's ability to perform sexually because of impotence or decreased libido. Chromosomal DNA can be affected, because sperm are produced every 72 days and are stored in the epididymis for 15 to 25 days, where they mature and begin to swim. These changes can cause fetal abnormality if fertilization takes place.

According to NORA, more than 1000 workplace chemicals can cause reproductive effects in animals. Many chemicals have never been tested and also may be implicated in birth defects. Additional information is available at www.cdc.gov

Female Reproductive Health Implications

Excessive exposure to ionizing radiation, waste anesthetic gases, and ethylene oxide during pregnancy may cause a spontaneous abortion or a congenital fetal anomaly. Pregnant employees may be more susceptible to fatigue from standing for prolonged periods, lifting heavy items, and eating and taking breaks at irregular intervals. Exposure to infectious diseases also is a hazard. The health care facility should have a policy for pregnant employees, which may include transferring a pregnant employee from a hazardous area such as the OR. For the safety of the fetus, assignments should limit exposures whenever possible. For example, a pregnant woman should not assist with the implantation of radioactive elements.

An employee who is pregnant is responsible for her own welfare and the safety of her fetus. Immunizations should be current, especially for hepatitis B and rubella, and she should follow the safeguards described in this chapter to limit her exposures to the lowest possible levels. Ultimately the employee should decide whether she wishes to continue working in the perioperative environment.

Latex Sensitivity/Allergy

Many items used in the OR, such as surgical gloves, catheters, drains, medication vial stoppers, tubing, anesthesia breathing circuits, endotracheal tubes, breathing bags, and syringe plungers, contain natural rubber latex (Table 13.1). Some synthetic products are referred to as latex but do not contain the protein that causes reaction. Natural rubber latex is manufactured from the milky sap obtained from rubber trees *(Hevea brasiliensis)*. A water-soluble protein in natural latex contains an antigen that can cause a fatal allergic response.

Two types of responses have been identified: local and systemic.[12] Local reactions are less severe and occur when latex comes into contact with the skin, causing skin rash, itching (**urticaria**), redness, and burning that usually subside within 24 hours.

A patient may have a systemic reaction when a latex product comes into contact with the mucous membranes, serosa, or peritoneum during a surgical procedure. This reaction is more severe, causing anaphylactic shock or death.[12] The signs of severe **anaphylaxis** are hypotension, tachycardia, bronchospasm, and generalized erythema.[12] Treatment of choice is adrenaline and IV fluids, either crystalloid or colloid, to manage hypotension associated with anaphylaxis.

FDA studies have shown that 6% to 7% of direct patient care personnel and surgeons are sensitive to natural rubber latex. Health care personnel who are frequently exposed to latex products can become sensitized. Several items used in the OR contain latex but are not identified as having natural rubber latex as its content (e.g., the elastic bands on caps and shoe covers or mattress and pillow covers). The manufacturer should be consulted to determine whether a product in use contains latex and whether a latex-free substitute is available.

Latex proteins can contaminate the starch on prepowdered gloves, thus providing a potential route of airborne exposure to allergens during donning. Sterile surgical nonlatex gloves are available commercially but are more expensive. They should be used only when an allergy is confirmed or is highly suspected in the user or in a patient receiving care.

Testing procedures are available for the detection of a latex allergy. Testing all personnel and patients would be a costly endeavor, but testing people suspected of having a latex sensitivity should be considered. According to the CDC, 8% to 12% of all health care personnel are sensitive, compared with 1% to 6% of the general population. Patients should be asked preoperatively if they have a known sensitivity (i.e., a history of a reaction after handling a toy balloon or wearing rubber gloves). Children with spina bifida, people with constant latex exposure, and those with multiple allergies are known to be prone to latex allergy. Allergies to certain foods, such as avocados, potatoes, bananas, tomatoes, chestnuts, kiwifruit, and papaya, may be implicated in natural latex allergies per NIOSH.

Risk Management

The perioperative environment is a high-risk environment. The risks can be minimized by adhering to the many safeguards discussed in this chapter. An effective risk management program continually seeks to provide working conditions that will not jeopardize the health and safety of employees. Such a program has at least four essential elements:

1. Administration
   a. Regulations, recommendations, guidelines, and laws should be enforced to prevent disastrous consequences of occupational hazards.
   b. Policies and procedures should be written, reviewed periodically, and updated as appropriate. All employees should have access to them.
   c. Protective attire and safety equipment should be made available to employees, as appropriate.
   d. Monitoring devices should be used in all hazardous locations as recommended by regulatory agencies.
   e. Employee health services should be provided for immunizations and in the event of injury.
2. Prevention
   a. Regular inservice programs should be conducted to keep employees informed about hazards and safeguards.
   b. Employees should be taught how to use and care for new equipment before it is put into service.
   c. Employees must know the location and use of emergency equipment, such as fire extinguishers and shutoff valves.
   d. Employees must wear protective attire, as appropriate.
   e. Routine preventive maintenance should be provided for all potentially hazardous equipment.
3. Correction
   a. Faulty or malfunctioning equipment should be taken out of service immediately.
   b. Any injury should be reported, with medical attention sought as soon as possible.
   c. Unsafe conditions should be reported.

TABLE 13.1 Care of the Latex-Sensitive Patient

Commonly Used Latex Products	Latex-Free Alternatives	Patient Teaching	Considerations
Anesthesia breathing circuit, endotracheal tube, Ambu breathing bag	Disposable plastic breathing circuits and endotracheal tubes	NA (not applicable)	Dispose of used equipment
Bite blocks for oral surgery	Dental rolls, rolled gauze squares, silicone blocks	NA	Avoid using counted radiopaque sponges
Catheters, enema tips, and drains	Silicone catheters and drains	Instruct patient to report irritation or discomfort in area of drain or catheter	Patients rarely have silicone sensitivity; check product for content in manufacturer's enclosed literature
Electrocardiogram (ECG) leads, dispersive electrodes, pulse oximeter leads	Nonlatex gel pads	Instruct patient to report irritation at application site	Patient may have sensitivity to conductive gel; may need to use water-soluble lubricant
Elastic bandages, antiembolism stockings	White cotton bandages	Instruct patient to report any sensory changes in bandaged part, such as tingling, pain, or loss of sensation	Nonelastic bandages or stockings may restrict movement and have less expansion properties; circulation may become impaired if applied too tightly
Elastic and adhesive tape	Plastic, paper, or silk tape	Instruct patient to report irritation around or under area of tape	Some patients have sensitivity to adhesive rather than tape backing
Elastic bands on surgical caps, shoe covers, urinary catheter leg bags, plastic pants, disposable diapers	Cloth towel or paper caps with ties to cover hair; cloth hook and loop leg bands, cloth diapers	Instruct patient to report irritation around hairline or leg(s)	Cloth diapers will not be impervious to leaks; cloth hook and loop bands may impair circulation to leg
Embolectomy catheters	Silicone catheters	NA	Check composition of entire catheter and balloon
Hypothermia/hyperthermia blanket, hot water bottle, heating pad, mattress cover	Disposable plastic warming blankets and pads	Instruct patient to report irritation or discomfort	Observe for temperature control of device to avoid skin injury
Latex gloves, finger cots	Plastic or other nonlatex gloves	Instruct patient that utility gloves used at home may contain latex	Use nonlatex sterile gloves; vinyl utility gloves for nonsterile activities
Positioning devices, such as egg crate–type, donuts, wedges, rolls	Silicone rolls	NA	Silicone gel pads can be rolled around bolsters for added height
Rubber shods	Silicone catheter or plastic tubes	NA	Should be radiopaque; plastic shods are not as pliable
Syringe plungers in plastic syringes	Glass syringes	Instruct patient that plungers in plastic syringes used for self-administered injectable medications contain latex	Air-powered autoinjector device or implantable medication dispensing mechanism is an option at home
Tubing as on blood pressure cuffs and endoscopic insufflators	Disposable plastic tubing and cuff covers	NA	Wrap limb with cotton sheet wadding to avoid contact

4. Documentation
   a. Records of preemployment medical examinations and periodic examinations for the surveillance and early detection of disease should be maintained for each employee. These records should be retained in a permanent file after termination of employment in case there is a future health problem.
   b. At the time of employment, new employees may be given a letter explaining the occupational risks.
   c. Accident reports regarding injuries to personnel and patients should be filed with the administration of the facility.

The prevention of injuries is vital to maintaining a safe environment. It is everyone's responsibility.

14 Surgical Microbiology and Antimicrobial Therapy

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Differentiate between microorganisms.
- Describe the natural lines of defense of the human body.
- Identify several favorable living characteristics of microorganisms.
- Describe how disease is spread.

KEY TERMS AND DEFINITIONS

Aerobic Microorganism that requires air or the presence of oxygen for maintenance of life.

Anaerobic Microorganism that grows best in an oxygen-free environment or one that cannot tolerate oxygen (e.g., *Clostridium* species that causes gas gangrene).

Antibiotics Substances, natural or synthetic, that inhibit growth of or destroy microorganisms. Used as therapeutic agents against infectious diseases; some are selective for a specific organism; some are broad-spectrum antibiotics.

Antimicrobial agent Chemical or pharmaceutical agent that destroys or inhibits growth of microorganisms.

Biofilm Three-dimensional layers of living bacteria embedded in a sticky matrix that persists on the surface of tissues and implanted medical devices. Commonly the cause of chronic infections, such as otitis media and rhinitis.

Bioterrorism Covert event involving introduction of microbial contamination and infection of humans or animals.

Community-acquired infection (CAI) Infectious disease process that developed or was incubating before the patient entered the health care facility.

Cross-contamination Transmission of microorganisms from patient to patient and from inanimate objects to patients and vice versa.

Endospore Forms of bacterial classes clostridia and bacillus that are generated when living conditions are not favorable. Protective capsule that forms inside specific bacterial species encircles and protects the genetic matter to resist destructive forces, such as disinfection or sterilization.

Epidemiology Study of occurrence and distribution of disease; the sum of all factors controlling the presence or absence of a disease.

Florae Bacteria and fungi normally inhabiting the body, resident or transient.

Hospital or Health Care-acquired infection (HAI) An infection that was not present when the patient was admitted to the health care facility. Infection may occur at the surgical site or as a complication unrelated to the surgical site (formerly known as nosocomial infection).

Infection Invasion of the body by pathogenic microorganisms and the reaction of tissues to their presence and to toxins generated by the organisms.

Logs of bacterial growth Colonies of bacterial microorganisms grow at doubling rates exponentially (binary fission). The rate of growth is measured by the number of bacterial logs. Before the log phase begins the bacteria adapt to the environment and are in a lag phase in which they are preparing to double in number. When the environment changes in nutrients, temperature, or basic living conditions, the bacteria begin to die at the same rate they are "born" and they enter a stationary phase that precedes the final death stage.

Microorganisms Living organisms, invisible to the naked eye, including bacteria, fungi, viruses, protozoa, yeasts, and molds.

Opportunists Microorganisms that do not normally invade tissue but are capable of causing infection or disease if introduced into the body mechanically through injury, such as tetanus bacillus, or when resistance of the host may be lowered, as by human immunodeficiency virus infection. Opportunistic infection.

Pathogenic Producing or capable of producing disease.

Prion Protein that contains no genetic material and in its pathologic form causes fatal neurodegenerative disease. Difficult to

inactivate. Requires special handling. Three types of disease transmission: sporadic, familial, and iatrogenic.

Sepsis Severe toxic febrile state resulting from infection with pyogenic microorganisms, with or without associated septicemia. Septicemia is a clinical syndrome characterized by significant invasion into the bloodstream of microorganisms from a focus of infection in tissues. Microorganisms may multiply in the blood. Infection of bacterial origin carried through the bloodstream is sometimes referred to as bacteremia.

Standard Precautions Procedures followed to protect personnel from contact with blood and body fluids of all patients (formerly referred to as universal precautions).

Superinfection Secondary subsequent infection caused by a different microorganism that develops during or after antibiotic therapy.

Surgical site infection (SSI) An infectious process that develops in one or more surgical sites.

Microorganisms: Nonpathogens versus Pathogens

Specific numbers of **microorganisms** with plantlike or animallike characteristics are considered nonpathogenic in the human if they are not transferred to a different location in the body. Nonpathogenic microorganisms do not pose a particular threat to health if they remain constant in microbial numbers (logarithms: referred to as *logs* [**logs of bacterial growth**]). Natural resident **florae** can be found in the reproductive tract secretions, gastrointestinal tract, nasopharyngeal mucus, respiratory passages, and any superficial ductal opening, such as sweat and oil glands.

Resident florae have specific roles in their natural location. Some resident florae of the large intestine aid in the synthesis of vitamin K, vitamin B_{12}, and folic acid, but can cause an infection if they are relocated to a surgical incision.

The term **infection** is used when nonresident florae invade a susceptible area. The term **superinfection** is used when resident florae are out of balance and the increased number causes a **pathogenic** condition. If the count of microbial colonies increases over what is considered normal or the colonies grow in an area where they are not usually found, an infection results and the microorganisms are considered pathogenic. They can invade healthy tissue through some power of their own or can injure tissue by producing a toxin. Pathogenic microorganisms can cause **sepsis**—a severe toxic febrile state, leading to organ failure or death.[1]

In a healthy state, body fluids such as urine and cerebrospinal fluid do not normally contain microorganisms and are considered sterile. Other fluids that under normal circumstances do not contain microorganisms include blood, peritoneal fluid, synovial fluid, amniotic fluid, tears, semen, and breast milk. Because microorganisms are not visible on gross inspection, exposure to any body substance, including respiratory exhalations, should be considered contaminated and treated accordingly.

Identification of Microorganisms

Microorganisms, with the exception of viruses, have intracellular DNA. The DNA is either enclosed in a nuclear membrane (eukaryotic) or loose in the cytoplasm (prokaryotic). Bacteria and blue-green algae are the only prokaryotic microorganisms. Bacteria remain in a primitive state unchanged by evolution. All other microorganisms are eukaryotic and have changed many times on an evolutionary scale.

Specimens and cultures of tissues or body fluids may be sent to the microbiology laboratory for identification. Treatment is prescribed according to the type of microorganism present in the body. The type of substance taken from the body for testing may be a clue as to the type of microorganism.

Accurate identification of the microorganism is critical to the selection of the appropriate therapy. The following criteria are used by laboratory personnel to identify the type of microorganism:

- Cell morphology
- Mobility or motility
- Presence or absence of spores
- Native pigment
- Gram-stain reaction
- Growth factors (optimal growth conditions, speed of replication/reproduction, and how it grows in various media)
- How it colonizes (log phase)
- Antibody detection in the host
- Metabolism and atmosphere requirements
- Biochemical activity (endotoxin or exotoxin)
- Sensitivity to exogenous chemicals or substances

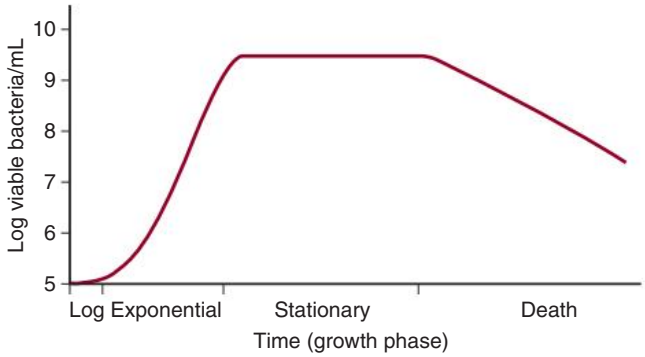
Viability of Microorganisms

Any microorganism can become a pathogen when transferred from one place to another. Each type of microorganism has its own method of duplicating itself. **Epidemiology** is the study of how microorganisms multiply and spread.

Bacteria pass through four phases during their colonization/duplication/reproductive stage:

1. *Lag phase:* The microorganism adjusts to the new environment.
2. *Log phase (logarithm, exponential) growth phase:* This is characterized by a maximum and constant rate of multiplication. If conditions are favorable, *Escherichia coli* can double in 20 minutes. *Mycobacterium tuberculosis* (tubercle bacillus) may require 5 hours.
3. *Stationary phase:* The multiplication rate and death of microbes equalize and balance. This period can last several days.
4. *Death:* The rate of microbial death exceeds the rate of multiplication. A few living cells can linger for several days or months but not at the same level as the growth phase.

The rate of bacterial growth is depicted in Fig. 14.1. The population of microbes will double during the log phase at a predictable interval referred to as *generation time* or *doubling time.* Changes in temperature, moisture, illumination, nutrients, and pH can influence the rate at which any microbe passes through



• **Fig. 14.1** Logarithmic growth of a bacterium.

doubling time. If all favorable living conditions are met, the microbe can proliferate into disease state. Bacteria secrete a slime that accumulates in layers known as **biofilm**.

Any change in the favorable conditions can alter the amount of time it takes for the microbe to pass through any one of the four phases. Box 14.1 describes the favorable living conditions associated with the proliferation of microorganisms.

The essential element in preventing pathogenic disease is to understand the microorganism's mode of transmission, life cycle, and favorable living conditions. Interference with the viability, doubling, and survival of pathogenic microorganisms can minimize the risk for infection.

Three Lines of Defense

The human body is remarkable in its ability to protect itself by intact barriers, membranes, and bacteriostatic secretions. Three lines of defense are particularly important for prevention of disease.

The first line of defense involves generalized good health and incorporates natural biochemical, mechanical, and anatomic protection through the following features:

- *Skin:* Stratified epithelium contains sweat (sudoriferous) and oil (sebaceous) glands, which are bactericidal. Natural florae inhibit each other. The epithelium must remain intact to afford protection. Desquamation and low pH impede bacterial colonization.
- *Mucous membranes:* An effective barrier when intact, these line all natural body orifices except the ears, which secrete cerumen (ear wax). Mucous membranes have bactericidal properties and a slightly acidic pH.

• BOX 14.1 Favorable Living Conditions for Microorganisms

- Can live with oxygen (aerobic) or without oxygen (anaerobic). Some require no special gaseous environment (facultative).
- Can live with or without moisture. Some can completely dry out and be reconstituted.
- Can live with or without light. Some like complete darkness.
- Can live in a neutral or alkaline pH. Most will die in an acidic environment.
- Can live with or without warmth. Some can grow in the freezer compartment of the refrigerator.
- Can get nourishment from a living host or decayed matter. Some can absorb nutrients from the environment of the host.

- *Reflexes:* Examples include vomiting, gagging, and blinking.
- *Sneezes:* Mucociliary escalator of the respiratory tree moves mucus and debris from the respiratory tract.
- *Genitourinary/reproductive tracts:* Immunoglobulin A (IgA), found in mucus, and enzymes are produced; these have a slightly acidic pH. Peristalsis is unidirectional.
- *Eyes:* Enzymes and IgA protect the conjunctiva and structures of the eye.
- *Cellular level:* Interferon is naturally formed in the cell to fight against viral attack.
- *Stomach acid:* Acid kills most pathogens.
- *Muscular closure of orifices:* Muscular closure provides a mechanical barrier against orifices such as the cervix and sphincters.

The second line of defense involves the collaborative effort of several body systems to prevent the proliferation of pathogenic microorganisms. These provide secondary protection if the microorganism breaks through the first line of defense. The second line of defense includes the following factors:

- *Inflammatory response:* This can be localized or systemic; biochemical, mechanical, and anatomic activities fight invading microorganisms and lay the groundwork for healing.
- *Antibody production:* Production is stimulated by the presence of an antigen. Some antibodies can be replicated for future exposures to the same microorganism.
- *Temperature elevation:* This can be localized or systemic. Some microorganisms are destroyed or repelled by heat.

The third line of defense can be acquired naturally or induced therapeutically. It requires actual exposure to the pathogen in some form during which temporary or quasipermanent resistance is attained. Methods include the following:

- *Passive immunity:* A "preformed" immunoglobulin (antibody) is introduced into the body. No memory for replication of the protective antibodies remains in the body.
- *Active immunity:* The body has the ability to develop a memory for production of antibodies in response to specific antigens. Live, dead, or attenuated microorganisms trigger the response. Some exposures require a booster injection to spark the memory and maintain immunity.

Pathogenic Invasion

Pathogenic microorganisms initially invade and aggregate in a body system or at a localized site, such as an abscess. The proliferation of infectious material is easily supported by warmth, chemical composition, moisture, and other components of the body.

Local spread is supported by the surface of the wound, necrosis of tissue, diminished or ineffective inflammatory response, and absence of anatomic barriers. Other pathways of infection include any body orifice, duct, or lumen of a broken blood vessel.

Veins are particularly vulnerable because they are often associated with venous sinuses and have low pressure. Venous stasis permits the growth of microbial colonies. The central nervous system shares a similar risk for infection because the cerebrospinal fluid is under lowered pressure and has components that are rich in nutrients. As microbial colonies increase in number, infection may be carried through the body in the lymphatic system and may eventually become bloodborne. Major organ systems can become involved and can result in multisystem organ failure and death. Any body fluid or substance is a potential carrier of pathogens (Box 14.2).

• BOX 14.2 Body Fluids and Substances That May Transmit Pathogens

- Amniotic fluid
- Any exudate or transudate
- Any open wound
- Aqueous humor
- Bile
- Blood
- Breast milk
- Carbon dioxide gas from deflation
- Cerebrospinal fluid
- Cerumen
- Feces
- Irrigation solution
- Nasal secretions
- Pericardial fluid
- Peritoneal fluid
- Plume from electrosurgery or laser
- Respiratory secretions and exhalations
- Saliva
- Sebum
- Semen
- Smegma
- Synovial fluid
- Tears
- Tissue
- Unfixed tissue specimen
- Urine
- Vaginal secretions
- Vitreous humor

According to the Centers for Disease Control and Prevention (CDC), 1 in 31 patients acquire one or more health care–acquired infections (HAIs). The full report can be accessed at www.cdc.gov. A **surgical site infection (SSI)** increases the length of stay and increases the cost of care.[2]

Knowledge of how the cycle of infection works is the most important element of prevention. Considerations include but are not limited to the following:

- Identifying the reservoir of the pathogen
- Identifying the portal of exit of the pathogen from the reservoir
- Identifying how pathogens are transmitted
- Identifying the portal of entry into a susceptible host
- Identifying the invasion of the susceptible host

Infectious Processes in the Body

Clinical infection is the product of the introduction, metabolic activities, and pathophysiologic effects of microorganisms in living tissue. It can develop in the surgical patient as a preoperative complication after an injury as a **community-acquired infection (CAI)** or as a postoperative complication acquired in the hospital referred to as an HAI.

A localized HAI infection may begin at the surgical site between the fourth and eighth postoperative days. Infection, usually bacterial in origin, develops as a diffuse, inflammatory process, known as *cellulitis,* and is characterized by pain, redness, and swelling. This inflammatory response is the body's second line of defense directed toward localization and containment of the infecting organism after it has passed through the first line of defense.

Red blood cells, leukocytes, and macrophages infiltrate the affected area, with pus formation (suppuration) often ensuing. An abscess forms as a result of tissue liquefaction with pus formation, supported by bacterial proteolytic enzymes that break down protein and aid in the spread of infection. Fibrinolysin, for example, an enzyme produced by hemolytic streptococcus, may dissolve fibrin and delay surgical-site healing.

The body attempts to wall off an abscess by means of a membrane that produces surrounding induration (hardened tissue) and heat. Localized pus should be drained promptly.

If localization is inadequate and does not contain the infectious process, spreading and extension occur, causing regional infection. Microorganisms and their metabolic products are carried from the primary invasion site into the lymphatic system, spreading along anatomic planes and causing lymphangitis. Failure of the lymph nodes to hold the infection results in uncontrolled cellulitis. Subsequently, regional and/or systemic infection may develop, characterized by chills, fever, and signs of toxicity.

Septic emboli may enter the circulatory system from septic thrombophlebitis of regional veins communicating with local infections. These emboli and pathogenic microorganisms in the blood seed invasive infection and abscess formation in remote tissues.[2]

Sepsis elevates the patient's metabolic rate 30% to 40% above average, imposing additional stress on the vital systems. For example, cardiac output is about 60% higher than normal resting value. The body's defenses and ability to meet the stress govern whether the infectious process progresses to systemic infection or septic shock. Multiple infection sites, the presence of shock, and inappropriate antibiotic therapy result in a poor prognosis.

Obviously the strategy to avoiding infection is prevention. However, if an infection begins, the next most important step is to identify the microorganism and treat it appropriately. More than one microorganism may be present; therefore treatment is highly individualized. Diagnosis of systemic infection may include any two of the following:

- Temperature more than 100.4° F (38° C) or less than 96.8° F (36° C) (late sign)
- Heart rate more than 90 beats/min
- Respiratory rate more than 20 to 22 breaths/min
- White blood cell count more than 12,000/mm^3 or less than 4000/mm^3

Septic shock may include decreased urinary output (less than 30 mL/hr), altered mental state, and hypoxemia. The patient usually becomes very hypotensive (low blood pressure) and has signs of blood-clotting defects, such as bruising.

The ultimate resolution of infection depends on immunologic and inflammatory responses capable of overcoming the infectious process. This is associated with drainage and removal of foreign material, including debris of bacteria and cells, lysis (breakdown) of microorganisms, resorption of pus, and sloughing of necrotic tissue. Healing then ensues.

Who Is at Risk for Exposure?

Perioperative personnel who provide direct and indirect patient care are at risk for exposure to potentially harmful microorganisms. Wearing personal protective equipment (PPE), such as gowns, gloves, and eyewear with side shields, decreases the risk but does not eliminate it. The risk for exposure is proportionate to the proximity to the patient in the operating room (OR).

PROS/CONS

Laboratory Coats

Pros

- Laboratory coats are a symbol of professionalism and identification in rank.
- White laboratory coats favorably influence trust and increase confidence during patient contact.
- Laboratory coats are also associated with an increased perception of a provider's competency.
- They are designed to be a barrier to protect the clothing under the laboratory coat from pathogens.

Continued

PROS/CONS—cont'd

Laboratory Coats

- They provide additional pocket space for personal items.
- They provide additional identity information when embroidered with name and position.

Cons

- White laboratory coats and long neck ties were identified as unhygienic by health care workers because they are not regularly laundered.
- Patients and health care providers have a different opinion of wearing laboratory coats. Health care workers have a negative attitude because of the placement of personal items in the pockets that are a risk for infection.
- Old laboratory coats with stains may potentially be a risk for transmission of microorganisms because microorganisms can harbor in the stain.
- Laboratory coats should not be worn outdoors or from facility to facility because they can carry pathogens with them.
- Methicillin-resistant *Staphylococcus aureus* (MRSA) and *Clostridium difficile* (an endospore) have been cultured on laboratory coats. They can be transmitted between individuals who have touched any object contaminated with these organisms.
- Storing contaminated laboratory coats in a personal locker encourages microbial growth and transfers the microbes to other items that may be taken home.
- Laboratory coats worn over scrubs need to be clean, buttoned closed, and laundered in an accredited laundry facility after each wear to effectively decrease contamination.
- If a laboratory coat is worn outdoors, it should be exchanged for a clean coat to prevent bringing in any risk for infection into the facility.
- The cuffs of the sleeves and pockets were the areas most contaminated based on what was touched and what was placed into the pockets.
- Staff may have inadequate knowledge of the principles of infection control.
- Unauthorized personnel can assume the identity of the person whose name may be embroidered on the front of the laboratory coat.

3. AORN: Guideline summary: surgical attire. In *Guidelines for perioperative practice*, Denver CO, 2019, The Association.

PROS/CONS

Wearing Scrub Jackets

Pros

- A long-sleeved cover jacket or scrub jacket should be worn by all nonscrubbed staff members.
- Scrub jackets are designed to cover the bare arms and help prevent shedding skin cells from dropping onto surfaces and/or becoming airborne.
- Scrub jackets should be provided by the facility and laundered daily because microorganisms can survive on fabric from 1 to 90 days.
- Studies have shown that microorganisms from skin cells dispersed into the air can be transferred to a patient putting them at risk for a surgical site infection (SSI).
- A long-sleeved scrub jacket should be worn during the surgical prep to prevent skin shedding over the surgical area.
- Scrub jackets should be made of low-linting, stain-resistant, durable, and tightly woven material.
- The proper size scrub jacket and how it is worn is important. The jacket should fit close to the body and arms and come down to the wrists. It should be completely closed with buttons or snaps to prevent the jacket material from coming into contact with a sterile area.
- Policies and procedures with recommended wear of surgical attire must be established by each health care facility. Policies should include proper attire when leaving the restricted and semirestricted areas.

Cons

- Many health care providers do not wear the correct size jacket or change them daily due to the lack of facility supply.
- Some health care providers wear their jackets multiple times and store them in their lockers, thereby putting themselves and patients at risk for infection.
- Oversized jackets can drag along contaminated surfaces and transfer microorganisms to oneself or a patient.
- Scrub jackets with pockets can get contaminated from any personnel item such as scissors, papers, or cell phones.
- Health care personnel's lack of knowledge and policy awareness puts everyone at risk for transferring microorganisms.
- Nonenforcement of surgical attire policies can lead to increased SSIs within a facility.

References

1. Phillips NM, Hornacky A: *Pass CNOR*. St. Louis, 2019, Elsevier.
2. AORN: Guideline summary: surgical attire. In *Guidelines for perioperative practice*, Denver, CO, 2019, The Association.
3. Rothrock JC: *Alexander's care of the patient in surgery*, St. Louis, 2019, Elsevier.

The closer to the surgical field (source of blood and/or body substance) one is, the higher is the risk for exposure. The surgeon, assistants, and scrub persons have a higher risk by role and proximity. They share an increased incidence of needlesticks and puncture wounds.[3] The circulating nurse, environmental services personnel, and instrument processors are also at increased risk for body substance exposure because of specimen handling, cleaning processes, and other contaminants in the environment. The Occupational Safety and Health Administration (OSHA) has provided guidelines for immediate treatment of a needlestick at www.osha.gov.

Exposure rates to blood and body substances for OR personnel must be reported. Sharps were responsible for 3 in 100 reported exposures. Of glove tears reported, most were in single-gloved caregivers who revealed a blood exposure. In double-gloved individuals who had a glove puncture, only a few individuals reported an inner-glove puncture. Double-gloving is not an assurance of avoiding puncture in the event of a needlestick. A majority of reported injuries with sharps were self-inflicted by carelessness. Individuals should act quickly, notify the supervisor, and follow the needlestick protocol for the facility.

The patient is also at risk. If a needlestick occurs, the needle may come into contact with the patient after penetrating the caregiver, thereby exposing the patient. Some patients have health conditions that predispose them to vulnerability for infection. Considerations related to higher risk include immunosuppression, an immature immune system (preterm and term infants), radiation therapy, burns, diabetes, nutritional depletion, smoking, chemotherapy for cancer, older patients, steroid use, sickle cell disease, alcoholism, liver and kidney disease, and preexisting infection being treated with antibiotic therapy (superinfection/opportunistic infection may ensue).

Biofilm

Biofilm forms when one or more species of bacteria, fungi, and other microorganisms adhere in layers to moistened surfaces, such

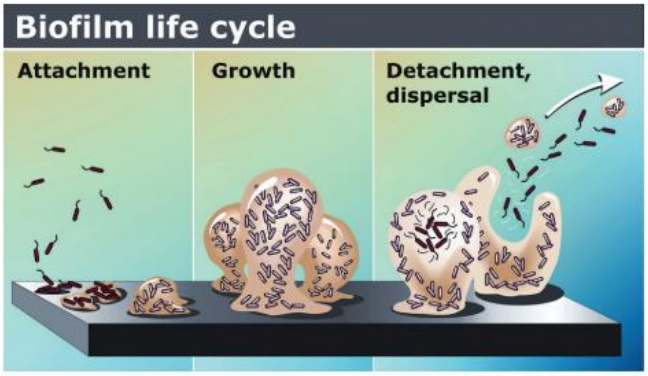
• BOX 14.3 Examples of Microbiologic Biofilms Associated with Chronic and Resistant Infections

Bacteria

- *Pseudomonas aeruginosa*
- *Staphylococcus aureus*
- *Streptococcus pneumoniae*
- *Haemophilus influenzae*
- *Moraxella catarrhalis*

Fungi

- *Candida albicans*
- *Cryptococcus*
- *Pneumocystis*
- *Aspergillus*
- *Coccidioides*



• Fig. 14.2 Biofilm Life Cycle. The process can be broken down into conditioning film formation and initial attachment of the organism to the surface, growth, and development of the biofilm, and organism detachment and dispersal. (From P. Dirckx, Montana State University Center for Biofilm Engineering, Bozeman, MT. Reproduced with permission.)

as biologic tissue, implantable metals, and plastics (Box 14.3). The slimy matrix that binds the microorganisms together creates a barrier against antibiotic treatment that results in a persistent disease state. Plaques can break off and attach elsewhere, causing a separate biofilm colony.

Biofilm can form on any biologic tissue surface or on inert devices implanted in the body, such as catheters, artificial joints, and mechanical heart valves. The biofilm begins as a single cell layer that attaches to a surface and multiplies and thickens rapidly (Fig. 14.2). Research has shown that biofilm is a genetically mediated process in which bacteria exchange intercellular information that gives rise to newly formed biofilm in a process known as *quorum sensing*.[4]

Persistent bacterial cells contain a gene *(HipA)* that codes for a toxic protein, which puts the cell into hibernation until the effects of a specific antibiotic have worn off. **Antibiotics** work only on growing, animated cells. When the antibiotic ceases to work, the cells reanimate and repopulate the site. Deleting or deactivating the *HipA* gene could end the ongoing battle with biofilm.

A biofilm infection may linger for months, years, or even a lifetime, regardless of the state of the patient's intact immune system. Bacteria in biofilm can be difficult to eliminate. The National Institutes of Health (NIH) points out that most of human chronic infections are attributed to biofilm. An infected implant may need to be explanted.

Mandatory Reporting of Health Care–Acquired Infections

The Healthcare Infection Control Practices Advisory Committee (HICPAC) of the CDC published a document in 2005 on reporting HAIs; updates can be found at www.cdc.gov. Infections to be reported include a wide range of patient-related infections that are traceable to health care intervention. Examples include, but are not limited to, the following infections:

- Indwelling catheter infections
- SSIs
- Ventilator-associated pneumonia
- Central line infections
- Communicable diseases
- Septicemia

Methodology and surveillance activities are described by HICPAC in the recommendations to the CDC. The pros include public reporting of infection rates; cons include a potential for misunderstanding by the general lay population and misrepresentation of published data.

Types of Pathogenic Microorganisms

Infections may be caused by one microorganism or a combination of them. Each type of microorganism has a specific set of characteristics that promotes survival and proliferation. Knowing the specific needs for microbial life aids in the prevention of infection. In this chapter each of the five main types of microorganisms is described according to structure, life cycle, and mode of transmission. Examples of each type of microorganism are provided in Table 14.1.

TABLE 14.1 Common Microorganisms in an OR Environment

Microorganism	Usual Environment	Mode of Transmission
Staphylococci	Skin, hair	Direct contact
	Upper respiratory tract	Airborne
Escherichia coli	Intestinal tract	Feces, urine
	Urinary tract	Direct contact
Streptococci	Oronasopharynx	Airborne
	Skin, perianal area	Direct contact
Mycobacterium tuberculosis	Respiratory tract	Airborne, droplet
	Urinary tract	Direct contact
Pseudomonas	Urinary tract	Direct contact
	Intestinal tract	Urine, feces
	Water	Water
Serratia marcescens	Urinary tract	Direct contact
	Respiratory tract	Water
Clostridium	Intestinal tract	Direct contact
Fungi	Dust, soil	Airborne
	Inanimate objects	Direct contact
Hepatitis virus	Blood	Bloodborne
	Body fluids	Direct contact

Bacteria

Bacteria are unicellular microbes essential to human life. We depend on many of their metabolic processes. Many antibiotics are derived from bacteria, such as erythromycin, chloramphenicol, and kanamycin. Some photosynthesizing types convert carbon dioxide to water and oxygen.

More than 5000 species of bacteria have been named, and many unidentified species exist. Most of the morphologic differences in bacteria are found in metabolism, chemical composition, or resultant effect on the host. Unfortunately, many varieties of bacteria are pathogenic or are capable of becoming pathogenic (Fig. 14.3).

Bacteria can survive in diverse environments. For example, *Thermoplasma acidophilum* is found in the hot springs of Yellowstone National Park and is capable of living in a 140° F (60° C) environment with an acidic pH of 1 to 2. *Geobacillus stearothermophilus* **endospores** (formerly known as *Bacillus stearothermophilus*) are used to test steam sterilizers because they can withstand temperatures up to 140° F. *Bacillus atrophaeus* endospores are used to test dry heat and low-temperature hydrogen peroxide sterilizers because they are destroyed at a lower temperature of 98.6° F (37° C).

Characteristics

1. *Structure:* Bacteria are microscopic, single-cell structures (1 to 10 mm). Two billion bacteria can be contained in a single drop of water. Bacteria have DNA but no formal nucleus (prokaryotic) and no membrane-bound organelles.
   a. Cocci are round. Examples include strains of *Staphylococcus* and *Streptococcus.* Diseases include impetigo and gonorrhea.
   b. Bacilli are rod shaped, and some can form endospores. They are the most common types of bacteria. Examples include *Bacillus, Clostridium, Escherichia, Proteus,* and *Pseudomonas* species.
   c. Spirochetes are spiral shaped. Diseases include syphilis, leptospirosis, and Lyme disease. In the later stages of illness, syphilis and Lyme disease can have fatal neurologic effects known as *neurosyphilis* and *neuroborreliosis* (Lyme).
   d. Pleomorphs can change shape from rod to round, making positive identification difficult. Diseases include mycoplasmal infection, typhus, rickettsial infection, chlamydia, psittacosis, and Rocky Mountain spotted fever. Rickettsia and chlamydia organisms must live in a host cell. They are intracellular parasites.
2. *Life cycle:* Bacteria can be **aerobic**, **anaerobic**, facultative, or microaerophilic. They can reproduce asexually by binary fission (split into equal halves). Some studies have shown that some genes may be transferred between bacterial species during viral infection (plasmid transfer).
3. *Communication:* Some bacteria are capable of communicating that conditions are adequate for reproduction and colonization. The process of cells gathering and communicating is known as *quorum sensing.* When the cells have populated an area to a sufficient degree, the process of formal infection takes place. Quorum sensing is commonly found in biofilm accumulations. Some bacteria can actually pass on DNA to their offspring asexually, producing two identical daughter cells. These cells can multiply the same way, causing infection.

   Studies have shown that engineered nanofactories show promise in the disruption of this form of communication between cells, thus decreasing the need for antibiotic administration. This works by allowing the bacteria to think there are enough cells in the area to cause infection. In reality the bacterial presence triggers immune response and there are not enough bacterial cells to combat the body's white cell activity. This may prove useful when antibiotic resistance is present because antibiotics do not play a role.
4. *Transmission:* Infection is passed along by direct contact or through animal or insect bites.
5. *Encapsulation:* Some bacteria are enclosed within a thick wall, which is a defense mechanism against phagocytic activity of leukocytes. These bacteria may be ingested by white blood cells, but instead of being killed and digested they remain within the phagocyte for a time and are then extruded in a viable condition. The presence of a capsule is associated with virulence among pathogenic bacteria. This is not to be confused with endospore formation, which is discussed in later paragraphs.

Differentiation of Bacterial Types

Gram Stain

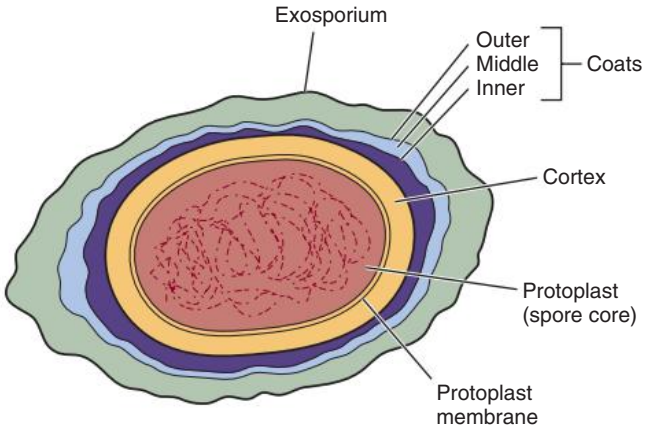
A universal way to determine the differences in bacteria is to stain the cell. Danish physician Christian Gram (1853–1938) developed a method of applying a solution of crystal violet and iodine (gentian violet) to the cell wall (bacterial coat) followed by exposure to 95% alcohol and acetone. Gram-positive bacteria retain a stain of dark purple-blue. Gram-negative bacteria retain only a stain of light pink after the rinsing process (Table 14.2). Gram stain is also used to identify nonbacterial substances such as trophocysts (helminth eggs) and larvae.

Endospores

Endospores are the resting, protective stage of about 150 species of gram-positive rod-shaped bacilli, specifically *Clostridium* and

TABLE 14.2 Bacterial Gram Stain Chart

	Gram-Positive Cocci	Gram-Negative Cocci	Gram-Positive Rods	Gram-Negative Rods
Aerobic	*Staphylococcus aureus* *Staphylococcus epidermidis* *Streptococcus pneumoniae* *Streptococcus pyogenes* *Streptococcus* viridans *Enterococcus faecalis* *Enterococcus faecium*	*Neisseria gonorrhoeae* *Neisseria meningitides* *Moraxella catarrhalis*	*Listeria monocytogenes* *Bacillus anthracis* *Corynebacterium diphtheriae*	*Escherichia coli* *Klebsiella pneumoniae* *Proteus mirabilis* *Serratia marcescens* *Pseudomonas aeruginosa* *Enterobacter* *Haemophilus influenzae* *Legionella pneumophila* *Salmonella* *Shigella* *Brucella* *Bordetella* *Campylobacter*
Anaerobic	*Peptostreptococcus* *Peptococcus*		*Clostridium difficile* *Clostridium perfringens* *Clostridium tetani* *Actinomyces*	*Bacteroides fragilis* *Fusobacterium*



• **Fig. 14.4** Bacterial endospore.

Bacillus. Gram-negative bacilli do not form endospores. The endospores encapsulate and protect their internal genetic matter (DNA and ribosomes) for future reproduction during exposure to a threatening environment. The process of forming an endospore is called *sporulation.* When conditions are suitable for survival, the endospore reverts back to its original bacterial cellular structure for active germination and outgrowth (Fig. 14.4). In the vegetative or active growth state, endospore-forming bacilli are no more difficult to kill than non–endospore-forming bacteria.

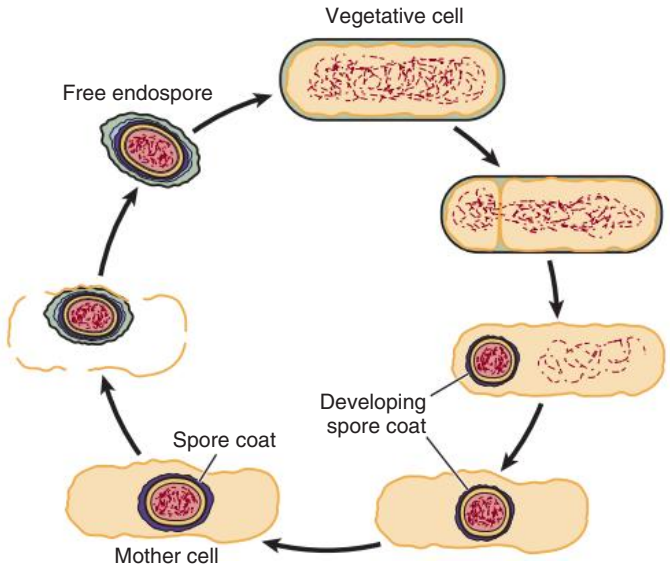
Endospore positioning within the bacterium is how the pathology department differentiates between species of endospore-forming bacteria. Examples of locations include central *(Bacillus cereus),* lateral *(Bacillus subtilis),* or at either terminal polar end *(Clostridium tetani).* Stains and dyes on the exterior wall of the bacteria can make definitive identification of the endospore difficult. In its natural state the endospore itself is clear. Stains have been developed to tint the endospore within the bacterial coat for visualization.

Most other microorganisms are killed easily by the processes of sterilization and disinfection, but bacterial endospores are not. Nonpathogenic varieties of the bacillus endospore-forming microorganisms are used in sterilizers to test for efficacy and by brewers for fermentation of spirits (e.g., *B. subtilis*). *Clostridium* is exceptionally pathogenic, being the cause of *C. difficile,* tetanus, anthrax, botulism, and gangrene (Fig. 14.5).[5] The strain of *C. difficile* known as ribotype 027 produces stronger toxins of A and B and is becoming resistant to vancomycin.[5]

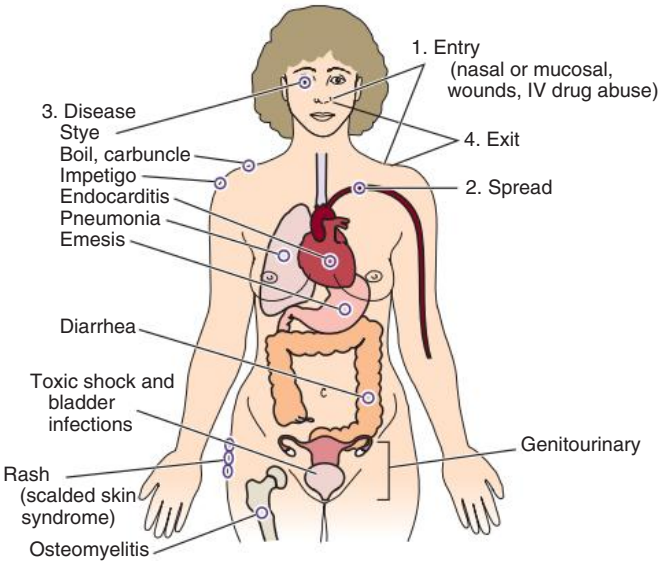
Bacterial Toxicity

Pathogenic microorganisms produce substances that on invasion adversely affect the host locally and/or systemically. Toxic substances affecting tissues, cells, and possibly enzyme systems diffuse from the microbial cells. The cellular substance of a wide variety of organisms is toxic also. In addition, harmful effects may be produced indirectly by activation of tissue enzymes by bacteria. The following list includes toxic substances:

1. *Exotoxins:* These classic bacterial toxins are the most potent toxins known. As little as 7 ounces (200 mL) of crystalline botulism type A toxin is said to be able to kill the world's entire population. Exotoxins appear to be proteins, are denatured by heat, and are destroyed by proteolytic enzymes, which break down protein. These bacteria are typically gram-positive and form spores. Examples of diseases are tuberculosis (TB), clostridia, diphtheria, anthrax, and leprosy.
2. *Endotoxins:* These toxins are contained within the cell wall of bacteria and are released when the cell wall is broken. They are heat stable and are not digested by proteolytic enzymes. On parenteral inoculation, they cause a rise in body temperature and are known as *bacterial pyrogens.* They



• **Fig. 14.5** Process of forming a bacterial endospore.



• **Fig. 14.6** *Staphylococcus aureus*.

increase capillary permeability with the resultant production of local hemorrhage.

Endotoxins cause injury to body cells at the site of infection, but more important they cause serious, often lethal effects by systemic dissemination and widespread injury to many tissues throughout the body. Endotoxic shock may occur in bacteremia caused by gram-negative bacteria. Examples of diseases are typhoid, shigellosis infection, and the plague. Microorganisms include *E. coli, Salmonella,* and *Pseudomonas.*

3. *Heterogeneous substances:* Microorganisms also form a variety of other heterogeneous (dissimilar) toxic substances, which may contribute to the disease process directly or facilitate the establishment of foci of infection. Toxins which diffuse from the intact microbial cell have the following various effects:
   a. Cytotoxic effect (leukocidin) destroys white blood cells (e.g., causing leukopenia, or reduction of the number of leukocytes below what is considered normal).
   b. Kinase effect interferes with the clotting mechanism of blood.
   c. Enzymatic effect causes bacterial hemolysins to dissolve red blood cells or fibrin, thereby inhibiting clot formation. Coagulase, an enzymatic substance of bacterial origin, is causally related to thrombus formation. Coagulase-positive *Staphylococcus, B. subtilis, E. coli,* and *Serratia marcescens* accelerate clotting of blood and induce intravascular clotting.

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is an acute condition caused by exotoxins secreted by strains of *S. aureus.* The pathogen can invade any part of the body. TSS is characterized by fever with temperature over 102° F (38.9° C), hypotension, erythematous rash, and injury to multiple organ systems. Diagnosis is based on the presence of abnormal clinical and laboratory findings. Prompt supportive treatment and antibiotic therapy are crucial. Desquamation, peeling of skin (usually from the palms of the hands and soles of the feet), occurs 1 to 2 weeks after onset.

Recovery is usually complete, but TSS is potentially fatal if untreated. It can originate from a surgical wound, burn, postpartum infection, or septic abortion infected or colonized with the implicated toxin. TSS can afflict any age-group of either sex (Fig. 14.6).

Septic Shock

Septic shock is a state of widely disseminated infection, often borne in the bloodstream (i.e., septicemia). Early septic shock may begin with fever, restlessness, sudden unexplained hypotension, confusion, hypoxia, tachycardia, tachypnea, and/or oliguria. One or more of these signs and symptoms may be present. Toxic or metabolic by-products increase capillary permeability, permitting loss of circulating fluid into the interstitial fluid. Endotoxins released by bacteria promote vasodilation and hypotension.

Septic shock is most frequently produced by gram-negative bacteria. As shock progresses the patient develops cold, clammy skin; sharply diminished urinary output; respiratory insufficiency; cardiac decompensation; disseminated intravascular coagulation; and metabolic acidosis. The high-risk category comprises patients with severe infection (e.g., peritonitis), trauma, burns, impaired immunologic status, diabetes mellitus, or extreme age, as well as patients who have undergone an extensive invasive procedure.

Treatment consists of control of the infectious process, early administration of antibiotics, fluid-volume replacement, and oxygen. Diuretics, sodium bicarbonate, vasoconstrictors, vasodilators, inotropic agents, or heparin also may be indicated. Corticosteroids may be used, but their use is controversial. A monoclonal antibody may be administered to reduce endotoxins.

Tuberculosis

TB is caused by the acid-fast gram-positive bacterium *M. tuberculosis.* Tubercle bacilli can remain dormant in the body, encased in a tough shell, for years after exposure.[6] This is not to be confused with endospore formation. The caseous coat of TB is a tough form of cell wall.

Tubercle bacilli usually infect the lungs (pulmonary TB), but they may be present in joints, kidneys, ovaries, or other organs. Acute miliary TB may be seen in an abdominal procedure as generalized peritonitis. *M. tuberculosis* is an opportunistic organism. Individuals at high risk for TB include those immunosuppressed

from human immunodeficiency virus (HIV) infection, corticosteroid therapy, chemotherapy, or malnutrition. Persons with diabetes mellitus, cirrhosis, alcoholism, silicosis or other lung disease or who have had prolonged contact with an actively infected person are also at risk.

Because TB may become airborne by droplets from the respiratory tract, the disease must be monitored and controlled to prevent cross-infection. Unsuspected active cases and inactive carriers represent a particular hazard. Patients with acute disease are isolated and placed on respiratory secretion precautions for approximately 2 weeks after initiation of treatment.

Therapy is long term (usually 6 to 12 months of drug therapy). Isoniazid (INH) and rifampin most effectively kill reactive bacilli and prevent reactivation. Clinicians note that widespread use of rifampin has resulted in multidrug-resistant TB (MDR-TB).[6] Pyrazinamide, ethambutol, and streptomycin also may be used for multidrug therapy; some other drugs that are less effective and have more side effects may be indicated. *M. tuberculosis* mutates and may become resistant to any single-drug or multidrug therapy regimen. MDR-TB and extensively drug-resistant TB (XDR-TB) can be fatal, especially in those infected with HIV.[6] The drug bedaquiline fumarate is used when other drugs have been ineffective. The drug must be taken for 24 weeks and can have multiple side effects. It is given in combination with other TB drugs. Patients with active TB should be isolated from the general public and follow the medication regimen. TB medications are recommended to be given by observation by another person to keep to the scheduled plan.[6]

The following recommendations should be used in the care of surgical patients who have active TB:

- Postpone elective surgical procedures, if possible, until the patient shows a response to drug therapy (i.e., is no longer infectious as confirmed by a negative sputum smear).
- Use disposable anesthesia equipment to the extent possible. Reusable equipment must be sterilized immediately after use. A bacterial filter on the endotracheal tube or at the expiratory side of the breathing circuit may be useful in reducing the risk for contamination of anesthesia equipment or the discharge of tubercle bacilli into ambient air.
- Use respiratory isolation precautions for patients with TB-positive sputum culture. OR team members should wear face-fitting masks that filter particles of 1 mm at a 95% efficiency level (i.e., a disposable high-efficiency particulate air [HEPA] filtered mask, valveless dust-mist respirator, or dust-fume-mist filtered respirator). This includes putting a HEPA mask on the patient during transport to the OR. The transporter also wears a HEPA mask.
- Perform the surgical procedure at a time when other patients and a minimum number of staff members are present in the OR suite (i.e., at the end of the day's schedule, if possible). Keep OR doors closed and traffic to a minimum.
- Sterilize critical items (i.e., those entering the bloodstream or body cavity); semicritical items (i.e., those in contact with mucous membranes only) may be sterilized or undergo high-level disinfection with a tuberculocide.
- Move the patient into an isolation room that has negative pressure ventilation with a local exhaust and HEPA air filtration and/or ultraviolet radiation lamps.
- Screen high-risk patients and test personnel at least annually. Testing includes a chest x-ray film and a Mantoux one- or two-step TB skin test. Exposed personnel should be retested every 6 months.
- A single blood test called interferon gamma release assay (IGRA) is also available for the diagnosis of TB.

TB is the leading fatal infectious disease in the world. In many facilities, yearly TB testing of all OR personnel is mandatory. The most accurate test is the Mantoux test, which is administered by injecting 0.1 mL of purified protein derivative (PPD) of tubercle bacillus subcutaneously in the forearm to form a small wheal under the skin. The site is examined in 24 to 72 hours. Redness, itching, and induration of 8 to 10 mm at the site of injection are considered a positive or a significant reaction. Many facilities have adopted the two-step method testing that involves performing the Mantoux test twice in succession 1 week apart.

Further testing and chest x-rays may be performed before treatment can begin. Reaction of less than 8 mm at the site of injection is considered an insignificant or negative reading, and no further action is needed. Any acute lung disease or symptoms should include TB in the differential diagnosis.

Sexually Transmitted Diseases

Any sexually active person who has multiple partners is at risk for acquiring a sexually transmitted disease. In addition to those previously discussed (hepatitis B virus [HBV], HIV, and herpes simplex virus [HSV] infections), gonorrhea, syphilis, and chlamydia are transmitted by sexual contact or by contact with infectious material containing the microorganisms. Splashes with infectious material to the face and eyes or transmission through broken skin during a surgical procedure can expose a caregiver to infection. According to the CDC, cases of gonorrhea, syphilis, and chlamydia have increased by 31%, with the highest rate reported in 2017.[7]

Gonorrhea

Neisseria gonorrhoeae most often infects the genitourinary tract, but it may infect the rectum, pharynx, or conjunctiva. Burning, itching, and pain around the vaginal or urethral orifice with purulent discharge are characteristic symptoms. If untreated, the infection can spread to cause inflammation within the peritoneal cavity and septicemia. Disseminated infection is more common in women than men. Gonorrhea is treated with penicillinase-inhibiting antibiotics. In 2015 the CDC updated its guidelines recommending dual treatment with ceftriaxone and azithromycin. A strain of antibiotic-resistant gonorrhea has been reported and has shown resistance to ceftriaxone.[7] Generally patients should be treated simultaneously for presumptive chlamydial infections.

As a prophylactic measure the CDC recommends a one-time instillation of erythromycin 0.5% ophthalmic ointment within 1 hour after birth to protect the neonate's eyes against potential contamination by vaginal secretions of an infected mother. Single-use tubes or ampules are preferable to multiple-use tubes to prevent **cross-contamination** between newborns. A newborn with a known gonorrheal infection will need further antibiotic treatment.

Syphilis

Routine screening for syphilis in hospitalized patients and couples applying for marriage licenses is a thing of the past. However, the incidence of syphilis is on the increase again. *Treponema pallidum* is a bloodborne spirochete that may infect any organ system. Syphilis is characterized by three distinct stages of effects over a period of years if it is untreated by antibiotics. Congenital syphilis results from prenatal infection unless the infected mother is treated within the first 4 months of pregnancy.

In the first stage (primary syphilis) a lesion on the skin or mucous membrane, most commonly around the anogenital region, quickly forms a chancre. This is a painless ulceration that exudes fluid laden with spirochetes. The chancre heals spontaneously within 40 days. During the second stage (secondary syphilis), spirochetes migrate from the chancre throughout the bloodstream. The disease can remain contagious for as long as 2 years during this stage.

The third stage (tertiary syphilis) may not develop for many years. When it does, secondary lesions may damage or destroy tissues and body structures, including the heart and central nervous system, with ensuing mental disability or death.

Chlamydia

Chlamydial infection is caused by *Chlamydia trachomatis* (bacteria). It is the most prevalent sexually transmitted disease—more common than gonorrhea and syphilis. It is transmitted only by person-to-person contact. It occurs more often in men than in women, but women are more frequently asymptomatic than are men.

Chlamydia can cause epithelial tissue inflammation, ulceration, and scarring of the urethra and rectum, as well as damage to reproductive organs. Pelvic inflammatory disease (PID) is a serious complication in women. Asymptomatic salpingitis is a major cause of tubal infertility or ectopic pregnancy. Exposure of infants to *C. trachomatis* in the birth canal can cause neonatal conjunctivitis and pneumonia.

Viruses

A virus is not an independent cell unit and is incapable of autonomous metabolism. It is an obligate intracellular parasite that is confined to living in a host cell, such as a somatic cell, or a bacterium. As a bacteriophage, a virus can attach itself to a bacterium and create an opening. While still attached, the nucleic acid of the viral capsule enters the bacteria. The empty capsule remains attached to the bacteria.

Once the virus is inside the host cell, regardless of the cell type, it uses the cell's genetic contents and metabolic machinery for replication. New viruses are passed out the cell membrane, and they in turn attach to other cells to repeat the replication process. Some viruses engorge the cell, causing it to rupture and disperse the virus into the host's body.

During viral infection the host cell reacts to invasion by producing an inflammatory response, antibodies, and interferon to slow the progression of viral replication. Some cellular immunity is developed (e.g., in mumps, chickenpox). Some viruses can attach to nerve cells and undergo activation, deactivation, and reactivation cycles, such as in herpes simplex types I and II (HSV). Some of the nerve cells destroyed by viral invasion include motor neurons, which when damaged cannot be repaired or replaced, such as in polio.

Until the discovery of viruses as a separate entity by Dmitri Iwanowski (1864–1920) in 1892, viruses were identified only by the diseases they caused. Martinus Beijerinck (1851–1931) made significant contributions to scientific knowledge by expanding the knowledge of viruses. The virus species can usually be identified by the specific alterations in structure and function effected in the host cell as seen under electron microscopy. Other diagnostics include detection of viral antigen, nucleic acid, or antiviral antibody in the serum.

Characteristics

- *Structure:* Viruses are composed of a protein capsule but have no true cellular components other than nucleic acid. They are categorized by the morphologic core structure of their nucleic material—either DNA or ribonucleic acid (RNA) (not both)—and the presence or absence of an envelope. They can mutate. Viruses are extremely small and are visible only by electron microscope.
- *Life cycle:* A virus must have a living biologic host cell. The virus enters a host cell and uses the host's genetic and other cellular protein material for replication.
- *Transmission:* Infection can be transmitted through blood and body fluids of animals and humans. Some viruses can be transmitted by insect bites, such as ticks or mosquitoes; other viruses are transmitted by the fecal-oral route. Direct contact of virus with nonintact skin or mucous membranes can allow entry.

Viral Disease Examples

Hepatitis Infection

Viruses can produce several types of acute and chronic inflammation of the liver. The pathogens causing viral hepatitis create an occupational hazard to health care providers. A patient may be in an acute stage of the infection but more commonly is an unknown carrier of one and occasionally two of the viruses that can cause hepatitis.

Hepatitis A. Hepatitis A virus (HAV) infection is an acute illness that is usually brief but can last for several months. It is spread by oral ingestion of contaminated water and food, especially shellfish, and by fecal contaminants. It is most infectious during the 2 weeks before the onset of symptoms and until after the first week of jaundice. The incubation period is 14 to 90 days, with an average of 28 days. Immune globulin may be effective if given within 2 weeks of exposure.

HAV infection is the most common type of viral hepatitis and causes critical disease if it occurs in combination with other types of hepatitis. HAV infection as a single entity is not a health care–associated problem because it does not have a chronic carrier state. It is usually self-limiting and does not typically cause chronic liver damage. A vaccine is available for areas where HAV is endemic.

Hepatitis B. Hepatitis B virus (HBV) infection is a major health care–associated problem. Carriers are a main source of cross-infection. Hepatitis B surface antigen is the carrier state of HBV. This can be harbored for prolonged periods of up to 15 years and has been found in practically all body fluids of infected persons. It is transmitted percutaneously or permucosally by blood, saliva, semen, and other body fluids. It is not found in feces or urine, according to the U.S. Department of Health and Human Services.

HBV can be transmitted by fomites, through sexual intercourse, and from an infected mother to a neonate during birth. The incubation period is 60 to 90 days before mild to severe symptoms become apparent. Chronic hepatitis, cirrhosis, or liver carcinoma may develop. A liver transplant may be necessary.

Serologic tests are used to diagnose infection, detect carriers, and monitor high-risk persons. Patients who have undiagnosed hepatitis, fail to reveal that they have chronic hepatitis, or are asymptomatic carriers can transmit the virus to health care providers. Perioperative, emergency department, blood bank, laboratory, and hemodialysis unit personnel are especially at risk. HBV

surface antigen is easily transmitted by direct contact with blood and body fluids via a needlestick or break in the skin, such as a minor cut or hangnail, or via a splash into the mucosa of the eye, nose, or mouth.

Preexposure immunization over a period of 6 months through a series of three injections of 10 mg (1 mL) of recombinant vaccine against HBV is recommended for all persons at risk. The injections are given in the deltoid muscle because injection in the gluteal muscle has been shown to not produce immunity. After exposure, such as after an accidental needlestick, both the vaccine and hepatitis B immune globulin are given.

Since 1991, OSHA has mandated that health care facilities make these immunizations available to personnel. The series may need to be repeated in 7 years if the titer falls below a detectable level in the serum.

Hepatitis C. Hepatitis C virus (HCV) is a bloodborne RNA virus. Recipients of multiple transfusions or chronic hemodialysis, intravenous (IV) drug users, and health care workers are at risk. Persons with acute HCV infection are asymptomatic but have a higher mortality if they are simultaneously exposed to HAV. A screening test detects the presence of antibodies in the blood. Incubation varies from 2 weeks to 6 months. The infection may progress insidiously in a carrier for as long as 25 years. Immediate HCV postexposure treatment consists of immune globulin injections.

Persons who become infected with HCV have a 40% to 60% chance of becoming chronic carriers. Newer treatments approved by the U.S. Food and Drug Administration (FDA) can cure hepatitis in 8 to 12 weeks with antiviral agents. The Infectious Diseases Society of America (IDSA) has guidelines for treatment, information, and new medications for providers at www.hcvguidelines.org. There are a group of antivirals, such as elbasvir, glecaprevir, and ledipasvir, for treatment. Many of these medications are very expensive. Medication selection is based on serologic testing.[8] Women should avoid becoming pregnant while taking these drugs.

HCV infection can precipitate chronic hepatitis, cirrhosis, and liver cancer if untreated. A liver transplant may be needed. Mortality rates associated with HCV infection exceed 10,000 deaths per year. This form of hepatitis may surpass HIV infection in the number of new cases reported each year. An estimated 3 million persons in the United States have HCV infection.

Hepatitis D. Hepatitis D virus (HDV) infection coexists with HBV infection or superinfects an HBV carrier. A defective RNA virus, HDV requires HBV for its survival and replication in both acute and chronic forms. HDV infection is communicable during all phases of active infection. It can lead to necrotizing liver disease and death. The majority of patients developing this complication of HBV infection are IV drug abusers who used contaminated needles. Immunization against HBV will also prevent hepatitis D.

Hepatitis E. Hepatitis E virus (HEV) infection is common in Asia, Africa, and Mexico. The incubation period is 15 to 64 days, with an average of 25 to 42 days in different epidemics. The characteristics of HEV are comparable to those of HAV, and there are no specific serologic tests for HEV at this time. HEV infection is spread via the fecal-oral route through contaminated water or food or from poor sanitation conditions. Current immunoglobulins do not provide protection. HEV infection has no known chronic carrier state, and full recovery in infected persons usually can be expected. The best protection is proper handwashing.

Hepatitis G. Hepatitis G virus (HGV) infection is rare (2000 cases diagnosed per year). Most infected persons have no clear symptoms. It is transmitted by infected blood, and exposure to HCV increases mortality associated with the disease.

Herpes Infection

Related DNA viruses that form eosinophilic intranuclear inclusion bodies are collectively called herpesviruses. The viral infections they cause may be acute and highly contagious, or they may remain latent for many years, even if antibodies are in circulation.

Herpes Simplex Infection. Herpes simplex virus (HSV) is the pathogen of herpes simplex infections. These cutaneous infections may cause localized eruptions, comparable to blisters, on the border of the lips or external nares, in the mouth, or in the genital or anal region. Transmission is by direct contact with vesicle fluid from lesions or with saliva. The infection may be transmitted to the neonate during passage through an infected birth canal. HSV also can cause cutaneous eczema, acute stomatitis, keratoconjunctivitis, acute retinal necrosis, and meningoencephalitis. Herpes simplex infections are common in HIV-infected and other immunocompromised patients.

Patients who have a history of HSV infection may be treated with oral acyclovir preoperatively to prevent an outbreak in the surgical wound. This prophylaxis is particularly important for patients who are having facial procedures, such as a chemical peel or face-lift.

Herpetic Whitlow. Herpetic whitlow, a herpesvirus infection of the fingers, is transmitted by direct contact with oral secretions from a person with active herpesvirus or from an asymptomatic carrier. Entry of the virus into the host is via a cut or break in the skin or in nail folds. Herpetic whitlow is an occupational hazard to nurses, physicians, dentists, and anesthesia providers.

Cytomegalovirus Infection

Cytomegalovirus (CMV) may infect salivary glands or viscera, causing enlargement of cells. Transmission can be by direct contact with body fluids, secretions, and excretions. CMV infection usually is asymptomatic in a healthy person, but it is an opportunistic pathogen in immunosuppressed patients with HIV infection or acquired immunodeficiency syndrome (AIDS). Lymphadenopathy, enteritis, and pneumonitis may persist. Chorioretinitis and blindness may result in the end stage of infection. CMV infection also may be associated with hepatitis. CMV may infect arterial smooth muscle cells, stimulating them to proliferate, which can contribute to the formation of atherosclerotic plaque.

CMV is the most common cause of congenital viral infection; it may be transmitted from an asymptomatic mother during pregnancy. A CMV-infected infant may develop neurologic problems. Latent CMV may become reactivated after organ transplantation. The incidence of primary and reactivated CMV infection is fairly high after renal, cardiac, and bone marrow transplantation.

Human Papillomavirus Infection

Condylomata (venereal warts) are caused by the human papillomavirus (HPV) and are transmitted through skin-to-skin contact during vaginal, anal, or oral-genital sexual acts. Condoms offer little protection because HPV is not dependent on the exchange of body fluids. Warts manifest within 3 months of exposure; however, they can be latent for years. Even with seemingly effective treatment, the recurrence rate is high.

The infectious process appears as accumulations of warts over the perineal and/or anogenital surface. HPV infection in women can lead to cervical carcinoma. More than 100 types have been identified via DNA testing, with 40 varieties specifically targeting mucosal surfaces such as in the perineal and oral mucosa. HPV types 6 and 11 are rarely associated with cancer. Types 16 and 18 are considered high risk for causing cervical cancer. HPV is not diagnosed via culture or blood test but is differentiated by the types of epithelial cells affected and DNA markers. HPV is associated with 90% of anal cancer; 40% of vulvar, vaginal, and penile cancers; and 12% of oral and pharyngeal cancers.

Some patients are infected simultaneously with multiple varieties of both carcinogenic and noncarcinogenic HPV. Administration of an HPV vaccine is recommended by the CDC as routine prophylaxis for girls as young as 9 years of age and all sexually active women up to age 26 years. The process is a series of three injections comparable to the administration of the hepatitis B vaccine.

HPV-positive girls should be vaccinated as prevention of acquisition of additional varieties of the virus. The vaccine has no effect on infections present before injection. The vaccine is not recommended for use during pregnancy; however, there are no restrictions concerning breastfeeding during the series of vaccine injections. The HPV vaccines are contraindicated for patients with sensitivity to components of the drug. Some types are manufactured using baker's yeast. Some of the prefilled syringes have latex plungers and can stimulate reactions in patients who are allergic or sensitive to latex.

Treatment for venereal warts includes cryotherapy with liquid nitrogen, electrosurgical removal, carbon dioxide laser ablation, chemical peel with trichloroacetic acid (TCA), and/or topical application of medication (podophyllum 10% to 25% in a benzoin tincture, podofilox 0.5% solution or gel, or imiquimod 5% cream). Patients with wart accumulations of 0.5 to 1 cm^2 respond to topical applications. Patients with larger areas greater than 10 cm^2 may require staged surgical intervention. Not all HPV warts are easily visible or pigmented for surgical treatment. A weak 1% to 3% solution of acetic acid (white vinegar) can be swabbed over the affected area to cause the warts to become erect and visible.

Some infections are extensive, and the treatment may leave the patient with chronic reflexive neurologic pain, such as vulvodynia. Patients should be advised that their sexual partners also need to be evaluated for venereal warts.

Pregnancy complicates treatment because the lowered immune response accelerates wart growth. Cesarean section is indicated to prevent exposure of the fetus during passage through the birth canal. Infants exposed to the infected vaginal environment risk development of laryngeal papillomatosis. Most of the topical medications have not been approved for safe use during pregnancy.

Studies have shown longer range issues associated with HPV infection. Increased incidence of head and neck cancer has been demonstrated by laryngeal biopsy and laryngectomy specimens.

Human Immunodeficiency Virus Infection

HIV clearly represents a worldwide threat to public health that is unprecedented in modern times. Since HIV was introduced into the United States in the late 1970s, the resultant infection has spread at an alarming rate via contaminated blood and infected persons. Clinical problems in seropositive patients began appearing in 1978. Because of its effect on the immune system and its unknown origin when first reported in 1981, this infection became known as acquired immunodeficiency syndrome (AIDS).

In 1983, researchers at the Institut Pasteur in Paris isolated the lymphadenopathy-associated virus (LAV). In 1984 a similar retrovirus called human T cell lymphotropic virus type III (HTLV-III) was reported by the National Institutes of Health in Bethesda, Maryland. Since 1986, LAV and HTLV retroviruses causing AIDS or related illnesses have been known collectively as HIV.

Retroviruses synthesize DNA from RNA, a reversal of the usual process. As a result of this reversal process, there is a rapid rate of mutation, making resistance to antiviral drugs a major problem. Normally when a virus enters the body, helper T lymphocytes (T cells) release proteins that activate the immune system to produce antibodies against the virus and macrophages to attack the virus. HIV is different from other viruses in that it attacks the cell membrane of these white blood cells. When the virus penetrates the T cell membrane, the viral RNA and enzyme are released into the T cell cytoplasm and converted into DNA. This newly formed DNA penetrates the T cell nucleus, causing replication of the HIV virus. The cell dies and the virus is released into the bloodstream to attack other helper T lymphocytes and macrophages, thus compromising the immune system.

HIV can live and reproduce in macrophages without stimulating the production of antibodies, because the viral composition resembles the host cell. HIV will survive in blood and any body fluid that contains white blood cells. The primary routes of transmission are through sexual intercourse and direct contact with blood and blood products. HIV may be transmitted to the fetus by the blood of an infected mother or to the neonate via breast milk. HIV is not transmitted by casual contact with an infected person. The virus is relatively fragile and easily destroyed outside the body.

After exposure, antibodies may not be identified through serologic testing for 6 to 12 weeks, and detection can be delayed for up to 18 months or longer. Enzyme immunoassays (EIAs) and Western blot analysis are used to test for the presence of antibodies. Blood banks test donor blood for HIV antibodies. Transplant donors also are tested. Blood screening for HIV has been routine in the United States since 1985, thus decreasing the potential for transmission by blood transfusion. Seropositive blood is destroyed, and the donor is notified.

The incubation period before symptoms of infection develop ranges from 6 months to 5 years or longer. Persons in whom the antibody is identified are considered infected and infective. They are classified by physical findings.

Acute Infection. The acute stage of HIV infection lasts 2 to 3 weeks. Signs and symptoms may be specific to an opportunistic infection or disease, but marked fatigue, prolonged diarrhea, weight loss, dry cough, enlarged lymph nodes, fever, and night sweats are striking features. Infections are primarily viral, mycobacterial, and fungal in origin. Oral candidiasis lesions (thrush) may be the first observable symptom. *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii)* pneumonia, an unusual lung infection caused by a fungal parasite, is a quite common occurrence.

Other common infections are CMV, HSV, cryptococcosis, and *Mycobacterium avium-intracellulare* complex disease. The patient may survive one infection only to succumb to another. Prophylactic drug therapy aims to prevent or delay the onset of infections. Malignancies and lymphomas also may develop.

Acquired Immunodeficiency Syndrome. As the HIV infection progresses, the cell-mediated immune system is irreversibly compromised. As concentration of the virus gradually increases, the

patient becomes symptomatic for clinical manifestations of AIDS. Clinical diagnosis of AIDS requires a positive test for HIV antibodies, any one of the specified opportunistic infections, and a lowered T cell count. AIDS is not a well-defined disease but rather a state of immune dysfunction.

AIDS causes persistent destruction of the helper T lymphocytes (white blood cells that stimulate production of antibodies), resulting in profound immunosuppression (diminished resistance to infection and disease). The acronym AIDS helps define the disease process:

- *Acquired:* HIV has passed from one person to another by blood or body fluid in direct cell-to-cell contact. Infection is not hereditary except through transplacental transfer from an infected mother to a fetus.
- *Immune:* The normal defense system protects the body against certain diseases and opportunistic infections. Immunity depends on the production of antibodies.
- *Deficiency:* The immune system becomes compromised (i.e., immunosuppressed against **opportunists**). The host is unable to protect the person with no previous history of immunodeficiency against opportunists.
- *Syndrome:* A group of symptoms or laboratory evidence indicates the presence of a particular disease, abnormality, or infection. Seroconversion is positive for HIV antibodies. *P. jiroveci* pneumonia is the most common opportunistic respiratory infection. *M. avium-intracellulare* complex, the most common AIDS-related bacterial infection, is a leading cause of the wasting syndrome (i.e., loss of body fat and weight). Kaposi's sarcoma, a vascular tumor, is the most common malignancy. HPV and HSV infection may be present. Neurologic disease may cause dementia. Lymphomas and opportunistic infections of the brain, spinal cord, and peripheral nerves are not uncommon.

Asymptomatic Infection. The patient may be completely asymptomatic of infection yet test seropositive for HIV antibodies, which confirms the presence of virus in the body.

Persistent Generalized Lymphadenopathy. Swelling or enlargement of lymph nodes suggests cellular immune dysfunction. Prolonged infection with HIV may occur without the formation of HIV antibodies.

HIV-Related Clinical Manifestations. Originally referred to as AIDS-related complexes, a variety of health conditions suggest an impaired immune system. The patient who does not have one of the specific opportunistic infections but is seropositive for HIV antibodies does not technically have AIDS. An infectious disease such as TB and some cancers may be a result of a deteriorating immune system. AIDS may develop within a year of seroconversion.

A patient may be infected with HIV but may not yet test positive. Health care providers who have a valid reason to be concerned that they may have been infected may request to be tested. Few health care providers seroconvert from a single needlestick or splash of blood on mucous membranes. Handling all needles and sharp instruments carefully and using barriers to avoid direct contact with blood and body fluids are the best measures to prevent work-related transmission of HIV. An HIV inhibitor such as zidovudine may be given immediately after exposure. A vaccine has not been developed for immunization. Antiviral agents interfere with the life cycle of the virus, reducing the viral load. Immune-modulating agents stimulate function of the suppressed immune system. Multiple medications are needed to prevent secondary infections. Information can be found at www.aidsinfo.nih.gov.

Prions

Stanley Prusiner created the term **prion** from the official scientific name *proteinaceous infectious particle that lacks nucleic acid.* Prions are natural protein-based helical structures with various gene encoding that can change or evolve. Prions are not alive and therefore cannot be "killed." Prions are resistant to deactivation or destruction by heat, chemicals, radiation, freezing, drying, and conventional detergents. Special handling is required when pathogenic prions are known or suspected.

Studies have shown that prions do not need RNA or DNA to change to another form in an evolutionary sense. The natural prion proteins in the body can change form when exposed to stimulus from a diseased prion.

Prions become infectious and cause disease when they sporadically mutate or are transmitted via direct tissue contact. Other modes of prion transmission include familial inheritance and, in some forms, oral consumption.

In pathologic prion disease the encoded helix converts from α-helical PrP^{Sc} to β-helical PrP^{Sc}. When diseased, prions fold over on themselves, causing vacuoles in the surrounding brain tissue that look like holes in a sponge. The term *spongiform* is used when referring to prion diseases. Clumps of plaques known as *amyloids* form and disrupt nerve signals in the brain. Because the patient's own tissue is changed, there is no inflammatory response to signal infection or disease.

Transmissible spongiform encephalopathy (TSE) is a family of prion-mediated diseases that cause fatal neurologic disorders. Known forms of TSE that affect humans and animals include the following diseases:

- Human forms:
  - Creutzfeldt-Jakob disease (CJD). CJD can be sporadic, familial, or iatrogenically introduced by contaminated instruments, blood transfusion, growth hormone, or exposure to neurologic tissue.
  - New variant Creutzfeldt-Jakob disease (vCJD). Not known to science before 1994; suspected to be transmitted by eating infected cattle.
- Animal forms:
  - Bovine spongiform encephalopathy (BSE) (cattle)
  - Scrapie (sheep and goats)

Creutzfeldt-Jakob Disease

Although rare, CJD is a progressive, fatal neurodegenerative disease characterized by dementia, myoclonus (muscle spasms), and multifocal neurologic signs and symptoms. It cannot be diagnosed by blood tests. The only definitive diagnosis is from neurologic tissue samples positive for protein prion folding and amyloid plaque formation. CJD is not the same as vCJD or BSE. Autopsies of the brains of patients with suspected Alzheimer's disease revealed that 13% had undiagnosed CJD, and the tissue sampled resembled that of other TSE-infected mammals.

CJD was first described in 1920 by German psychiatrists Hans Gerhard Creutzfeldt and Alphonse Maria Jakob. Thought to be associated with genetic factors that influence susceptibility to the formation of abnormal neurologic protein, the condition may be dormant for more than 30 years before the onset of symptoms around the age of 65 years. The disease then progresses rapidly, leading to coma and death, usually within 2 to 5 years of onset of symptoms.

Studies have shown that items contaminated with prions can cause infection many years after initial contamination. One study

demonstrated that brain probes caused CJD in an animal subject 2 years after being used in a contaminated patient.

Managing Pathogenic Prion-Contaminated Instruments

Adequate cleaning, soaking in deactivator, and sterilization can render noncomplicated instruments safe for use. Allowing the instruments to dry out before processing makes decontamination difficult. Disposable instruments are preferred when working with a suspected prion infection. Flashing instrumentation for immediate use is never appropriate. Persons processing instrumentation should always wear PPE. Current literature, the World Health Organization (WHO), and AORN (the Association of periOperative Registered Nurses) recommend the following procedures for deactivating prions before handling contaminated items for processing:

1. Keep the instruments moist until they can be cleaned.
2. Wearing appropriate PPE, clean separately from other instruments with an alkaline detergent.
3. Soak contaminated items in sodium hydroxide (NaOH [lye]) or sodium hypochlorite (NaClO [bleach]) for 1 hour. Rinse well. Review the safety data sheets (SDSs) before using these solutions:
   a. *Sodium hydroxide (NaOH):* Available as a commercially prepared solution. Very caustic. Terminology concerning the premixed concentration of the NaOH solution is 1 mole or 1 normal. This means 40 grams of solid NaOH is mixed into 1 liter of water. The container will read "1 molar solution."
   b. *Sodium hypochlorite solution:* 1 part bleach to 5 parts water.
4. Terminally steam sterilize instruments after rinsing for 1 hour at 274° F (134° C) for 18 minutes in a prevacuum sterilizer or at 272° F (132° C) in a gravity displacement sterilizer for 60 minutes before handling.
5. The Joint Commission recommends quarantine of the instrument tray until the patient has been officially declared pathogenic prion free.
6. Environmental surfaces can be cleaned with 1:5 or 1:10 solution of sodium hypochlorite or sodium hydroxide with a contact time of 15 minutes. This includes the instrument tray and sinks used for instrument cleaning. The internal aspect of the washer-sterilizer should be cleaned before using for routine set cleaning resumes.

The process of soaking instruments in sodium hydroxide followed by steam autoclaving is deleterious to surgical instruments and the autoclave, according to the CDC. Autoclaving an instrument immersed in the chemical without a sealed lid can release a gaseous form of sodium hydroxide that may be harmful to humans.

Transmission of Prion Disease

Standard precautions for prevention of bloodborne exposure must be strictly observed. A bloodborne source has been confirmed in the United Kingdom. At least four confirmed cases of vCJD transmission through blood transfusion have been identified. Human illness has been demonstrated after ingestion of beef from BSE-contaminated cattle. As a precaution the FDA recommends that individuals who have spent 6 months or more in the United Kingdom since 1980 defer from donating blood and body tissues for transplantation.

Contaminated neurologic tissue sources include dural grafts, corneal transplants, and human growth hormone. Prion contamination has been found in tonsil tissue, lymphatics, Peyer's patches in the bowel, and the spleen. Suction canister contents and used cleaning solutions should not be disposed of in the sanitary sewer system. Solidifiers may be an alternative disposal method. Incineration is the preferred method for destroying prion contamination.

Postexposure Prophylaxis for Transmissible Spongiform Encephalopathy

Any percutaneous exposure to known or suspected TSE-infected central nervous system tissue should be irrigated with 0.5% sodium hypochlorite (bleach solution). Skin exposure requires a thorough handwash with sodium hydroxide. Mucous membrane exposure should be followed by cleansing with soap and water. To date, no known direct transmission from patient to OR personnel has been reported in the literature.

Fungi

More than 100,000 species of fungi have been identified. Not all fungi are pathogenic (causing mycosis). A *Penicillium* variety is used to make the antibiotic penicillin and give flavor to Roquefort cheese. The blue color of the cheese is caused by collections of spores.

The body responds with an inflammatory response to tissue invasion by a fungus. Respiratory responses include hypersensitivity reaction to fungal antigens. According to statistics compiled by the CDC, the number of health care–associated fungal (mycotic) infections doubled between 1980 and 1990. Fungal infections are classified according to the degree of tissue involvement and mode of transmission.

Characteristics

- *Structure:* Fungi are plantlike structures that lack chlorophyll and therefore are unable to photosynthesize. True fungi are nonmotile. Fungi are eukaryotic and range in size from microscopic to large mushroom forms. Yeast species are single cell but cling together with similar cells. Fungi are aerobic. Molds are multicellular and reproduce by airborne spores that can be inhaled.
- *Life cycle:* A fungus grows as a mold (filamentous, spore forming) or a yeast (round, budlike cells). Molds can reproduce sexually and asexually by forming spore sacs. Yeasts produce buds. A parasitic saprophyte that thrives in a dark, damp, aerobic, warm environment, a fungus lives on decaying material. It can produce toxins referred to as *aflatoxins* and *mycotoxins,* which are found in moldy foodstuffs.
- *Transmission:* Infection can be transmitted by spores in direct contact with the respiratory system, nonintact skin, or mucous membranes.

Fungal Disease Examples

- *Superficial:* Dermatophytes such as tinea (ringworm). Localized to skin, hair, and nails; *Candida albicans* (thrush and vaginitis), athlete's foot.
- *Subcutaneous:* Confined to the dermis and subcutaneous tissue.
- *Systemic:* Infections of internal organs can gain entry via intestinal tract, IV line, or lungs. Respiratory fungal diseases include aspergillosis *(Aspergillus fumigatus),* histoplasmosis (*Histoplasma capsulatum,* commonly found in bat and bird excreta), cryptococcosis (*Cryptococcus neoformans,* found in pigeon excreta).

- *Opportunistic: Pneumocystis* pneumonia (*P. jiroveci,* which was originally thought to be a protozoan. DNA and RNA studies showed it was a red yeast fungus possibly carried on dogs).

Protozoa

Although microscopic, protozoa are relatively large. They grasp and ingest food particles and are motile. Protozoa have many diverse pathogenic mechanisms, although most types are not harmful to healthy humans. Protozoa become pathogenic as a result of opportunistic infection. Each species has a distinct reproductive cycle. Some parasitic protozoa reproduce only in a living host, such as in a female mosquito of the genus *Anopheles* (e.g., *Plasmodium malariae*).

Other species of protozoa living free in watery environments split by binary fission to form two daughter cells. Cryptosporidiosis (*Cryptosporidium parvum* from calves) and toxoplasmosis (*Toxoplasma gondii* from domestic cats) are examples of parasitic diseases that currently cause diseases in humans living in contemporary cities.

Characteristics

- *Structure:* Protozoa are animal-like parasites that are single-cell microorganisms without a morphologically distinct cell wall. They are eukaryotic with chromosomes and aerobic.
- *Life cycle:* Protozoa reproduce sexually (in a sanguineous host) or by binary fission (free in nature). They are capable of walling off and resist drying out by becoming cystic. They can be reactivated by moisture and prefer to live in a watery environment. Larger and more complex than bacteria, they ingest decaying organic matter. They have some diffusion through the cell membrane.
- *Transmission:* Contact is through ingestion of a cyst in soil or water, the fecal-oral route, or more commonly a bug bite. Dissemination is commonly bloodborne directly to major organs. There may be direct contact with the organism through mucous secretions from the genitourinary tract.

Protozoan Disease Examples

Intracellular

- Bloodborne protozoa passed by insect vectors include *P. malariae* that is found in red blood cells and liver cells.
- A localized parasitic infestation passed by the sandfly is leishmaniasis (nonhealing skin lesions. The *Leishmania* organism lives in macrophages).
- A parasite from cats is *T. gondii.*

Extracellular

- Intestinal protozoa acquired free in nature include *Giardia lamblia* (enteritis), which is commonly misdiagnosed because symptoms mimic colitis.
- Genitourinary protozoa include *Trichomonas vaginalis.* Vulvovaginitis or urethritis can be transmitted through sexual contact or fomites.
- Amebic dysentery protozoa include *Sarcodina* and *Entamoeba* species.
- *Trypanosoma cruzi* (South American: Chagas's disease can be extracellular and intracellular; lives in macrophages and muscle cells) and *Trypanosoma rhodesiense* (African sleeping sickness) (parasite lives freely in blood).

Helminths

Adult helminths (worms) are not true microorganisms but are considered parasites in humans and animals. Most adult worms are visible to the naked eye, but the eggs and larvae are microscopic. Symptoms are increased as the number of worms increases. The host responds by increasing immunoglobulin E (IgE) and macrophage levels in the blood to fight the invasion. The eggs and larvae are very irritating to tissues, causing intense granulomatous inflammation.

Large volumes of invading worms can cause mechanical obstruction of lumens, such as in the gastrointestinal tract, or tunnel through organs, such as the heart or lungs. Many intestinal varieties cause nutritional and/or hematologic depletion of the host. If a worm dies while in the host's tissue, it becomes encased in inflammatory exudate. Helminths may be found in immigrant communities or in populations living in rural farmlands with feces in the soil. Young children may acquire pinworms through fecal-oral ingestion in daycare or school settings.

Characteristics

- *Structure:* Morphologically more complex than protozoa, helminths can be round and tubular (nematodes), flat (cestodes), or flat and large (trematodes).
- *Life cycle.* Helminths are hermaphrodites. Eggs are laid in a host and are passed through excreta. Eggs hatch, becoming larvae and reentering a host by penetration or introduction through a vector. Larvae mature in the host, becoming adults capable of self-reproduction. They can become bloodborne and lymph-borne.
- *Transmission.* Introduced by insect bites, some can self-penetrate host tissues and skin and some are acquired by ingesting undercooked flesh from an infected animal or shellfish. Fecal-oral route transmission of eggs and/or larvae is common. Wading in contaminated water permits penetration of skin by active larvae.

Helminth Disease Examples

- Nematode diseases include intestinal pinworms and hookworms, and trichinosis in skeletal muscle of pigs. Filarial worms cause filariasis (elephantiasis), which is transmitted by fly or mosquito bites and becomes bloodborne.
- Cestode diseases include intestinal tapeworms.
- Trematode diseases include bloodborne flukes.

Antimicrobial Therapy

Antimicrobial drugs or agents are adjuvants to—not substitutes for—strict adherence to aseptic and sterile techniques. Perioperative patients receive antibiotics or antimicrobials in several ways in the OR. Routes for administration include the following:

- Oral (PO) administration preoperatively or postoperatively
- IV administration
- Irrigation and lavage
- Implantable disks or timed-release base (i.e., bone cement with timed-release beads)
- Topical solutions or ointments
- Surgical skin prep antiseptics

Antibiotics

Antibiotics act by killing bacteria (bactericidal) or inhibiting the growth of bacteria (bacteriostatic). Antibiotics do not attack other body cells because a higher order cell wall and advanced synthesis are not recognized by the drug.

To be effective, the bacteria must be sensitive to the activity of the antibiotic. Some antibiotic classes are broad spectrum and attack many aerobic and anaerobic bacteria; others selectively destroy specific species. Antibiotics do not affect viruses and many fungi and yeasts. Antibiotics can be used alone or in combination with other antimicrobial drugs. The main actions that enable antibiotics to work include inhibiting cell wall synthesis, inhibiting protein synthesis, or inhibiting genetic activity. These actions can be bactericidal (killing) or bacteriostatic (stopping). Antibiotic categories that inhibit cell wall synthesis are listed in Table 14.3. Antibiotic categories that inhibit protein synthesis are listed in Table 14.4. Antibiotic categories that alter genetic activity are listed in Table 14.5.

The incidence of allergic reactions to antibiotics is relatively high. Patients should be questioned about allergies and known reactions before any drug is administered and should be closely watched for signs of toxicity as evidenced by skin rash, gastrointestinal disturbance, renal disorder, fever, or blood dyscrasias.

The efficacy of antibiotics is greatly reduced when multiple organisms are involved in an infection and if a biofilm has formed. Antibiotics are usually given as follows:

1. Therapeutically to eliminate sensitive viable organisms during a clinical course of infection and in grossly contaminated and traumatic wounds. The choice of antibiotic and the duration of therapy should be determined by clinical factors (i.e., pathogen, severity and site of infection, and clinical response). A broad-spectrum drug may be given while awaiting results of culture and sensitivity tests.
2. Prophylactically to prevent the development of infection. Prophylaxis implies that the microorganism is attacked by the **antimicrobial agent** when it harbors in tissue before colonization takes place. A prophylactic antibiotic is given 30 minutes to 1 hour before the surgical incision and continued for 24 hours postoperatively. These agents are effective as supplements to host defense mechanisms in selected patients. Antibiotic prophylaxis is commonly used as follows:
   a. For procedures associated with brief exposure to possible infection; evidence indicates that antibiotics can reduce infection (e.g., cystoscopy after cystitis).
   b. As of 2010 the CDC recommends using only erythromycin ophthalmic ointment 0.5% for neonatal ophthalmic prophylaxis immediately after birth either vaginally or by cesarean section.
   c. For procedures not frequently associated with infection but when occurrence would have disastrous or life-threatening consequences (e.g., clean wounds; insertion of a prosthetic implant such as a heart valve, vascular graft, or total joint replacement).

TABLE 14.3 Antibiotics That Inhibit Cell Wall Synthesis in Bacteria

Categories	Drug Name Examples	Mechanism	Action	Generation	Gram Stain	Considerations and Cautions
Penicillins (PCN) β-Lactam antibiotics	Amoxicillin Ampicillin Augmentin Carbenicillin Piperacillin Ticarcillin Timentin	Inhibition of cell-wall synthesis	Bactericidal		Pos	Narrow spectrum Safe in pregnancy Hypersensitivity reaction hemolytic anemia, interstitial nephritis Interacts with allopurinol, warfarin, and methotrexate
Cephalosporins β-lactam antibiotics	(see Generations)		Bactericidal	1st Cephalexin 2nd Cefuroxime 3rd Rocephin 4th Cefepime	Pos Neg	Broad spectrum Surgical prophylaxis Safe in pregnancy Renal excretion 10% cross-link to penicillin Colitis
Carbapenems	Doripenem Ertapenem Imipenem Meropenem		Bactericidal		Pos Neg	Broad spectrum Good for anaerobes Given IV Renal excretion
Glycopeptides	Vancomycin		Bactericidal		Pos	Narrow Treat *Clostridium difficile*, endocarditis Ototoxic, nephrotoxic Interacts with cyclosporin, aminoglycosides, diuretics
Monobactams	Aztreonam		Bactericidal		Neg	Found in breast milk and crosses the placenta Hepatotoxic, bone marrow depression
Polypeptides	Bacitracin Polymyxin B Colistin Neomycin		Bactericidal		Pos Neg	Topical prophylaxis for skin infection

TABLE 14.4 Antibiotics That Inhibit Protein Synthesis in Bacteria

Categories	Drug Name Example	Mechanism	Action	Gram Stain	Considerations and Cautions
Macrolides	Erythromycin Azithromycin Clindamycin Ketolide: Telithromycin Cethromycin	Inhibition of protein synthesis	Bacteriostatic	Pos	Broad spectrum, penicillin alternative Ketolide used in anthrax and lung infection Jaundice, hepatitis, prolonged cardiac QT, found in breast milk Interacts with antiarrhythmics, warfarin, statins
Tetracyclines	Doxycycline Minocycline		Bacteriostatic	Pos Neg	Broad spectrum. Not used in pregnancy. Discolors teeth and bones of children younger than 8 years, nephrotoxicity Malaria prophylaxis Treats acne Interacts with warfarin, phenytoin, and carbamazepine
	Gentamycin Streptomycin Tobramycin Neomycin Kanamycin Amikacin		Bactericidal	Pos Neg	Broad spectrum. Not used for anaerobes. IV use for treating septicemia, meningitis. Can be used with other antibiotic treatment Nephrotoxic, ototoxic, aggravates myasthenia gravis Interacts with methotrexate, digoxin, diuretics, and other antibiotics
Chloramphenicols	Chloromycetin		Bacteriostatic	Pos Neg	Broad spectrum. Treats conjunctivitis Not safe in pregnancy or lactation. IV treatment of typhoid Marrow suppression, aplastic anemia. Interacts with anticoagulants, phenytoin, and oral hypoglycemic
Lincosamide	Clindamycin		Bacteriostatic	Pos	Broad spectrum for anaerobes; weaker for aerobes. Excellent bone penetration Treats protozoa, toxoplasmosis, osteomyelitis, intraabdominal sepsis, malaria, and toxic shock. Decreased effectiveness of estrogen contraceptives
Oxazolidinones	Linezolid		Bacteriostatic	Pos	Treats VRE Bone marrow suppression, low platelet count
Glycylcycline	Tigecycline		Bacteriostatic	Pos Neg	Broad spectrum for gram positive. Given IV for intraabdominal and complicated skin infections. Related to tetracycline

IV, Intravenously; *VRE,* vancomycin-resistant *Enterococcus.*

TABLE 14.5 Antibiotics That Inhibit Nucleic Acid Synthesis and Replication in Bacteria

Categories	Drug Name Example	Mechanism	Action	Generation	Gram Stain	Considerations and Cautions
Ansamycin	Rifampin	Inhibition of nucleic acid synthesis	Bactericidal		Pos Neg	Effective for TB, leprosy, and osteomyelitis. Taken with other antimicrobials. Taken on empty stomach. May cause discolored (red-orange) body fluids when taken with clofazimine (dye-based). May need to increase the dose of warfarin. Reduces the effectiveness of hormonal contraceptives. Excreted in breast milk and may cause skin pigmentation in infant. Hepatotoxic
Fluoroquinolones	Clinafloxacin		Bactericidal	1st cinoxacin 2nd ciprofloxacin 3rd levofloxacin 4th trovafloxacin	Pos	Renal excretion. Phototoxicity Interacts with seizure drugs, theophylline, glyburide, and warfarin. May impair bone healing by interfering with chondrocytes
Quinolones	Ciprofloxacin Norfloxacin		Bactericidal		Pos Neg	Broad spectrum. Treats anthrax, salmonella, campylobacter. Central nervous system toxicity. Interacts with phenytoin, NSAIDS, thyroxin, and warfarin Contraindicated in lactation

Continued

TABLE 14.5 Antibiotics That Inhibit Nucleic Acid Synthesis and Replication in Bacteria—cont'd

Categories	Drug Name Example	Mechanism	Action	Generation	Gram Stain	Considerations and Cautions
Sulfanomides	Sulfadoxine Triple sulfa Bactrim Septra Gantrisin		Bacteriostatic		Pos	Treats urinary infections Can cause blood dyscrasia. Avoid in third trimester of pregnancy
Nitroimidazoles	Metronidazole		Bactericidal		Pos Neg	Narrow spectrum. Good with anaerobes. Treats *Clostridium difficile,* trichomoniasis, giardia, should not be used during lactation or 1st trimester of pregnancy (mutagenic). Peripheral neuropathy, intolerance to alcohol Interacts with warfarin and cytotoxics
Nitrofurantoin	Macrobid		Bactericidal		Pos Neg	Treats urinary tract infection, found in breast milk
Other synthesis inhibitors	Isoniazid		Mycobacterial inhibitor		N/A	Treats tuberculosis by inhibiting mycolic acid synthesis
Antifolates	Pyrimethamine		Antimalarial		N/A	Treats malaria by blocking folic acid synthesis
Combination drugs	Artesunate-amodiaquine, artemether-lumefantrine, atovaquone-proguanil					Treats malaria by disrupting the metabolism of the infected cells

NSAIDs, Nonsteroidal antiinflammatory drugs.

d. For procedures associated with a high risk for infection. Organisms are predictable and susceptible to antibiotics (e.g., clean-contaminated wounds such as a biliary tract with obstruction or transection of the colon).
e. Intraoperative irrigation to minimize bacterial colonization; for example, some surgeons use bacitracin 50,000 units/mL of sterile 0.9% sodium chloride, lactated Ringer's solution, or sterile water. Although bacitracin is absorbed by the peritoneal and mediastinal membranes, it is most effective against gram-positive bacteria. It is slowly excreted through the renal system and is contraindicated in patients with renal failure. The irrigation decreases the surface tension of the wound and may decrease the development of biofilm.

The probability of infection is determined in the first few hours after bacterial invasion, when capillary permeability and host inflammatory response are at a peak immediately after bacterial contamination. Therefore timing and duration of drug administration are crucial. To be effective the prophylactic antibiotic must be present in adequate concentration in tissues at the time of wound creation or contamination.

Studies are under way in the prevention of biofilm formation on implants and the potential for disrupting biofilm in situ. Antibiotic hydrogel coatings are being tested on the surfaces of several types of implantable medical and surgical devices. The mechanism is not merely a timed release but a stimulated release in response to ultrasonic waves. Unnecessary antibiotic exposure is avoided, but is there if needed. This provides a more controlled distribution in the site of implantation.

Selection of the appropriate drug and early use are pertinent factors (Box 14.4). The antibiotic regimen is governed by the site of the surgical procedure, potential pathogens to be found, and the patient's history of drug sensitivities. The metabolism and excretion of the drug should be considered, as well as any inherent toxicities. The CDC recommends the following regimen:

- Except for cesarean section, parenteral antibiotic prophylaxis should be started within 1 to 2 hours before a surgical procedure to produce a therapeutic level during the surgery and should not be continued for more than 48 hours. A 12-hour limit is desirable for most types of wounds. Parenteral use for

• BOX 14.4 Selection of Antibiotics According to Gram Stain Reaction

Aerobic Bacteria
- Amikacin
- Ciprofloxacin
- Aztreonam
- Gentamicin
- Ceftriaxone
- Tobramycin

Anaerobic Bacteria
- Chloramphenicol
- Metronidazole
- Clindamycin

Anaerobic-Aerobic Coverage
- Ampicillin-sulbactam
- Imipenem-cilastin
- Cefotan
- Piperacillin-tazobactam
- Ticarcillin-clavulanate
- Cefoxitin
- Ceftizoxime

more than 24 hours increases the risk for antibiotic toxicity and development of resistant strains of bacteria or superinfection and does not further reduce the risk for infection.
- For cesarean section, prophylaxis may be given intraoperatively after the umbilical cord is clamped.
- Oral absorbable prophylactic antibiotics should not be used to supplement or extend parenteral prophylaxis. They should be limited to 24 hours before the surgical procedure when used prophylactically in colorectal operations.
- Topical antimicrobial products used in the wound should be limited to agents that will not cause serious local or systemic side effects.

Resistance to Antibiotic Therapy

Antibiotic resistance is a serious problem costing more than $30 billion annually in the United States. A drastic change in the pattern of life-threatening infections has occurred since the advent of broad-spectrum antibiotics and penicillinase-resistant penicillins. Many of the products used in health care end up in the water supply, causing conditions supportive of an increased antibiotic resistance in environmental microorganisms.

Gram-negative bacilli, both aerobic and anaerobic, deeply concern clinicians, because the incidence of infections by bacteria of supposedly low virulence (e.g., *Serratia* and *E. coli* organisms) is increasing.[9] These microorganisms are capable of causing deep, latent infections, rapidly colonize, and are transferred among individuals by hands or equipment.

Many of these organisms develop plasmid-mediated resistance to antibiotics. This means that a bacterium carrying genetic particles (plasmids) that allow it to replicate will be resistant to it. Resistance can be inherent or acquired.[9] Mechanisms by which bacteria resist antibiotic action include, but are not limited to, the following:

1. Inherent resistance
   a. Bacterium does not absorb the antibiotic by forming an impermeable biofilm membrane. The bacterial cell can coat its molecules or the molecules of the antibiotic with protein to prevent binding between the cell wall and the antibiotic.
   b. Bacterium is able to physically expel, or pump out, the antibiotic. This process is referred to as *efflux.*
   c. Bacterium can render the antibiotic ineffective by chemical or enzymatic means. The action of the antibiotic is changed by material synthesized by the bacterial cell.
   d. Bacterium can alter the molecular or ribosomal target of the antibiotic. A bacterium can physically alter itself, making interaction between the antibiotic and the bacterial cell harmless.
2. Acquired resistance
   a. *Vertical evolution:* A bacterium spontaneously mutates and imparts a chromosome to a member of its own bacterial population.
   b. *Horizontal evolution:* A bacterium with a resistant gene releases that resistant gene to a different bacterial type.

Methicillin-Resistant *Staphylococcus aureus*

MRSA is not plasmid mediated. However, it is resistant not just to methicillin, a penicillin, but to other categories of antibiotics as well. This resistance has probably developed as a result of overuse of these broad-spectrum agents. Clinically MRSA poses an important health care–associated problem, whether by infection of patients or colonization in health care workers.[10] Some patients arrive at the hospital already colonized with community-acquired MRSA. Preoperative bathing with chlorhexidine and or intranasal mupirocin can prevent the patient from developing an infection with MRSA postoperatively.

Vancomycin-resistant enterococci (VRE) have flourished since 1989. Studies have shown that VRE genes can be passed on to other gram-positive cocci, such as vancomycin-resistant *Streptococcus pneumoniae* and *S. aureus* (VRSA). Cases of VRSA have been reported in Japan. The CDC is currently compiling statistics on gram-positive vancomycin resistance. Previous treatment with vancomycin or treatment with multiple antimicrobial therapies increases the risk for VRE. The greatest routes for spread of VRE are the hands of caregivers and contaminated equipment. According to the CDC, prevention of VRE includes, but is not limited to, the following guidelines:
- Education of the staff
- Prevention of transmission by isolating known colonized or infected patients
- Early detection of colonization or infection with VRE
- Screening of all enterococci isolated from blood and body substances (except urine) for vancomycin resistance
- Prudent use of vancomycin

Approved antimicrobial agents have been shown to be effective for the cleaning and disinfection of medical devices and environmental surfaces used in the care of antibiotic-resistant patients. The CDC has not issued timelines for periods of isolation or contact precautions for VRE-infected patients, but three successive negative cultures, 1 or more weeks apart, is one possible guideline that has been used by some institutions.

Antifungal and Antiviral Drugs

Fungal and viral infections can be problematic. Topical antifungal drugs usually control fungus. *C. albicans,* for example, can lead to a fatal opportunistic systemic infection. Candicidin is a specific fungicide for this organism.

Viruses are not usually a risk to a healthy patient undergoing an elective procedure. Hepatitis and HIV present a unique challenge because they are potential threats to the caregiver. Knowledge of the medication and the disease it treats may be required for perioperative patient education. Dosages will vary. As of 2019, there are seven antiviral drug classes available depending on the stage of the HIV virus.[11] Combination drugs are now available for convenience. Examples of available antiviral agents include, but are not limited to, the following medications[11]:
- Ribavirin for respiratory syncytial virus infection
- Zidovudine/dideoxyinosine for HIV infection
- Ganciclovir for CMV infection
- Acyclovir/famciclovir/valacyclovir, tenofovir for HSV infection
- Rimantadine/amantadine for influenza
- Trogarzo, didanosine for retrovirus infection
- Lamivudine, efavirenz for retrovirus infection
- Combination antiretrovirals: Atripla, Biktarvy, Genvoya, Stribild, Cimduo, Combivir, Truvada

Microorganisms in Mass Casualty and Bioterrorism

Health care workers should have a basic familiarity with microorganisms associated with **bioterrorism**. Many terrorist acts against populated areas have resulted in mass casualties that enter the hospital systems. In many circumstances the hospital system will

• BOX 14.5 Microbiologic Agents Used in Bioterrorism

- Anthrax
- Arenavirus
- Botulism
- Brucellosis
- Cholera
- Ebola
- Glanders
- Lassa fever
- Melioidosis
- Plague
- Psittacosis
- Q fever
- Ricin toxin
- Shigella
- Smallpox
- Tularemia
- Typhus

be the first agency to recognize clusters of infections that signal a biologic terrorist attack. Each facility should have a response and reporting plan in place as a first responder to bioterrorism. Agents used in bioterrorism are listed in Box 14.5.

Perioperative personnel should be aware that in the event of a mass casualty, patients may arrive at the facility in a biologically contaminated state. The facility should have a plan for decontamination of these patients before permitting them to enter the general patient population. (Additional information is available at www.ahrq.gov under the search term *mass casualty* and at www.cdc.gov under the search term *bioterrorism.*)

Principles of Aseptic and Sterile Techniques

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Define aseptic technique.
- Define sterile technique.
- Describe the transmission of microorganisms.
- List several principles of Standard Precautions.
- Discuss the obligation of the team to practice aseptic and sterile techniques.

KEY TERMS AND DEFINITIONS

Aerosol Dispersion of fine mist, droplets, or particulate matter into air (transitive verb: aerosolize, to become airborne).

Antisepsis Prevention of sepsis by the exclusion, destruction, or inhibition of growth or multiplication of microorganisms from body tissues and fluids.

Antiseptics Inorganic chemical compounds that combat sepsis by inhibiting the growth of microorganisms without necessarily killing them. They are used on skin and tissue to arrest the growth of endogenous microorganisms (resident flora), and they must not destroy tissue.

Asepsis Absence of microorganisms that cause disease; freedom from infection; exclusion of microorganisms. Not the same as sterile.

Aseptic technique Methods by which contamination with microorganisms is prevented (alternative term: aseptic practice, to maintain asepsis).

Barrier Material used to reduce or inhibit the migration or transmission of microorganisms in the environment. Barriers include attire of personnel, drapes over furniture and patients, packaging of supplies, and filters in ventilating system.

Carrier Person who has potentially pathogenic microorganisms on or in his or her body and disperses them into the environment without becoming ill from the pathogen.

Contaminated Soiled or infected by microorganisms.

Cross-contamination Transmission of microorganisms from patient to patient and from inanimate objects to patients and vice versa.

Decontamination Cleaning and disinfecting or sterilizing processes carried out to make contaminated items safe to handle.

Disinfection Chemical or mechanical destruction of most pathogens rendering an object safe to handle.

Fomite Inanimate object that may be contaminated with infectious organisms and that serves to transmit disease.

Irreducible minimum Microbial burden cannot get any lower. Object is sterile to its highest degree.

Isolation Special precautions taken to prevent the transmission of microorganisms from specific body substances.

Pathogenic Producing or capable of producing disease.

Pathogenic microorganisms Microorganisms that cause infectious disease. They can invade healthy tissue through some power of their own or can injure tissue by a toxin they produce.

Sepsis Severe toxic febrile state resulting from infection with pyogenic microorganisms, with or without associated septicemia.

Spatial relationships An awareness of sterile, unsterile, clean, and contaminated areas and their proximity to each other. This includes the height of scrubbed team members in relation to each other and the sterile field. The circulating nurse must be aware of closeness to the sterile field and the appropriate means to control environmental contaminants.

Standard Precautions Procedures followed to protect personnel from contact with the blood and body fluids of all patients (formerly referred to as Universal Precautions).

Sterile Free of living microorganisms, including all spores.

Sterile field Area around the site of incision into tissue or site of introduction of an instrument into a body orifice that has been

prepared for the use of sterile supplies and equipment. This area includes all furniture covered with sterile drapes and all personnel who are properly attired in sterile garb.

Sterile technique Methods by which contamination with microorganisms is prevented to maintain sterility throughout the surgical procedure.

Terminal sterilization and terminal disinfection Procedures carried out for the destruction of pathogens at the end of the surgical procedure in the operating room or other areas of patient contact (e.g., postanesthesia care unit [PACU], intensive care unit [ICU], nursing unit).

Unsterile Inanimate object that has not been subjected to a sterilization process; the outside wrapping of a package containing a sterile item; a person who has not prepared to enter the sterile field (syn: nonsterile).

What Is the Difference between Aseptic and Sterile Techniques?

The terms *aseptic* and **sterile** are not synonymous, although aspects of both are closely related. An object can be aseptic without being sterile. **Asepsis** literally means "without dirt," and it implies the absence of **pathogenic microorganisms** that cause infection. **Aseptic technique** and **sterile technique** are based on sound scientific principles and are carried out primarily to prevent the transmission of microorganisms that can cause infection. The degree of processing, whether disinfected or sterile, depends on the importance of the item's use in patient care.

Spaulding's Levels of Importance of Patient Care Items

Depending on their intended purpose and body contact, the items and equipment for patient care are classified into the following categories described by Spaulding according to the level of sterility necessary for safe patient care use:

- *Critical:* Any item entering the bloodstream, body tissues underlying the skin, and mucous membranes must be sterile (i.e., free of microorganisms, including endospores). Items include invasive devices, implants, surgical instrumentation, endoscopes, and instrumentation that can come in contact with the vascular system.[1] Critical items must go through the sterilization process, with biologic indicators confirming sterility. These items are handled using sterile technique to maintain sterility.
- *Semicritical:* Semicritical items require high-level disinfection.[1] These items are clean and safe to handle with bare hands (i.e., mechanically cleaned and disinfected to reduce microorganisms, but **unsterile**). Some items are disinfected immediately before use and are handled using aseptic technique to prevent contamination before use. Other items are terminally sterilized between uses on different patients, but sterility is not maintained during storage or use. Examples include vaginal probes, respiratory and anesthesia equipment.
- *Noncritical:* Items that will come into contact with only intact skin or mucous membranes in an area remote from the surgical site may be cleaned, terminally disinfected, and stored unsterile between patient uses. Items include tourniquets, blood pressure cuffs, linens, and positioning devices. No special technique in handling is observed.

Surgical procedures are performed under sterile conditions; contamination with microorganisms is prevented to maintain sterility throughout the procedure. A **sterile field** is created around the site of incision into tissues or the site of introduction of sterile instruments into a body orifice. Conversely all materials and equipment used during a surgical procedure are terminally decontaminated and sterilized after use with the assumption that every patient is a potential source of infection for other persons.

It is essential that all members of the perioperative team know the common sources and mechanisms of contamination by microorganisms in the perioperative environment. The practices of sterile and aseptic techniques are the particular responsibility of everyone caring for the patient in the operating room (OR). All members of the OR team must be vigilant in safeguarding the sterility of the sterile field, because any contamination must be remedied immediately.

Aseptic Technique

It is impossible to exclude all microorganisms from the environment, but for the safety of both patients and personnel, every effort is made to minimize and control these microorganisms. Microorganisms are present in the air and on animate and inanimate objects at all times. To effectively apply the principles of asepsis, environmental control, and sterile techniques discussed in this chapter, the meaning of terms related to aseptic technique must first be understood. Therefore the basis of prevention is the knowledge of causative agents and their control, as well as the principles of aseptic and sterile techniques.[2]

The methods by which microbial contamination is contained in the environment are referred to as *aseptic technique.* The OR in the restricted area is aseptic at best because the room and air cannot ever be 100% free of microbial content. Some key elements of asepsis include the following facts:

- Aseptic technique is sometimes referred to as *clean technique.*
- Items have been cleaned and decontaminated so they are safe to handle with clean, bare hands.
- Items in use in patient care are handled with examination gloves for the protection of both the caregiver and the patient.
- Items have been cleaned, decontaminated, disinfected, or terminally sterilized, and stored in a clean, dry place.
- Items may start out sterile but are not maintained or used under sterile conditions. Skin preps may be packaged sterile, but skin cannot be sterilized. The process is aseptic.
- Contamination is contained. Extraneous contamination is avoided.
- Items are set up on clean towels or drapes and used with examination gloves.
- Items are not sterile or maintained sterile during use. Extraneous contamination is avoided.
- Disposable items are not cleaned and reused for another patient.
- Items are classified as *semicritical* or *noncritical* by Spaulding's classification of the importance of patient care items.

- Items can be used outside the confines of the restricted area.
- Items are used on intact skin or mucous membranes.
- Items are not used when the patient's vascular system will be entered.

Sterile Technique

Sterile technique incorporates many processes associated with asepsis but to a higher, more controlled degree. In sterile technique all microorganisms must be maintained at an irreducible minimum, meaning as low as absolutely possible.

Keep in mind that a sealed sterile package must be opened at some point during patient care to use the contents. That means opening the package to the room air. Even in the restricted area the room air has a microbial count that we cannot eliminate. We try as hard as possible to minimize the room traffic and maintain environmental controls to maintain the sterile field. Essential elements of sterile technique include the following factors:

- Items are used only in a sterile field in the restricted area.
- Items are used by sterile team members wearing appropriate sterile attire.
- Items are used in areas of the patient's body where the site has been prepped.
- Items may be used in invasive surgery.
- Items may be used in body areas with nonintact skin and membranes and may enter the patient's vascular system.
- Items are classified as *critical* according to Spaulding's level of importance of patient care items.
- Items have been cleaned, decontaminated, and packaged before sterilization.
- Items processed by sterilization are stored wrapped and remain so until use by a sterile team member.
- Items are for individual patient use only. Reusable items can be reprocessed and resterilized for use with another patient. Disposable items are discarded after use. If opened and unused, disposable items are discarded.
- Items that become **contaminated** are discarded and replaced immediately.

Transmission of Microorganisms

People remain the major source of microorganisms in the environment. In the OR the surgical team is the most common source of transmission, followed by contaminated instrumentation. Everything on or around a human being is contaminated by the body in some way. The action and interaction of personnel and patients also contribute to the prevalence and dispersion of microorganisms.

There are many sources of contamination in the OR environment. Transmission-based precautions should be implemented in the perioperative environment and in any area with the potential to transmit potentially pathogenic microorganisms. Transmission-based precautions are described in Box 15.1. Perioperative personnel are concerned primarily with protecting the environment of the OR suite because surgical procedures should be performed under optimal conditions.[2]

Most microorganisms grow in a warm, moist host, but some aerobic bacteria, yeasts, and fungi can remain viable in the air and on inanimate objects. Because the OR can provide only an aseptic environment, infection control practices for the minimization of microbial counts include the following options:

- OR ventilation, humidity, and temperature controls
- **Decontamination**, **disinfection**, and sterilization methods

• BOX 15.1 Transmission-Based Precautions

Airborne

The use of special air handlers and ventilation and respiratory protection is recommended for susceptible people. Contaminated air currents can settle on or be inhaled by those who are susceptible.

Particles smaller than 5 mm may carry airborne droplet nuclei. Examples of airborne diseases include varicella, tuberculosis, and rubeola.

Droplet

A distance of more than 3 ft from the source patient is recommended. Masks should be worn by those closer than 3 ft and should be worn by the source patient during transport. Droplet particles are larger than 5 mm and are disseminated during coughs, sneezes, and talking. Droplets do not travel more than 3 ft and are not suspended in the air. Examples of droplet diseases include diphtheria, mumps, pertussis, and influenza.

Contact

The use of gloves when coming into contact with items contaminated with blood or body substances is recommended. Gowns are recommended if there is a potential for contamination of clothing.

Cleaning and disinfecting patient care equipment after use protects other patients.

Data from U.S. Department of Health and Human Services: (website). www.hhs.gov; and Centers for Disease Control and Prevention: (website). www.cdc.gov.

- Improved **barriers**, such as impervious drapes between sterile, clean, and contaminated surfaces
- Surgical technique and tissue handling
- Antimicrobial prophylaxis is used only as appropriate

Despite advances, surgical-site infections (SSIs) continue to cause significant morbidity and mortality in surgical patients. Emergence of resistant microorganisms is complicated by patients with comorbid disease and the increasing numbers of implants and transplants. Microbiologic considerations and specific microorganisms that concern the perioperative team are described in Chapter 14.

Factors to consider when evaluating the reasons for the emergence of antibiotic-resistant microorganisms include the following:

- Inadequate or inappropriate uses of antibiotic
- Overuse of antimicrobials and **antiseptics** shed into the waterways and environment
- Sequestered microorganisms in biofilm or retained foreign body
- Inadequate infection control practices

Human-Borne Sources of Contamination

Skin

The skin of patients, OR team members, and visitors constitutes a microbiologic hazard. Sebaceous (oil) and sudoriferous (sweat) glands contain abundant resident microbial flora, many of which have the potential to become **pathogenic** if colonized in greater than average numbers or if colonized on a weakened host. In an average individual an estimated 4000 to 10,000 viable contaminated particles are shed by the skin each minute. Some disperse up to 30,000 particles per minute; these individuals are referred to as *shedders.* Shedders are densely populated with virulent organisms, such as *Staphylococcus aureus,* and shed contaminated skin cells into the environment.

Patients who are shedders have a much higher incidence of infection at the surgical site. On all individuals the major areas of

microbial shedding include the head, neck, axillae, hands, groin, perineum, legs, and feet. Cosmetic detritus and body powders are also laden with potential pathogens. Microbial shedding is contained effectively by appropriate antiseptic cleansing and maximum skin coverage.[2]

The following list includes vital points for all personnel entering the OR:

- Bathe daily with soap and water.
- Wash hands before entering the OR suite and after every patient contact to prevent infection and cross-infection. Hands should be washed before donning gloves and after removing them, because gloves are not 100% impervious. Handwashing technique involves vigorously rubbing together all surfaces of well-lathered, soapy hands, followed by rinsing under a stream of water.
- Don clean OR attire for each entry into the OR suite. Unsterile team members should wear long-sleeved warm-up jackets that are fully buttoned.
- Cover any cuts and abrasions. Open wounds on the skin are portals for infection, and infected wounds can disseminate microorganisms.
- Wear gloves when handling blood, body fluids, or tissue specimens, and wash hands after removing sterile and unsterile gloves.

Hair

Hair is a gross contaminant and a major source of staphylococci. The extent to which the microbial population is attracted to and shed from hair is directly related to the length and cleanliness of the hair. Hair follicles and filaments harbor resident and transient flora. Hair can become a mechanical irritant in wound healing and cause a foreign body tissue reaction. Hair should be shampooed frequently. Clean caps or hoods are worn to cover the scalp, all hair, including facial hair.[3] The nape of the neck and ears should be covered. Surgeon's skullcap styles do not enclose the hair at the nape of the neck and do not cover the ears. Hair should be contained at all times in semirestricted and restricted environments.[4]

Microorganisms forcibly expelled by talking, coughing, or sneezing give rise to bacteria-laden dust and lint as droplets settle on surfaces and skin. **Carriers** harbor many organisms, most notably group A streptococci and *S. aureus,* without experiencing the harmful physical effects of infection. Surgeons and anesthesia providers may be carriers more so than other caregivers because of their intimate contact with patients' respiratory tracts.

Shedders and carriers may be identified through nasopharyngeal culturing. Some departments, such as obstetrics and the newborn nursery, may require routine periodic nasal cultures as a condition of employment. Positive nasal carriers can be treated with antimicrobial nasal spray or ointment. When multiple patients develop the same or comparable postoperative infections, infection control teams at the facility actively seek the source of the infection.

Masks are worn in all restricted areas to cover the nose and mouth and should be changed after caring for each patient. Masks protect the wearer and the patient. Coughing and sneezing explode droplets into the environment, and therefore people with a respiratory infection should not be permitted in the OR suite. Talking should be kept to a minimum. The contaminated mask should be handled only by the ties and not by the facial portion for disposal.

Human Error

Direct person-to-person contact is the most common route of transmission. Human error is an exogenous source of contamination, and it is not to be underestimated. Failure to follow the principles and applications of sterile and aseptic techniques places the patient and personnel at risk—a risk that could be prevented. Errors should be readily admitted and corrected.

Cross-Infection

Every patient in the OR should be considered a potential source of infection. **Standard Precautions** and routine aseptic techniques are observed whether or not a patient is known to have an infectious condition. All patients should be treated as though they have a known infection. Care, caution, and conscientiousness on the part of all team members are essential at all times. Thorough handwashing after every patient contact is important.

Nonhuman Factors in Contamination

Fomites

Fomites are contaminated particles present in the dust that rests on inanimate objects such as furniture, OR surfaces (e.g., walls, floors, cabinet shelves), equipment, computer keyboards, cabinet handles, supplies, and fabrics. Covert contamination may result from improper handling of equipment such as anesthesia apparatus or intravenous (IV) lines and fluids. Contamination also may result from the administration of unsterile medications or the use of unsterile water to rinse sterile items. Any unsterile item placed within the sterile field causes contamination and increases the risk for infection.

In maintaining an aseptic environment, the following points should be considered:

- Prompt disinfection and decontamination of used equipment and reusable supplies.
- Prompt disinfection of OR surfaces (e.g., disinfecting furniture, lights and floors, disposing of waste and laundry).
- Separation of clean and soiled items. Sterile storage areas are physically separated from decontamination areas.
- Proper packaging and storing of supplies. External shipping cartons should be removed before bringing supplies beyond the unrestricted area in the OR suite. Insects and rodents can gain entrance to the suite in corrugated cartons.
- Placement of dust covers over sterile items during transport and while in prolonged storage.
- Dispensing medication to the sterile field in the correct form and with the recommended device.

Air

The perioperative environment contains thousands of particles per cubic foot of air. During a long surgical procedure the particle count can rise to more than 1 million particles per cubic foot. Air and dust are vehicles for transporting particles laden with microorganisms. Heat rises and therefore the lights and other heat-generating equipment of the OR produce convective up-currents referred to as thermal plume.

Personnel walking about the room can generate airborne contamination; every movement increases the potential for infection of the surgical site. Traffic should be kept to an absolute minimum. Particulates bearing microorganisms become airborne and settle in an open wound.

Between 80% and 90% of the microbial contaminations found in an open surgical site come from ambient (room) air.

Beta-hemolytic streptococci have been directly traced from contaminated personnel and contamination of a patient. The actual microorganism was recovered from the room air.

Microorganisms have an affinity for horizontal surfaces, of which the floor is the largest. From the floor, microorganisms are projected into the air. Endogenous flora from the patient's skin, oropharynx, tracheobronchial tree, and gastrointestinal tract, as well as exogenous flora, also are significant. Microorganisms from patients or carriers settle on equipment and flat surfaces and then become airborne. Airborne particles increase significantly during the activity before incision and after wound closure. Relief personnel create significant air currents. The potential for contamination increases each time the door to the OR opens and closes.

An effective ventilation system is essential to prevent patients and personnel from breathing potentially contaminated air, which can predispose them to infection.

Sources of Infection

The incidence and types of infections that occur in surgical patients may be the result of a preexisting localized infectious process, a systemic communicable disease, or an acquired perioperative complication.

Community-Acquired Infection

Community-acquired infections are natural disease processes that developed or were incubating before a patient's admission to the hospital or ambulatory care facility. Patients known to be carriers of nasal microorganisms can be treated preoperatively to minimize some of the risk.

Communicable Infection

Systemic bacterial, viral, or fungal infections may be transmitted from one person to another. These infections are discussed in detail in Chapter 14.

Spontaneous Infection

Examples of localized infections that require surgical diagnosis and treatment for management or that occur as an adjuvant to medical therapy include acute appendicitis, cholecystitis, and bowel perforation with peritonitis. Therapy consists of identification of the infection site and causative microorganism, excision or drainage, prevention of further contamination, and augmentation of host resistance.

Health Care–Acquired Infection

An infection is considered health care–acquired (HAI; formerly referred to as *nosocomial*) during the course of health care if it was neither present nor incubating when the patient was admitted. The nurse admitting the patient must document anything that was present on admission or the assumption is that the patient became infected at the facility. This is grounds for Medicare to deny payment.

Approximately 25% of all health care–acquired *S. aureus* infections develop in surgical patients.[2] They may occur as complications of surgical or other procedures performed on uninfected patients. They also may occur as complicating infections in organs unrelated to the surgical procedure that occur with or as a result of postoperative care. The majority of HAIs are related to instrumentation of the urinary and respiratory tracts. Microbial colonization is the primary component of HAI. The potential for SSIs can be conceptualized in the following equation:

$$\frac{\text{Dose of contamination} \times \text{virulence}}{\text{Resistance of the host}} = \text{Risk for SSI}$$

The following list includes examples of HAIs:

- Urinary tract and respiratory tract infections and infected pressure and stasis ulcers
- Cellulitis and abscess formations in pressure sores
- Thrombophlebitis, which is a regional extension of postoperative IV infection
- Bacteremia and septicemia, the postoperative systemic infections that result from dissemination of microorganisms into the bloodstream from a distributing focus
- Septicemia caused by intravascular catheters
- Persistent infections at the site of surgical implants

Exogenous

An exogenous HAI is acquired from sources outside the body such as personnel or the environment. **Cross-contamination** occurs when organisms are transferred to the patient from another individual or inanimate object.

Endogenous

An endogenous infection develops from sources within the body. Most postoperative wound infections result from seeding by endogenous microorganisms. Disruption of the balance between potentially pathogenic organisms and host defenses permits the invasion of microorganisms for which the patient is the primary reservoir. For example, abdominal **sepsis** may result from enteric flora if the intestine is perforated or transected.

Criteria for Defining a Surgical Site Infection

According to the Centers for Disease Control and Prevention (CDC), an SSI is the most common type of infection reported. For example, the hospital stay was significantly increased, thereby exposing the weakened patient to increased risk for additional infections. A synopsis of the criteria for defining an SSI as described by the CDC is presented in Table 15.1.

Environmental Controls

Control of the environment is a necessary part of overall infection prevention. The inanimate and animate environment of the OR suite presents a risk for the transmission of microorganisms. The aim of a microbiologically controlled environment is to keep contamination to a minimum. The key to controlling microorganisms lies in the knowledge of their favorable living conditions. Best practices in asepsis should be rooted in prevention of proliferation and spread of microorganisms.

All health care facilities should incorporate into their policies and procedures the recommendations for infection control from the CDC, as well as the regulations for the prevention of exposure to bloodborne pathogens from the Occupational Safety and Health Administration (OSHA). [5,6]

The perioperative environment is designed to optimize function, safety and protect patients from sources of contamination. The surgical suite includes specific areas for traffic, support systems, administration, communication, and storage, as described in Chapter 10.

Traffic patterns are designed to flow smoothly and prevent backtrack and crossover traffic. Clean and soiled activities, areas,

TABLE 15.1 Criteria for Defining a Surgical Site Infection (SSI)

Superficial Incisional SSI	Deep Incisional SSI	Organ/Space SSI
Infection occurs within 30 days of the surgical procedure. Infection involves only skin or subcutaneous tissue of the incision and at least one of the following symptoms from the superficial incision unless the wound is culture negative: 1. Purulent drainage from the incision, x-ray with or without laboratory confirmation 2. Organisms isolated from an aseptically obtained culture of fluid or tissue 3. At least one of the following signs or symptoms of infection: a. Pain or tenderness b. Localized swelling c. Redness or heat d. Surgeon deliberately opens the incision 4. Diagnosis of superficial incisional SSI by the surgeon or physician Do not report the following conditions as superficial SSI: 1. Stitch abscess (minimal inflammation and discharge) confined to the points of suture penetration 2. Infection of episiotomy or newborn circumcision site (these have separate criteria) 3. Infected burn wound	Infection occurs within 30-90 days after the procedure. Infection involves deep soft tissues (e.g., fascial and muscle layers) of the incision and at least one of the following symptoms unless the site is culture negative: 1. Purulent drainage from the deep aspects of the incision but not the organs or compartments 2. A deep incision spontaneously dehisces or deliberately opened by the surgeon because of: a. Fever >100.4° F (38° C) b. Localized pain 3. Diagnosis of deep SSI by physician or surgeon Additional factors: 1. Report combined superficial and deep infections as deep SSI 2. Report organ space or deep infection that drains through the incision as deep SSI	Infection occurs within 30-90 days after the procedure. Infection involves any part of the anatomy (e.g., organs or spaces) other than the incision that was opened or manipulated during an operation and at least one of the following symptoms: 1. Purulent drainage from a drain that is placed through a stab wound into the organ or space 2. Organisms that are isolated from an aseptically obtained culture of fluid or tissue in the organ or space 3. An abscess or other evidence of infection involving the organ or space that is found by direct examination or by x-ray

From the Centers for Disease Control and Prevention: Surgical site infection event: procedure-associated module 2019 (website). www.cdc.gov (Accessed 5 November, 2019).

and personnel and sterile and unsterile supplies should be distinctly separated.

Impervious barriers such as sterile drapes, gowns, and gloves protect sterile areas, isolate surgical sites, and keep the number of microorganisms to an **irreducible minimum**. These barriers must remain impervious to the passage of microorganisms under ordinary operating conditions. Procedures are established to use barriers effectively against microorganisms from any potential source of contamination.

Environmental Services/Housekeeping

Housekeeping practices that use the most effective supplies, techniques, and equipment available are an important aspect of infection control. Policies and procedures for cleaning should be in place. Employees should be educated in the spread of pathogens and special disinfection products. Proper training and cleaning procedures are mandatory requirements. Housekeeping procedures include cleaning and disinfecting the perioperative environment, handling soiled laundry, and disposing of solid waste. Disinfectants are used in combination with thorough mechanical cleaning. These procedures are performed by environmental service personnel under supervision and are carried out according to established practices, policies, and schedules, as described in Chapter 12. Of primary concern are locations that by design or construction are difficult to clean (e.g., lavatories, workrooms) and areas that may be touched by patients or personnel.

Any equipment requiring water in its operation can support microbial growth, especially if the water is not changed frequently. Unsterile water, the universal solvent and transporter, can support, maintain, and protect almost every contaminant produced by human beings. Water especially supports the growth of gram-negative bacilli, including *Serratia* and *Pseudomonas.*

Airborne aerosolized particles produced during hand scrubs can contaminate the area around the scrub sink. Disinfectants reduce the contamination potential of unsterile cleaning water.

The following housekeeping points are especially relevant to infection control and the prevention of cross-infection and are listed to emphasize the importance of aseptic environmental control:

- The faucet head should be of a type that does not hold water and should be removed for **terminal sterilization**. Containers for antiseptic hand hygiene agents should be disassembled, cleaned, and terminally sterilized before refilling.
- No surface should remain wet, which would support microbial growth and the formation of biofilm.
- Organic debris should be promptly removed from walls and other surfaces with a disinfectant to prevent drying and airborne contamination.
- Lights should be cleaned after every procedure. Overhead tracks should be cleaned upon completion of the day's schedule.
- The entrance to the OR suite and the floors in corridors and rooms should be cleaned at the end of the day's schedule.
- Housekeeping equipment should be cleaned and dried for storage. Moisture and darkness are conducive to microbial growth.
- Disposable trash should be separated into infectious and noninfectious waste and put in impervious receptacles.
- Service elevators rather than chutes should be used to remove soiled laundry and waste/trash from the OR suite. Chutes become grossly contaminated with airborne particles and are a fire hazard.
- Waste should be contained at the source of origin to prevent **aerosol** generation during handling. Contaminated waste is decontaminated and/or sterilized before compaction or disposal in

the general environment. Incineration is the most effective means of waste disposal, especially of infectious wastes. However, health care facilities must comply with local, state, and federal regulations for contamination control and waste disposal.

- Adequate time must be allowed between patients for proper **terminal disinfection** of the OR. A patient must not be assigned to an inadequately cleaned OR, which could be a source of an SSI.
- All areas and equipment throughout the perioperative environment should be cleaned on a scheduled basis as defined by institutional policy. These areas include the grilles, vents, and filters of the air conditioning system; storage shelves and cabinets; lighting fixtures; walls; and other areas in offices, lounges, dressing rooms, storage areas, workrooms, and corridors. Handles of cabinets and push plates of doors should be cleaned several times daily.

Control of Airborne Contamination

Air currents and movement in the OR should be kept to a minimum to prevent airborne contamination. Viable microorganisms from the air settle on horizontal surfaces. Proper cleaning of these surfaces helps control this contamination. The ventilating system and efforts to minimize air turbulence and contaminants also are important factors. Doors to the OR should remain closed during the procedure to maintain a positive pressure atmosphere.

When properly designed, installed, and maintained, a conventional air conditioning system effectively reduces the number of airborne organisms by removing dust and aerosol particles. Air contaminated by dust and lint is removed as fresh, clean outside air is supplied. Recirculation of filtered air at a minimum rate of 20 volume exchanges per hour, at least four of which are fresh air, is considered safe and economical as recommended by the American Institute of Architects in collaboration with the 2018 Facility Guidelines Institute *Guidelines for Design and Construction*. However, fire codes in some states require 100% outside fresh air. All air, whether recirculated or fresh, is filtered before entering the OR. The system uses high-efficiency particulate air (HEPA) filters to remove particles larger than 0.3 mm.

Air enters from a ceiling vent, is diluted, and passes through vents at floor level. Filters are located downstream from the air-processing equipment so microorganisms will not be drawn into the room. The system maintains a positive pressure if the doors to the room remain closed.

Laminar Air System

Often referred to as ultraclean airflow, a special air-handling system for the filtration, dilution, and distribution of air may be installed in one or more ORs. High-risk procedures such as total joint replacement, cardiac surgery, and organ transplantation are performed in this environment. Laminar airflow is a controlled, unidirectional, positive pressure stream of air. More information about laminar airflow is found in Chapter 10.

Doors

The doors to the OR should be kept closed except as necessary for passage of the patient and personnel and supplies and equipment. If the door is left open, the positive air pressure in the room equalizes with the negative air pressure in the hallway. Disrupted pressurization mixes the clean air of the OR with the corridor air, which has a higher microbial count. Cabinet doors should also remain closed.

Traffic and Movement

Traffic in and out of the OR is kept to a minimum. Only essential personnel should be allowed inside the OR. The amount of activity in the room increases as the number of people present increases. This in turn increases the potential for contamination as a result of the shedding and air turbulence that carries microbes to the wound. Movement in the OR should be reduced to a minimum.

Lint

Agents are added to the final rinse during laundering to minimize the lint that results from the friction of woven fibers against each other. Disintegrated paper from disposable nonwoven products is another source of lint on fabrics. Therefore paper products should not be discarded in the same receptacle as soiled reusable woven fabrics.

Isolation Precautions

The **isolation** of patients by diagnosis or body substance is related to the mode of transmission of pathogenic microorganisms (i.e., air, droplet, contact). A patient with a communicable disease could need emergency surgery, and perioperative personnel should know about appropriate patient handling and exposure precautions. A communicable disease such as tuberculosis (TB) could be diagnosed via bronchoscopy.

Isolation precautions and guidelines are discussed in detail in hospital procedure books and in the CDC's *Guidelines for Isolation Precautions in Hospitals* and the www.osha.gov web-site. There are different methods of the isolation technique, as follows[5,6]:

- Category-specific isolation precautions for patients with suspected or confirmed communicable disease transmitted either by droplets via the airborne route (e.g., pulmonary TB) or by enteric excretions, drainage, or secretions
- Disease-specific isolation precautions for contact with patients known to be infected with specific pathogens
- Body-substance isolation precautions incorporating Standard Precautions for contact with all body substances of all patients, regardless of the diagnosis (all patients are considered contaminated)
- Protective isolation for immunosuppressed patients

The purpose of these precautions is to prevent the transmission of pathogenic microorganisms. Isolation and barrier techniques protect both personnel and other patients. Each hospital may incorporate into its procedures whichever methods are most appropriate for its particular needs and patient population.

The perioperative staff should be informed that a patient requires isolation precautions before that patient comes to the OR. Some situations, such as pulmonary TB, require the use of HEPA masks for the staff and the patient.

For most patients the same precautions apply in the OR as on the patient care unit, and a commonsense approach is used. In all types of isolation the most important infection control measure is thorough handwashing before and after close patient contact; after handling contaminated objects, body fluids, and excretions; and between patients.

Isolation techniques must not be implemented in a way that causes the patient to feel ostracized. Patients should be educated to understand that the isolation protects them as well as the caregiver and that they must comply with the regimen.

Standard Precautions

As established by the CDC and enforced by OSHA, Standard Precautions (formerly referred to as Universal Precautions) protect

health care workers from contact with blood and body fluids of all patients. Standard Precautions include the following considerations:

- All body fluids
- Handwashing
- Barrier clothing
- Handling of used patient care equipment and linen
- Occupational exposure to bloodborne pathogens
- Patient placement and management

Recommendations for Standard Precautions have been modified to reflect routes of transmission. The format for the CDC's identification of routes of transmission includes airborne, droplet, and contact precautions. The potential for becoming infected through skin exposure depends on colonization, duration of contact, the presence of skin lesions on the hands, and immune status.

Standard Precautions supplement other recommended practices for environmental controls and are the minimum precautions for all invasive procedures. An invasive procedure involves any entry into body tissues or cavities in any procedural environment. Standard Precautions are in effect for any procedure during which bleeding occurs or for which the potential for bleeding or exposure to body substances exists. The following list involves Standard Precautions[6]:

1. *Protective barriers and personal protective equipment (PPE):* Appropriate barriers, such as PPE, prevent contact of the skin and mucous membranes with blood and body substances. PPE and other barrier materials must prevent blood and other fluids from passing through or reaching the wearer's clothing or body. The type of PPE used depends on the task and the degree of anticipated exposure. Examples include gloves, eyewear, gowns, hair covers, and masks.
   a. Gloves reduce contamination of hands. Intact gloves, both sterile and unsterile, are used. Latex, vinyl, and other materials are used in the manufacturing of these gloves. Care is taken to avoid natural rubber latex when either the patient or the caregiver has a latex sensitivity. Vinyl may be more permeable to some viruses than is latex.
      (1) Sterile gloves are worn for procedures that involve the invasion of body tissues when a sterile field is created.
         (a) Double-gloving does not prevent puncture wounds but may be appropriate for procedures in which the risk for glove tears is high.
         (b) Sterile glove liners may provide protection from glove tears and skin cuts, particularly when working with heavy orthopedic equipment. Double-gloving also may substantially reduce the risk for exposure from the seepage of blood and fluid through gloves onto hands during long procedures or in the presence of voluminous blood loss. No glove is 100% impervious.
      (2) Unsterile latex or vinyl examination gloves are worn for procedures that do not require a sterile field, such as handling specimens, placentas, newborns, and contaminated items (e.g., sponges). Powdered gloves leave a residue that may carry latex particles.
      (3) General purpose utility gloves are worn for cleaning instruments and for decontaminating and housekeeping procedures involving potential blood contact. These heavy-duty gloves may be decontaminated and reused.
      (4) Gloves are changed after every contact with patients or contaminated items. Latex and vinyl gloves are discarded. Washing gloves between patient contacts is not an acceptable practice.
      (5) Hands are washed immediately after glove removal. All gloves have microscopic holes and may be permeable to certain substances or microorganisms. The mechanical and chemical actions of handwashing significantly decrease the risk associated with the permeability of glove materials.
   b. Masks protect personnel from aerosols and patients from droplets. They are worn for all invasive procedures. Specialty masks to filter laser plume are commercially available. The mask should be changed immediately if grossly contaminated by a splash of blood or body fluid. Patients with a known infectious process such as varicella, TB, or rubeola should wear a HEPA mask during transport to and from the OR.
   c. Eyewear with side shields protects the mucous membranes of the eyes and full face shields protect the mucous membranes of the eyes, nose, and mouth. They are worn for procedures in which blood, bone chips, amniotic fluid, and the aerosol of other body fluids may splash or be projected into the eyes. Goggles with enclosed sides and chin-length face shields offer better protection than do simple eyeglasses.
   d. Gowns or aprons made of fluid-resistant material protect the wearer from a splash with blood and body fluids. A plastic apron may be worn under a woven fabric gown. Impervious gowns offer better protection. Disposable impervious gowns are preferred.
   e. Shoe covers or boots protect the wearer when gross contamination on the floor can be anticipated. Grossly soiled shoe covers or knee-high disposable boots are removed before the wearer leaves the room.
2. *Prevention of puncture injuries:* Needles, knife blades, and sharp instruments present a potential hazard for the handler and user. Skin may be punctured or cut if caution is not taken. Specific recommendations for handling disposable surgical needles, syringes and needles, and knife blades (collectively referred to as *sharps*) include the following guidelines:
   a. Do not manipulate sharps by hand. Use an instrument such as a heavy hemostat to attach and remove the scalpel blade. Arm the needle directly from the suture packet when possible. Do not bend or break an injection needle. Pass needles in a needle holder or use a "neutral zone" to transfer sharps on the field. Sharp instruments and needles may be passed on a puncture-resistant tray or magnetic mat for a hands-free technique rather than from hand to hand. Remove instruments from the surgical field after use, and return them to the Mayo stand or instrument table promptly.
   b. Do not recap used injection needles by hand except with a recapping safety device. Use a one-handed technique in the sterile field.
   c. Do not remove the needle from a disposable syringe by hand after use. Use a hemostat or other instrument to exchange or remove a hypodermic needle from the syringe.
   d. Place all used sharps in a puncture-resistant container for disposal.
3. *Management of puncture injuries:* If a glove is torn or punctured, remove the puncturing sharp or instrument from the sterile field immediately and change the glove promptly, using the open-glove method. If the skin is punctured or cut, remove both gloves immediately. If both gloves are not removed, the risk for introducing microorganisms from the remaining contaminated glove is increased. Squeeze the skin to release blood. Wash out contaminants under running water with an antiseptic; then irrigate the wound with a virucidal disinfectant such as an iodophor, bleach, or hydrogen peroxide.

   Report the incident immediately, and document all actions on the appropriate forms. Baseline testing may be necessary for both the punctured individual and the patient. These actions

are necessary to protect the employee and the patient should either party seroconvert to a positive status at a later date. OSHA has provided guidelines for immediate treatment of a needlestick at www.osha.gov.[6]

4. *Oral procedures:* Contact with blood-contaminated saliva and gingival fluid is expected during dental and surgical procedures in the oropharyngeal cavity. Mouth protection, Ambu bags, and/or other ventilation devices should be available for emergency airway resuscitation. Respiratory secretions coughed up during endotracheal procedures are often infectious.
5. *Care of specimens:* All specimens and cultures of blood, body fluids, and tissues should be contained in a puncture-resistant container to prevent leaking during transport to the laboratory. The outside of the container should be clean and enclosed within a biohazard-labeled plastic bag. Care is taken not to get blood and body fluids on the pathology requisition slip.
6. *Decontamination:* All instruments are thoroughly decontaminated and cleaned before sterilization or high-level disinfection. The surfaces of furniture and floors are cleaned and decontaminated with a detergent-disinfectant. Blood or body fluids that have spilled on the floor during a procedure should be wiped up immediately and the area decontaminated. Gloves, masks, and eyewear are worn for cleaning procedures.
7. *Laundry:* Soiled woven fabrics should be handled as little as possible and are transported to the laundry in leakproof bags. Unused, folded linens should be completely opened before placing in the linen hamper. All laundry is considered contaminated and should be handled only by gloved hands. Laundry should be washed in water at 160° F (71.1° C) or higher with 50 to 150 parts per million (ppm) of chlorine bleach. Temperatures lower than 160° F can be used for washing laundry if the appropriate antimicrobial detergent is used.

   Commercial dry cleaning uses chemicals that reduce the transmission of pathogens. Home laundering of surgical scrub suits may not consistently meet parameters for adequate disinfection.
8. *Waste:* Blood and suctioned fluids may be safely poured down a drain connected to a sanitary sewer. A solidifying agent can be added to disposable suction containers to disinfect the contents and convert it into solid waste. Trash is disposed of by incineration or sent to a sanitary landfill in sealed containers as required by local ordinances or state regulations. Trash bags must be leakproof and of sufficient thickness and strength to ensure integrity during transport. For disposal purposes, waste may be differentiated as either infectious or noninfectious. Bags are either color-coded (e.g., red for infectious waste) or labeled as biohazard.
9. *Handwashing:* Thorough handwashing with an approved antimicrobial agent after every contact with a patient, contaminated items, or suspected contamination protects both the patient and personnel and cannot be overemphasized. Hands should be washed after removing contaminated gloves because gloves are not 100% impervious.
10. *No touching of mucous membranes:* Eating and drinking are prohibited in any area where there is a risk for exposure. Applying lip balm or cosmetics or adjusting contact lenses in the perioperative environment significantly increases the risk for exposure. Hand-to-mouth and hand-to-eye contact can contribute to microbial transmission.
11. *Prophylaxis:* Perioperative personnel are encouraged to know their human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV) antibody status. The disclosure of a positive status to the appropriate facility is recommended. Personnel who participate in invasive procedures are at risk for bloodborne exposure and should have the HBV immunization series. Some facilities require personnel to get vaccinated or prove immunity by having titers drawn before being hired. Personnel who choose not to have the immunization series because of a past allergic reaction or special circumstance need documentation and should sign a release stating the declination. The CDC offers a 2019 recommended adult immunization schedule. Individuals should consult a physician about necessary immunizations.

For personal protection and the safety of patients, all health care providers should be familiar with policies and procedures and must understand the need for Standard Precautions. A health care provider should report a blood or body fluid exposure as defined by policy. The surgeon and first assistant usually are at greatest risk. Comparably a patient should be informed of any incident in which he or she is exposed to the blood of a health care provider.

Principles of Sterile Technique

Sterile technique is the foundation of modern surgery. The patient is the center of the sterile field, which includes the personnel wearing sterile attire and the areas of the patient, operating bed, and furniture that are covered with sterile drapes. The level of the surgical site is the central focus of the level of the sterile field. Strict adherence to the recommended practices of sterile technique reflects the surgical conscience of the perioperative team and is mandatory for the safety of the patient and personnel in the environment. The principles of sterile technique are applied under the following conditions:

- In preparation for an invasive procedure by sterilization of necessary materials and supplies
- In preparation of the sterile team to handle sterile supplies and intimately contact the surgical site by scrubbing, gowning, and gloving
- In the creation and maintenance of the sterile field, including skin preparation and draping of the patient
- In the maintenance of sterility throughout the entire surgical procedure; breaches in sterility are remedied immediately
- In terminal decontamination, disinfection, and sterilization at the conclusion of the surgical procedure

Only Sterile Items Are Used Within the Sterile Field

Items such as sterile instrument sets, drapes, sponges, and basins are obtained from the sterile core. Only if absolutely necessary, items such as unwrapped instruments may be steam sterilized immediately before the surgical procedure and taken directly from the sterilizer to the sterile field. This rapid steam sterilization method is referred to as *flashing* and must be used only if no other alternative is available. Facilities must keep a record of each time flashing is used and the items, parameters, and individuals involved.

Every person who dispenses a sterile item to the field must be sure of its initial and continued sterility until used. Proper packaging, sterilizing, delivery to the field, and handling should provide such assurance. If there is any doubt about the sterility of any item, it should be considered unsterile and therefore should not be used. The phrase "when in doubt, throw it out" applies to this situation. Examples of questionably sterile items include, but are not limited to, the following situations:

- If a sterilized package is found in a contaminated area (e.g., the general unsterile workroom, the locker room).

- If uncertain about the actual timing or operation of the sterilizer. Items processed in a suspect load are considered unsterile. Other items processed in that load may need to be recalled to the processing department for reprocessing (e.g., the external process monitor has irregular color changes).
- If the instruments are still assembled, are clamped closed, or contain debris.
- If an unsterile person or object comes into close contact with a sterile table and vice versa.
- If a sterile table or unwrapped sterile items are not under constant observation (e.g., a sterile field under a table cover is not directly visible).
- If the integrity of the packaging material is not intact.
- If a sterile package wrapped in a material other than plastic or another moisture-resistant barrier becomes damp or wet. Humidity in the storage area or moisture on hands may seep into the package.
- If a sterile package wrapped in a pervious woven material drops to the floor or other area of questionable cleanliness. These materials allow the implosion of air into the package. A dropped package is considered contaminated on the outside. If the wrapper is impervious and the area of contact is dry and intact, the outer wrapper is removed and item may be transferred to the sterile field. Packages that have been dropped on the floor should not be put back into sterile storage.

Sterile Personnel Are Gowned and Gloved

- Gowns are considered sterile only from the chest to the level of the sterile field in the front, and from 2 inches above the elbows to the cuffs on the sleeves (Fig. 15.1). When wearing a gown, only the area that can be seen in front down to the level of the sterile field should be considered sterile. Keep in mind that the level of the patient's surgical site actually establishes the level of the sterile field (Fig. 15.2). Usually this does not extend below waist level. The following practices are observed:
- Self-gowning and gloving should be done from a separate sterile surface to avoid dripping water or skin cells onto sterile supplies or a sterile table. Closed gloving technique is preferred for the person who is establishing the sterile field and gowning and gloving others.
- The stockinette cuffs of the gown are enclosed beneath sterile gloves. The stockinette is absorbent and retains moisture; therefore this part of the gown does not provide a microbial barrier and permits the transfer of microorganisms. Once the cuff has been contained within the closed glove, it should not be pulled back over the hand for any regloving procedure because it is contaminated. Regloving should be performed using the open-assisted gloving technique. Another sterile team member can assist with this process as necessary.
- Sterile people must keep their hands in sight at all times and at or above waist level or the level of the sterile field (Fig. 15.3).
- Hands are kept away from the face and the elbows are kept close to the sides. The hands are never folded under the arms because of perspiration in the axillary region. The neckline, shoulders, and back also may become contaminated with perspiration. The back of the gown is not under constant observation and therefore is considered contaminated.
- Sterile people are aware of the height of team members in relation to each other and the sterile field. Changing levels at the sterile field is avoided. All team members must be aware of **spatial relationships** at all times. The gown is considered sterile only down to the highest level of the sterile working field. If a sterile person must stand on a platform to reach the surgical site, the standing platform should be positioned before this person steps up to the draped area. Sterile personnel should sit only when the entire procedure will be performed at this level. If one person on the team sits, the entire team should be seated (Fig. 15.4).

• **Fig. 15.1** Zones of Sterility on Front of Gown. The zones of sterility can change based on position of draped patient and sterile team.

• **Fig. 15.2** Zones of sterility when standing at sterile field with patient as the baseline for the level of the sterile field.

• **Fig. 15.3** Sterile personnel keep hands in sight at or above waist or level of sterile field. Gowns are considered sterile only in front from the chest to the level of the sterile field, and the sleeves from above the elbows to the cuffs.

• **Fig. 15.4** Seated Team for Upper Extremity Procedure. The zones of sterility change based on the placement of the team in relation to the type of surgical procedure.

• **Fig. 15.5** Circulating Nurse Pouring Sterile Solution into Sterile Basin. Note that only the lip of bottle is over the basin. The unsterile person avoids reaching over sterile field.

Tables Are Sterile Only at Table Level

Because tables are sterile only at table level, OR personnel must adhere to the following procedures:

- Only the top of a sterile, draped table is considered sterile. The edges and sides of the drape extending below table level are considered contaminated. The Mayo stand, when covered by a sterile drape, may be placed over the sterile field. Minimal contact is had with the underside of the Mayo drape.
- Anything falling or extending over the table or OR bed edge, such as a piece of suture or suction tip, is contaminated. The scrub person does not touch the part hanging below the level of the established sterile field.
- When unfolding or applying a sterile drape, it is unfolded away from the sterile person and the part that drops below the table surface is not brought back up to table level. Once placed, the drape is not moved or shifted.
- Cords, tubing, and other materials are secured on the sterile field with a nonperforating clip to prevent them from sliding over the edge of the operating bed.

Sterile Personnel Touch Only Sterile Items or Areas; Unsterile Personnel Touch Only Unsterile Items or Areas

- Sterile team members maintain contact with the sterile field by means of sterile gowns and gloves.
- The unsterile circulating nurse does not directly contact the sterile field.
- Supplies are brought to sterile team members and opened by the circulating nurse using aseptic technique. The circulating nurse ensures a sterile transfer to the sterile field. Only sterile items touch sterile surfaces.

Unsterile Personnel Avoid Reaching Over the Sterile Field; Sterile Personnel Avoid Leaning Over an Unsterile Area

- The unsterile circulating nurse never reaches over a sterile field to transfer sterile items.
- The circulating nurse holds only the lip of the bottle over the basin when pouring solution into a sterile basin to avoid reaching over a sterile area (Fig. 15.5). He or she should avoid making contact with the bottle and the basin and avoid splashing solutions. The entire contents of the bottle should be dispensed in one pouring motion. If some of the solution is not poured, it is considered contaminated and may not be recapped for later use or dispensed to another sterile basin. Once the cap is off, the solution is considered contaminated.
- The unsterile solution may be saved for cleaning the patient's skin after the incision is dressed and the surgical site is undraped.
- The scrub person sets basins or medicine cups to be filled at the edge of the sterile table; the circulating nurse stands a safe distance away from the edge of the table to fill them. Medications are drawn up in a syringe, the needle is removed, and the drug is dispensed to the cup without aerosolization. It is unsafe to draw up a drug if another person is holding the bottle. This is no different from recapping a needle by hand. It is not advised to dispense the drug via syringe and needle because the needle could cause an aerosolization of a drug to which a team member might be sensitive.
- The team uses sterile light handles for manipulation and adjustment of the surgical lights. Light handles should not be placed until after the patient is fully draped.
- The surgeon or team member steps away from the sterile field to have perspiration removed from the brow by the circulating nurse.
- The scrub person drapes an unsterile table by:
  - Unfolded drape. Placing the drape over the unsterile surface nearest himself or herself first and carefully completing the coverage of the far side. This protects the front of the gown from coming into contact with the unsterile surface being covered. Gloved hands are protected by cuffing a drape over them (Fig. 15.6).
  - Folded drape. Unfolding toward self first to protect the gown when working with a folded drape (Figs. 15.7 through 15.9). When completing the coverage, the rest of the drape is unfolded away from self.
  - The scrub person stands back from the unsterile table when draping it to avoid leaning over an unsterile area.

The Edges of Anything That Encloses Sterile Contents Are Considered Unsterile

The boundaries between sterile and unsterile areas are not always rigidly defined (e.g., the edges of wrappers on sterile packages and the caps on solution bottles). The following precautions should be taken:

- When opening sterile packages a margin of safety is always maintained. The inside of a wrapper is considered sterile to within 1 inch of the edges. The circulating nurse opens the top flap away from self and then turns the sides under. The ends of the flaps are

• **Fig. 15.6** Sterile Scrub Person Draping a Small Table. Sterile personnel avoid reaching over unsterile field. The scrub person therefore drapes unsterile table first toward self, then away. Gown is protected by distance, and hands are protected by cuffing drape over them.

• **Fig. 15.7** Draping Large Unsterile Table. Scrub person holds sterile fan-folded table drape high and drops it on center of table, standing back from table to protect gown.

• **Fig. 15.8** Scrub Person Unfolding Sterile Table Drape. Scrub person stands back from unsterile table and unfolds drape first toward self. Note that hands are inside sterile cover to protect them.

secured in the hand so they do not dangle loosely. The last flap is pulled toward the person opening the package, thereby exposing the package contents away from the unsterile hand.

- Sterile personnel lift contents from packages by reaching down and lifting them straight up, holding their elbows high.
- The flaps on peel-open packages should be pulled back, not torn, to expose the sterile contents. The contents should not be permitted to slide over the edges. The inner edge of the heat seal is considered the line of demarcation between sterile and unsterile. The sterile item should be presented to the scrub person. Flipping can cause air turbulence, and the item may miss its mark and fall to an unsterile area. Staplers and comparable devices should not be flipped, because they may be damaged by impact with the table and may misfire when used.
- If a sterile wrapper is used as a table cover, it should amply cover the entire table surface. Only the interior and surface levels of the cover are considered sterile.
- After a bottle of sterile solution is opened the contents are either used or discarded. The cap cannot be replaced without contaminating the pouring edges.
- Steam reaches only the area within the gasket of a sterilizer. Instrument trays should not touch the edge of the sterilizer outside the gasket when being removed after flash sterilization.
- When using a rigid closed container system with an inner sterile basket, the edges of the rigid outer container are not sterile. The inner basket is carefully lifted out by the scrub person and set on the sterile field. Sterile items should never be dispensed into the rigid container because of the high risk for contamination by the edges.

• **Fig. 15.9** Scrub Person Continuing to Unfold Sterile Table Drape. Note that the hands are inside sterile cover for protection. Scrub person may now move closer to table because the first part of unfolded drape now protects gown.

The Sterile Field Is Created as Close as Possible to the Time of Use

The degree of contamination is proportionate to the length of time that sterile items are exposed to the environment. Precautions must be taken as follows:

- Sterile tables are set up just before the surgical procedure. There is not an established time period or duration wherein the table is considered sterile or unsterile. Setting up as close to the time of use is in the best interest of the patient.
- If a table is not used immediately after setup, it may be covered by a sterile drape placed halfway with a cuffed edge horizontally. A second sterile cuffed drape is placed from the opposite side completely overlapping the first cuff. When removing the drapes to uncover the table, the top drape is removed first without touching the second drape. The hands must remain under the cuffed edge as each drape is removed in succession. None of the edges that overhang the edges may be brought over the sterile surface when being removed.
- A transparent drape with a seam that separates in the middle is made for covering tables.[7]
- Covering sterile tables prepared earlier for later use is not recommended as a general practice.

- It is not appropriate to set up a room and leave it unattended. Taping the door shut is not a guarantee of continued sterility.

Sterile Areas Are Continuously Kept in View

Inadvertent contamination of sterile areas must be readily visible. To ensure this principle, the following steps must be taken:

- Sterile personnel face sterile areas.
- Someone must remain in the room to maintain vigilance when sterile packs are opened in a room or a sterile field is set up. Sterility cannot be ensured without direct observation. An unguarded sterile field should be considered contaminated.

PROS/CONS

Covering a Sterile Table

Pros

- Sterility is event related, and a cover can help prevent contamination.
- The sterile field can be preserved if the case is delayed. If a sterile field needs to be covered, it should be done by a person in sterile attire using sterile technique.
- AORN recommends a sterile field be covered using two cuffed drapes placed horizontally over the sterile surface. The second drape should completely overlap the cuff of the first drape.
- A single transparent drape made specifically to cover set-up tables is acceptable. It separates in the middle for removal.
- The drapes should be removed sequentially, with the last drape being removed first.

Cons

- Avoiding contamination of the sterile field cannot be guaranteed regardless of the method used.
- Nonwoven paper drapes can become airborne and shift as personnel walk by.
- The proper technique of drape placement or removal is not always followed or known by staff. A single drape must never be used, because nothing should pass over the open sterile field during covering or uncovering.
- The covered field must be continuously monitored.
- Some organizations recommend never covering tables because of contamination risk.
- Traffic patterns can cause contamination even if a table is covered.
- Tables should be set up as close to the case time as possible.
- "When in doubt, throw it out."
- Staff should know the rationale and timing for covering a table.
- The table should not be set up, covered, and moved to another area in the department.

Sterile Personnel Keep Well within the Sterile Area

Sterile persons allow a wide margin of safety when passing unsterile areas and observe the following rules:

- Sterile personnel stand back at a safe distance from the OR bed when draping the patient.
- Sterile personnel pass each other back to back at a 360-degree turn (Fig. 15.10).
- Sterile personnel turn their backs to an unsterile person or area when passing.
- Sterile personnel face a sterile area to pass it.
- Sterile personnel ask an unsterile individual to step aside rather than risk contamination.
- Sterile personnel stay within the sterile field. They do not walk around or go outside the room.
- Use shielding devices during x-ray to prevent leaving the room or stepping away from the sterile field.
- Movement within and around a sterile area is kept to a minimum to avoid contamination of sterile items or personnel.

Sterile Personnel Keep Contact with Sterile Areas to a Minimum

To keep contact with the sterile areas to a minimum, sterile personnel observe the following rules:

- Sterile personnel do not lean on sterile tables or the draped patient. Leaning on the patient can cause injury to tissues and structures.
- Sitting or leaning against an unsterile surface is a break in technique. If the sterile team sits to operate, they do so without proximity to unsterile areas.

Unsterile Personnel Avoid Sterile Areas

Unsterile personnel maintain an awareness of sterile, unsterile, clean, and contaminated areas and their proximity to each. They must be aware of their closeness to the sterile field. A wide margin of safety must be maintained when passing sterile areas by observing the following rules:

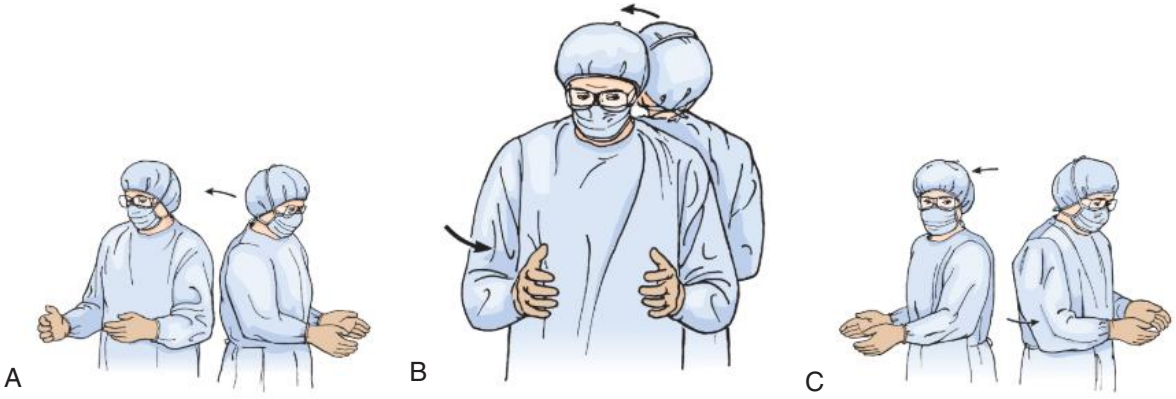
- Unsterile personnel maintain a distance of at least 1 foot (30 cm) from any area of the sterile field.
- Unsterile personnel face and observe a sterile area when passing it to be sure they do not touch it.
- Unsterile personnel never walk between two sterile areas (e.g., between sterile instrument tables).
- The circulating nurse restricts to a minimum all activity near the sterile field.

Destruction of the Integrity of Microbial Barriers Results in Contamination

The integrity of a sterile package or sterile drape is destroyed by perforation, puncture, or strike-through. Strike-through is the soaking of moisture through unsterile layers to sterile layers or vice versa. Ideal barrier materials are resistant to abrasion and impervious to permeation by the fluids or dust that transports microorganisms. The integrity of a sterile package and the appearance of the process monitor must be checked for sterility just before opening.

To ensure sterility, the following precautions should be taken:

- Sterile packages are laid only on dry surfaces.



• **Fig. 15.10** Sequence of One Sterile Person Going Around Another. They pass each other back to back, keeping well within the sterile area and allowing a margin of safety between them.

- If a sterile package wrapped in absorbent material becomes damp or wet, it is discarded or wrapped in fresh wrappers and resterilized. The package is considered unsterile if any part of it comes into contact with moisture.
- Drapes are placed on a dry field.
- If solution soaks through a sterile drape to an unsterile area, the wet area is covered with impervious sterile drapes or towels.
- Packages wrapped in woven fabric or paper should cool after being removed from the sterilizer and before being placed on a cold surface; this prevents steam condensation and the resultant contamination.
- Sterile items are stored in clean, dry areas.
- Sterile packages are handled with clean, dry hands.
- Undue pressure on sterile packs is avoided to prevent forcing sterile air out and pulling unsterile air into the pack. Peel packs should be stored on their sides to prevent pressure that could rupture the integrity of the package.

Microorganisms Must Be Kept to an Irreducible Minimum

Sterile technique in the surgical site is an ideal to be approached; it is not absolute. All microorganisms in the environment cannot be eliminated, but this does not obviate the necessity for strict sterile technique. There is general agreement about the following guidelines:

- Skin cannot be sterilized. Skin is a potential source of contamination in every invasive procedure. Inherent body defenses usually can overcome the relatively few organisms remaining after preparation of the patient's skin. Microorganisms on the face, neck, hair, hands, and arms of the OR team and patient are a hazard. All possible means are used to prevent the entrance of microorganisms into the wound. Preventive measures include the following techniques:
  - Mechanical washing and chemical **antisepsis** is used to remove or inactivate transient and resident flora from the skin around the surgical site of the patient and from the hands and arms of sterile team members.
  - Gowning and gloving of the OR team is accomplished without contamination of the sterile exterior of gowns and gloves.
  - Sterile, gloved hands do not directly touch the skin and then touch deeper tissues. Instruments used in contact with skin are discarded and not reused.
- If a glove is torn or punctured by a needle or instrument, it is changed immediately. The puncturing needle or instrument is removed from the sterile field.
- A sterile dressing should be applied to the surgical site before the drapes are removed to reduce the risk for the incision being touched by contaminated hands or objects.
- Some areas cannot be scrubbed. When the surgical site includes the mouth, nose, throat, or anus, the number of microorganisms present is great. Various parts of the body, such as the gastrointestinal tract and vagina, usually are resistant to infection by the flora that normally inhabit these parts. However, the following steps may be taken to reduce the number of microorganisms in these areas and prevent them from scattering:
  - The surgeon makes an effort to use a sponge only once and then discards it.
  - The gastrointestinal tract (especially the colon) is contaminated, and measures are used to prevent spreading this contamination.
  - Irrigation and suction may be employed to remove gross debris.
  - Aseptic technique is generally used when these mucous membranes are intact, but if the vascular system of the patient is entered, the items in use should be sterile. No case should ever be considered "dirty" when the vascular system is entered.
- Infected areas are grossly contaminated. The team avoids disseminating the contamination.
- Air is contaminated by dust, droplets, and shedding. The following environmental control measures are used:
  - Drapes placed over the anesthesia screen or attached to IV poles at the head of the bed separate the anesthesia area from the sterile field.
  - Movement around the sterile field is kept to a minimum to avoid air turbulence.
  - To avoid the dispersion of lint and dust, drapes are not flipped, fanned, or shaken.
  - Talking is kept to a minimum in the OR. Moisture droplets are expelled with force into the mask during the process of articulating words.
  - OR attire is worn properly: The mask covers the nose and mouth; the scalp and hair is completely covered, with long or loose pieces tucked into the cap; and body covers are close fitting. Unsterile personnel should wear long-sleeved warm-up jackets with knitted cuffs. Fronts of jackets should be completely buttoned.

No Compromise of Sterility

There is no compromise with sterility. In clinical practice an item is considered either sterile or unsterile. Team members should always be as certain of sterility as possible. That certainty rests on the fact that the necessary conditions have been met and that all factors in the sterilization process have been observed. Obviously it is impossible to prove that every package is free from bacteria, but a single break in technique can compromise the life of a patient.

OR personnel must maintain the high standards of sterile technique that they know are essential. Every individual is accountable for his or her own role in infection control. The patient should be considered an extension of the caregiver's own body. The patient completely trusts the team to provide safe care and protection from infection. This is a solemn obligation, with moral implications.

Appropriate Attire, Surgical Hand Hygiene, and Gowning and Gloving

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Identify the components of appropriate operating room attire worn in specific areas of the surgical suite.
- Identify the components of personal protective equipment donned before performing surgical hand cleansing.
- Identify the sterile parameters of a surgical gown.
- Demonstrate the correct method of gowning and gloving before establishing the sterile field.
- Demonstrate the appropriate method of changing a contaminated glove during a surgical procedure.
- Demonstrate the proper method for removing a contaminated gown and gloves.

KEY TERMS AND DEFINITIONS

Antimicrobial agent Antiseptic soap or cleanser used for cleaning the skin of patients and caregivers; has a fast-acting, broad-spectrum action to reduce the count of microorganisms before a surgical procedure.

Attire Appropriate operating room attire consists of body covers such as a two-piece pantsuit, head cover, mask, and shoe covers (shoe covers are used as appropriate).

Barrier Physical or mechanical obstacle between a person and a hazardous substance or microorganism.

Closed-assisted gloving Method for applying sterile gloves to another person who has his or her hands enclosed within the cuffs of a sterile gown.

Closed-gloving Method of self-applying gloves while the hands are concealed within the cuffs of a sterile gown.

Double-gloving The wearer applies two pairs of sterile gloves. The inner gloves should be a half size larger than the outer glove to create a comfortable air cushion. The inner glove can be a different color to help detect a tear in the outer glove. Wearing two gloves of the same size can cause compression of the median nerve and aggravate carpal tunnel syndrome in some susceptible people.

Gloving Applying or donning gloves using one of several methods.

Gowning Applying a sterile gown to self or other member of the sterile team.

Hand hygiene Scrubbing the hands with a brush, water, and antiseptic agent or brushless antiseptic gel hand rub.

Indicator gloves Specialized sterile colored gloves worn under a pair of sterile surgical gloves that reveal color, commonly green or blue, when the outer glove is punctured.

Open-assisted gloving Method for applying sterile gloves to another person who has his or her hands exposed through the cuffs of a sterile gown

Open-gloving Method of self-applying gloves while the hands are exposed with or without a sterile gown. This is how gloves are reapplied after a contaminated glove is removed by the circulating nurse. The cuffs are not pulled back over the hands because they are absorbent and considered contaminated.

Personal protective equipment (PPE) Eyewear, mask, hair cover, shoe covers, gown, apron, and/or gloves worn to prevent airborne, droplet, or contact-based transmission of potentially hazardous substances or microorganisms between caregiver and patient.

Scrub suit Appropriate attire intended for wear in the operating room. Consists of a shirt, pants, and fully buttoned long-sleeved jacket. Attire should be laundered within the facility to prevent transmission of infectious material.

Sterile attire Consists of basic appropriate attire for the operating room with the addition of sterile gown and sterile gloves for entering the sterile field.

Subungual Under the fingernails.

Surgical hand hygiene (surgical scrub) Process by which the hands and arms of the team are rendered clean by mechanical and chemical action before a surgical procedure.

Appropriate Operating Room Attire

Purpose of Appropriate Attire

Sebaceous and sweat glands in and around hair follicles over the entire surface of the body contain microorganisms that are continually shed into the environment. The purpose of operating room (OR) **attire** is to provide effective **barriers** that both prevent the dissemination of microorganisms to patients and protect personnel from blood and body substances of patients. OR attire has been shown to reduce microbial shedding and prevent contamination of the surgical site and sterile field by direct contact.

Definition

OR attire consists of body covers such as a two-piece pantsuit, head cover, mask, and shoe covers, as appropriate. Each cover has an appropriate purpose to combat sources of contamination exogenous (external) to the patient. A sterile gown and gloves are added to this basic attire for sterile team members at the sterile field. Appropriate attire is a part of aseptic environmental control that also protects personnel against exposure to communicable diseases and hazardous materials. **Personal protective equipment (PPE)** such as eyewear and other protective items are worn by personnel as appropriate for anticipated exposure to blood and body fluids. Box 16.1 describes attire for the OR according to specific areas.

Considerations for Appropriate Attire

The OR should have specific written policies and procedures for proper attire to be worn within the semirestricted and restricted areas of the OR suite. The dress code should include aspects of personal hygiene important to environmental control. Protocol is strictly monitored so everyone conforms to established policy, such as the following rules:

1. Dressing rooms located in the unrestricted area adjacent to the semirestricted area of the OR suite are reached through the outer unrestricted corridor. Street clothes are not worn beyond the unrestricted area.
2. Only approved, freshly laundered attire intended for use in the OR is worn within the semirestricted and restricted areas. This policy applies to everyone entering the OR suite, both professional and nonprofessional personnel and visitors. Home laundering of **scrub suits** may cause cross-contamination between hospital and home microflorae. Laundry conditions at home are not controlled for temperature and cleaning products and may not consistently take microbial counts to an irreducible minimum.[1]
   a. Clean, fresh attire is donned each time on arrival in the OR suite and as necessary at other times if the attire becomes wet or grossly soiled. Bloodstained or soiled attire, including shoe covers, is not only unattractive but also can be a source of cross-contamination. Soiled attire is not worn outside the OR suite.
   b. An adequate supply of clean scrub suits should always be available and laundered daily, preferably in the hospital's laundry facilities. These suits should not be taken home for laundering because standardized sanitation processes may not be followed. The risk for contamination of family members might be increased if clothing were contaminated with resistant microorganisms (e.g., prions causing Creutzfeldt-Jakob disease, or *Mycobacterium tuberculosis* causing tuberculosis [TB]).
   c. Masks should be changed between patients and whenever wet or soiled.
3. OR attire should not be worn outside the OR suite or outdoors. This protects the OR environment from microorganisms inherent in the outside environment and protects the outside from contamination normally associated with the OR. Before leaving the OR suite, everyone should change to street clothes. Surgeons who wear scrubs back and forth to the office place their patients at risk for exposure, not to mention that their appearance is unprofessional.
   a. On occasion, such as for lunch breaks, a single-use cover gown or other jacket may be worn over OR attire outside the suite. The practice of wearing cover gowns is not encouraged. After a gown is worn it should be placed in a laundry hamper or it should be discarded if it is disposable. Some hospitals provide laboratory coats. These are completely buttoned and worn only once.
   b. OR attire should not be hung or put in a locker for wearing a second time. It should be discarded in the trash if disposable or put in a laundry hamper after one use, as appropriate. Shoes should be stored in an area that prevents contamination of street clothes.
4. Impeccable personal hygiene is emphasized. Each person should bathe daily with an antimicrobial product and apply deodorant as appropriate. Body odor is the result of microorganisms in the hair-bearing areas of the body. This becomes unpleasant when confined to an OR while wearing a gown and gloves under hot lights. This is augmented when working with pediatric or geriatric patients where the room temperature has been intentionally elevated for patient care.
   a. A person with an acute infection, such as a cold or sore throat, should not be permitted within the OR suite. Personnel with cuts, burns, or skin lesions should not scrub or handle sterile supplies because serum, a bacterial medium, may seep from the eroded area. An open skin lesion may be a portal of entry for cutaneous contact with bloodborne pathogens.
   b. Some sterile team members who are known carriers of pathogenic microorganisms should be treated with appropriate medications, until nasopharyngeal culture findings are negative.
   c. Fingernails should be kept short (i.e., should not extend past the fingertips). Routine manicures prevent cracked cuticles and hangnails. **Subungual** areas harbor the majority

• BOX 16.1 Attire in the Specific Surgical Suite Areas

Appropriate Attire for the Unrestricted Area

- Street clothes
- Basic scrub attire: scrub suit

Appropriate Attire for the Semirestricted Area

- Basic scrub attire: scrub suit, hair cover

Appropriate Attire for the Restricted Area

- Basic scrub attire: scrub suit, warm-up jacket, hair cover, and mask
- Sterile attire for scrubbed person: scrub suit, hair cover, mask, sterile gown, sterile gloves, and protective eyewear. Shoe covers are added if necessary.

of microorganisms on hands. Fresh nail polish on short, healthy nails may not alter the microbial count on fingernails. Polish may seal crevices. However, damaged nails and chipped or peeling polish may provide a harbor for microorganisms. Studies have shown that artificial nails and other enhancers harbor organisms, especially fungi and gram-negative bacilli. These are prohibited from the OR.

d. Jewelry, including rings and watches, should be removed before entering semirestricted and restricted areas. Organisms may be harbored under rings, thus preventing effective handwashing. Necklaces or chains can grate on the skin, increasing desquamation. They might break and fall into a wound or contaminate a sterile field. Pierced-ear studs should be confined within the head cover. Dangling earrings are inappropriate in the OR.
e. Facial makeup should be minimal.
f. Eyewear or spectacles should be wiped with a cleaning solution before each surgical procedure and secured to the face with a head strap to prevent slippage.
g. External apparel that does not serve a functional purpose should not be worn. Identification badges should be secured to prevent their contact with the sterile field or equipment used for patient care. Lanyards are a source of microbial carriage.
h. Hands are washed frequently and thoroughly to remove bioburden.[2] **Hand hygiene** should be performed before and after every patient contact, before and after wearing gloves, before and after eating, before and after using the restroom, and before leaving the facility.[2] Clean hands are the first-line defense against transmitting microorganisms. Using hand cream regularly helps prevent chapped, dry skin. Bacteriostatic varieties may help reduce microbial counts on the skin. Hand sanitizer can be of benefit in reducing flora.

5. Comfortable, supportive, skid-proof shoes should be worn to minimize fatigue and for personal safety. Shoes should have enclosed toes and heels. Clogs may not provide a safe surface for fast walking or running during an emergency, especially while pushing a crash cart. Cloth shoes do not offer protection against spilled fluids or sharp items that may be dropped or kicked. Shoes are cleaned frequently, whether or not shoe covers are worn.

PROS/CONS

Wearing Jewelry

Pros

- Jewelry is a way to express personality and wealth.
- It can have sentimental meaning, such as a wedding ring.
- Cultural artifacts can define a certain religion or custom.
- Jewelry that can be contained under clothing and head covering may be permitted according to facility policy.
- Lanyards are worn in the clinical setting to hold an identification badge.
- Jewelry should be removed and placed in a locker or attached to clothing for safekeeping.

Cons

- According to the World Health Organization, a wedding ring may be acceptable if it is worn for religious or cultural purposes. It is, however, not recommended in high-risk areas such as the OR.
- Bacteria and fungi are carried on or under jewelry. Jewelry worn below the elbow such as bracelets, watches, and rings are barriers for appropriate handwashing or hand hygiene.
- Ringed hands carry a significantly higher colony of gram-negative bacilli than ringless hands and provide an ideal environment for microbial growth because they trap moisture, build up irritants underneath, and cause contact dermatitis.
- Long earrings that stick out of the head covering should be removed because they are a shedding risk and can be dislodged. A patient may become restless and catch on a hanging earring, tearing through the earlobe of the wearer.
- Dislodged jewelry may become lost or fall into the sterile field, thereby contaminating it.
- Lanyards and necklaces are a risk for infection because they are not routinely cleaned and frictional forces increase bacterial fallout.
- Rings may have sharp edges that can tear gloves.
- Inability to remove a tight ring may lead to long-term carriage of pathogenic bacteria that are not easily removed with routine handwashing.
- Body piercings and jewelry must be removed from patients before surgery because electrical burns can occur with the use of electrocautery. A sterile plastic intravenous catheter may be placed through the patient's pierced area to keep the subcutaneous tract open after the skin prep.
- Visible facial piercings above the mask line, such as eyebrow rings or nasal bridge bars, can cause distrust of the caregiver by the patient.
- Jewelry can cause injury to the wearer or patient because it may be caught on patient moving devices or appliances used in patient care. Jewelry on the hands or wrists can cause skin abrasions.
- Jewelry should not be worn in restricted areas and the OR for safety reasons.
- Policies restricting jewelry are not often enforced.

PROS/CONS

Home Laundered Scrubs

Pros

- Home laundering is economic for the facility.
- Facilities save on hiring staff, washing machines, and chemicals.
- Active barrier textiles repel fluids from uniforms.
- Tightly woven scrub attire material reduces microbes.
- Some materials are treated with antimicrobials.
- Low-linting materials prevent transfer of microbes.
- Durable stain-resistant materials reduce pathogen transmission.
- Detergent of choice can minimize skin sensitivity.

PROS/CONS—cont'd

Home Laundered Scrubs

Cons

- Health care workers may wear uniforms multiple times before laundering.
- Microorganisms can be transferred during transport of soiled clothes to home.
- Dirty scrubs can contaminate tote bags, electronic devices, cars, or any personal item.
- Microbes, organisms, and endospores can contaminate washing machines.
- Water temperature at facilities reaches 160° F; water temperature at home reaches 110° F.
- Facilities monitor water quality, correct measurement of cleaning chemicals, water temperature, mechanical action, duration of cycle, and drying temperature and time.
- Healthcare Laundry Accreditation Council and Centers for Disease Control and Prevention follow standards.
- Laundered uniforms worn from home into a facility can harbor microorganisms and pet dander.
- Fragrance from home detergent can cause sensitivity in others.

• **Fig. 16.1** Appropriate attire for the restricted area in preparation for scrubbing.

Components of Appropriate Attire

Each item of OR attire is a specific means for containment of or protection against the potential sources of environmental contamination, including skin, hair, and nasopharyngeal flora and microorganisms in air, blood, and body substances. Scrub suits and head covers are worn by all personnel in the semirestricted areas of the OR suite (Fig. 16.1). Masks also are worn in the restricted areas. Additional items, such as protective eyewear, gloves, and shoe covers, are worn during a surgical procedure and for protection during hazardous exposure.

Body Cover

Everyone dons attire intended for use within a semirestricted or restricted area (e.g., scrub suit). A variety of scrub suits—two-piece pantsuits or one-piece coveralls—are available in either a solid color or an attractive print. All should fit the body snugly. Pantsuits confine organisms shed from the perineal region and legs more effectively than do dresses; 90% of bacterial dissemination originates from the perineum. Pantyhose do not contain this shedding and may in fact increase it by constant friction.

Shirt and waistline drawstrings are tucked inside pants to avoid their touching sterile areas. Microorganisms multiply more rapidly beneath a covered area. A tunic top that fits snugly may be worn on the outside of pants. The scrub suit should be changed as soon as possible whenever it becomes wet or visibly soiled.

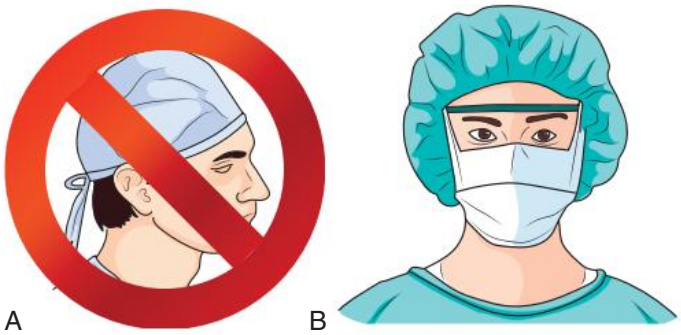
Those who will not be sterile team members should wear long-sleeved jackets with front closures over a scrub suit. The sleeves help contain shedding from axillae and arms and help protect from biologic contamination caused by splashes. The jacket should be closed to prevent a bellows effect and the possibility of brushing against the sterile field during movement.

A one-piece coverall, head cover, mask, and shoe covers are convenient garb for a visitor whose presence in the OR will be brief (e.g., pathologist, laboratory personnel). These coveralls are usually made of white, disposable, tear-resistant material and resemble jumpsuits with a zipper down the front.

Head Cover

Because hair is a gross contaminant, a cap or hood is put on before the scrub suit to protect the garment from contamination by hair. Hair should not be combed while one is wearing a scrub suit. Bald heads should be covered to prevent the shed and dispersal of scalp dander.

All facial and head hair is completely covered in the semirestricted and restricted areas. Various types of lightweight caps and hoods are available. Most of them are made of disposable, lint-free, nonporous, nonwoven fabrics. If hair is long, a bouffant-style hat or hood is worn to cover the neck area. Skullcaps do not cover the entire head, and hair can shed from the inferior edges. Headgear should fit well so that it confines and prevents escape of any hair (Fig. 16.2).



A B

• **Fig. 16.2 A,** Skull cap does not cover all hair and should not be worn. **B,** All hair must be covered.

Some facilities permit the wearing of reusable cloth bouffant-style caps. These should be freshly laundered daily. Many facilities require the use of a disposable bouffant cap over a cloth hat. Personnel wearing turbans for cultural or religious reasons should completely cover the headwear with a bouffant cap. Anyone with a scalp infection should be excluded from the OR and treated.

PROS/CONS

Wearing Cloth Surgical Caps

Pros

- Head coverings function to contain the outflow or shedding of organisms from the hair and scalp. Wearing appropriate headgear can reduce the number of bacteria in the air. A clean surgical head cover or hood should contain the ears; all hair, including sideburns; and hair on the nape of the neck. The head cover should be put on before the scrub suit to keep it free from shedding. At the end of the day the scrub top should be removed before the cap to protect the hair from contamination by the clothing.
- Cloth surgical caps are reusable caps that are purchased from a store or sewn by employees. They are usually the bouffant style or hood. The cloth caps can be made out of material with any pattern that may reflect the wearer's personality, emotion, hobby, favorite colors or pattern, sports team, college, favorite animals, or whatever pattern makes him or her feel good. It is usually the only piece of surgical attire that may be different from the rest of the staff.
- If a cloth cap is allowed, it must be made of a tight-woven, low-linting material. The cap should be washed daily; the preferred method is for the cap to be washed by an accredited laundry facility.
- Hair spray has been shown to diminish bacterial counts for all types of head covers.

Cons

- Allowing the use of cloth caps differs from facility to facility. It is recommended that reusable cloth caps NOT be worn because surgical site infections have been traced to bacteria from hair, scalp, and skin. This is to protect the wearer and patient from cross-contamination of pathogens.
- Most health care workers who wear cloth caps wear them for a whole day and do not change them after every procedure. This puts the wearer and patient at risk for cross-contamination. Contamination can come from the hands when removing the cap when leaving restricted areas, placing it in a locker or pocket, and putting the cap back on when returning to restricted areas.
- Proper attire is not something that is usually on a health care worker's mind; it is usually a habit. Health care workers usually have several cloth caps in their locker and have a habit of taking their cap off at the end of the day and placing it back into their locker and donning a new pattern the next day.
- Many workers have a habit of laundering the caps after they have been worn several times. Some studies have shown that 25% to 40% of surgical personnel were colonized with *Staphylococcus aureus.*
- Most facilities do not wash personnel cloth caps. If caps are taken home to be laundered, staff must follow the facility policy for home laundering. AORN (the Association of periOperative Registered Nurses), Association of Surgical Technologists (AST), and the CDC do not recommend home laundering for any attire worn in surgery.
- If a cloth cap gets soiled, it must be immediately removed and laundered. The health care worker may take home a bloody soiled cap and transport it in a tote bag or purse. This leads to possibly contaminating themselves, their washing machine, or family with pathogens.
- Every health care facility should have policies in place regarding wearing proper attire and staff compliance. Health care facilities need to address wearing of head covers and the rationale behind each type of cover. Some facilities permit cloth caps if covered with a disposable bouffant head cover.

PROS/CONS

Wearing Skull Caps

Pros

- Each facility offers a variety of head covers.
- Skull caps can be markers of individuality and status of each surgeon.
- Skulls caps are comfortable.
- Emotional and self-esteem.
- Personal preference.
- Male surgeons find skull caps more masculine than the bouffant cap.

Cons

- Skull caps do not cover all the hair, ears, facial hair, sideburns, and nape of the neck.
- Folding the edges of the skull cap into a cuff for a better fit shortens the coverage around the head and ears.
- Bouffant caps are preferred because they offer more complete coverage.
- It is recommended to place a bouffant cap over the skull cap.
- Hair, scalp, and skin shedding are sources of infection because they harbor bacteria. *Staphylococcus aureus* and *Staphylococcus epidermidis* adhere to hair and are not completely removed with routine shampooing.
- The 2019 recommended practices from AORN and CDC are not followed.
- Skull caps can become contaminated with sweat, especially on the forehead.

PROS/CONS—cont'd

Wearing Skull Caps

- Staff may not have adequate knowledge of infection control principles.
- Skull caps may not be changed after every case.

References

Shoe Covers

Shoe covers may be worn in the semirestricted and restricted areas as needed to protect from blood and fluid. Knee-high impervious styles will protect the wearer from spills into or onto shoes during procedures wherein extensive fluid irrigation and/or blood loss can be anticipated. Some surgeons wear plastic or rubber boots. The legs of scrub pants are tucked into the boots.

Studies have not shown a significant correlation between footwear and wound infection. However, the flow of traffic is one critical factor in airborne dispersal of microbes from the floor. Unprotected street shoes can increase floor contamination and conversely carry biologic material home from the OR. Shoes restricted to wear in the OR are preferable in reducing microbial transfer from the outside into the OR suite.

Protective gloves should be worn to change shoe covers whenever they become wet, soiled, or torn. Shoe covers can inadvertently become soiled and harbor microorganisms. They should be removed before entering the dressing room area and must be removed before leaving the OR suite.

PROS/CONS

OR-Specific Shoes or Shoe Covers: Do They Really Make a Difference?

Pros

- Shoe covers are provided by the facility to protect the footwear and feet from the exposure of blood and bodily fluids. Shoe covers are kept close to semirestricted areas for easy access. OSHA requires that shoe covers or knee-high boots be worn in a situation in which gross contamination can be anticipated.
- Knee-high boots made of an impervious material are recommended if a large amount of irrigation fluid will be used or there is an anticipation of contact with blood or other body fluids. They also protect the bottoms of the scrub pants from getting wet and contaminated.
- Disposable shoe covers are made to be worn in the restricted and semirestricted areas. Shoe covers are not designed to be worn outside the surgical department.
- Shoe covers are also disposable so that they can be changed after every procedure or if soiled during a procedure.
- Facilities have policies about wearing OR-specific shoes so that health care workers do not bring microorganisms in from the outside or take them home.
- OR-specific shoes should be made of rubber or leather; be comfortable, breathable, and supportive; have nonskid bottoms; provide protection; and be easily cleaned. Shoes should remain intact and impermeable to prevent foot contamination. OSHA requires shoes to be enclosed with no opened backs.

Cons

- Many health care workers do not wear shoe covers because they wear a specific OR shoe such as a closed back clog that can be wiped off if soiled. This type of footwear is designed specifically for the OR and should not be worn outside of the surgery department.
- Shoes made of soft permeable material, open toe shoes, sandals, and high heels do not meet the standards for health care facilities.
- Many health care workers do not change their shoe covers unless visibly soiled. Shoe covers might be soiled with blood, have holes in them, or be worn outside of the restricted areas, such as to the cafeteria, locker room, or outdoors. Shoe covers must be changed daily or if wet or soiled. They should be removed with gloves in the OR suite before leaving it and disposed in the appropriate trash receptacle, and then hand hygiene should be performed.
- Contamination of the hands was a bigger concern when studying shoe covers. Studies found that the bacterial counts of staff that just put on or took off their shoe covers had a higher bacterial count on their hands. This transferred organisms from the floor, to staff hands, and directly to patients if hand hygiene was not performed.
- Shoe covers must not be worn outside of the surgical suite to avoid tracking any contaminants in or out of the department. It is recommended that clean shoe covers be donned when returning from outside the department.
- Studies have been inconclusive about shoe covers. Shoe covers are not considered infection prevention, but as a protective barrier. The wearing of shoe covers has not proven to decrease the bacterial counts on operating room floors. Some studies have proved that room traffic is responsible for some surgical site infections because the microorganisms from the floor may become airborne.
- Studies are conflicting about OR-specific shoes and transfer of microorganisms. OR-specific shoes are recommended to prevent bringing in pathogens from the outside and taking pathogens back outside. Outdoor shoes have been shown to harbor more bacteria than OR-specific shoes.
- Every facility has a policy regarding shoe covers and OR-specific shoes. It is recommended that shoe covers be removed before leaving the restricted area. OR-specific shoes worn without shoe covers must not be worn outside the department. Recommended standards are the responsibility of the health care facility to establish policies and procedures for surgical attire. These policies and procedures should be reinforced to protect everyone.

Mask

A single mask is worn in the restricted area to hold and filter droplets containing microorganisms expelled from the mouth and nasopharynx during breathing, talking, sneezing, and coughing. Some tight-fitting masks also effectively reduce exposure to submicron particles by filtration of inhaled air. Many masks filter approximately 99% of particulate matter larger than 5 mm in diameter but only approximately 45% to 60% of particles 0.3 mm in diameter.

Aerosolized particles and viruses dispersed in laser and electrosurgical plume or by power instruments may be this small. Masks provide some protection to the sterile team members from bloodborne pathogens that may splash or spray toward the nose or mouth. Wearing double masks forms a barrier instead of a filter and may actually cause expulsion of airborne particles to escape from the cheek folds.

Reusable cotton masks are obsolete; they filter ineffectively as soon as they become moist. Contemporary disposable masks of soft, cloth-like material in very fine synthetic fiber materials fulfill the following essential criteria:

- They are at least 95% efficient in filtering microbes from droplet particles in exhalations and also filter inhalations. A fluid-resistant mask is advantageous.
- They are cool, comfortable, and nonobstructive to respiration.
- They are nonirritating to the skin. Disposable masks are made of polypropylene, polyester, or rayon fibers. Some have fiberglass filters. Sensitive persons should try another brand.
- Mask styles include rectangle shapes with four strings or cup-shaped, formed masks with an elastic band that fits around the head.
- High-efficiency particulate air (HEPA) filtration masks are cup shaped and are worn when working with patients who have TB. Employers should have each employee fitted so the size worn will be known. The patient should wear a mask during transport as well.
- Laser masks are high-filtration masks worn when plume from a laser or electrosurgical unit is in the environment. These masks filter airborne viruses.

Some experts believe that masks should be worn to protect team members, rather than patients, from moisture droplets. However, current practice recommendations of AORN are that masks be worn at all times in the restricted area of the OR suite, areas where sterile supplies will be opened and scrubbed personnel may be present and areas where scrub sinks are located.

Masks should always be worn in the OR, whether or not a surgical procedure is in progress. Masks are worn on entering the room before, during, and after the surgical procedure (i.e., from setup through cleanup). This includes terminal cleaning at the end of the day and restocking of supplies. The policy in some OR suites may be less restrictive. All team members, departmental staff, and visitors should follow the institution's written policy.

To be effective, a mask filters inhalations and exhalations. Therefore it is worn over both the nose and the mouth. Air must pass only through the filtering system; thus the mask must conform to facial contours to prevent leakage of expired air. Venting, the drawing of air back and forth, can occur along the sides, top, and bottom of the mask. The inside of the mask is covered with droplets from the mouth and nose and should not be touched with the hands.

Masks are designed with pleats or are conical, like a cup, for a close fit, but improper application can negate their efficiency. The strings should be tied tightly, if this is the method of securing the mask, to prevent the strings from coming loose during the surgical procedure. The upper strings are tied at the back of the head; the lower strings are tied behind the neck (Fig. 16.3). The strings are never crossed over the head, because this distorts the contours of the mask along the cheeks.

• **Fig. 16.3** Mask covers nose and mouth and conforms to the facial contours. Upper strings are tied at back of head; lower strings are tied behind neck.

Masks have an exterior pliable metallic strip that can be bent to contour the mask over the bridge of the nose. A close-fitting mask or a small strip of nonallergenic tape over the nosepiece also helps avoid fogging of eyewear. To prevent cross-infection, personnel should follow these steps:

1. Handle the mask only by the strings, thereby keeping the facial area of a fresh mask clean and the hands uncontaminated by a soiled mask. Do not handle the mask excessively. Hand hygiene should be performed any time the mask is handled.
2. Never lower the mask to hang loosely around the neck, never place the mask on top of the head, and never place the mask in a pocket. Avoid disseminating microorganisms.
3. Promptly discard the mask into the proper receptacle on removal. Remask with a fresh mask between patients.
4. Change the mask frequently. Do not permit the mask to become wet. Limit talking to a minimum.

If a sneeze is imminent, one should step back and away from the field and sneeze directly into the mask without turning the head sideways. Expelled air will be forced out the sides of the mask and directly into the sterile field through the vent if the head is sideways. The purpose of the mask is to filter air through the filtration material. Ideally, stepping away from the field and turning the head 180 degrees with the back of the head to the field may minimize exposure of the field. It may be necessary to remove the gown, gloves, and mask.

The hands should be washed with antimicrobial soap before and after cleaning the nose and applying a new mask. The hands should be rescrubbed before donning a sterile gown and gloves.

PROS/CONS

Wearing Masks in the Restricted Area

Pros

- Masks are worn as a barrier to protect the wearer from fluid, blood, smoke particulate, and microorganisms that contaminate the air. They also protect the patient against any pathogen from the caregiver.
- Masks are part of the standard respiratory based precautions. A surgical mask should cover the mouth and nose and prevent venting of air from the sides of the mask.

PROS/CONS—cont'd

Wearing Masks in the Restricted Area

- Health care facilities must provide personal protective equipment (PPE) according to federal laws. PPE includes masks, gloves, gowns, eye protection, shoe covers, and any other special protection device.
- Special fitted masks for airborne droplet precautions are individually fitted for face size and features. They are tested with the caregiver performing certain maneuvers. If a patient has a respiratory disease such as tuberculosis (TB), a caregiver must wear a special fitted mask such as a HEPA, N95, N99, or N100. This is an OSHA standard, and only caregivers following these policies can provide direct patient care. These masks may be referred to as respirators because they filter aerosolized particles and viruses. These special masks may be given to patients to wear when not in isolation or to visitors. Signs must be posted when entering a respiratory protection room so proper precautions can be taken.
- A respiratory protection program must be in place that trains employees how and when to use their special masks, conducts fit testing, inspects and maintains respirators, and instructs how to dispose of contaminated items.
- Masks come in many styles and shapes. Most facilities offer a selection to employees to protect them and also provide comfort.
- Masks should always be worn in the restricted areas. They should be put on before entering the OR, during the procedure, and during cleanup.

Cons

- Not every caregiver changes his or her mask after each procedure. A fresh mask should be donned before each new procedure and changed if it gets wet from personal excretions or soiled from a patient's fluids. Contaminated masks should be placed in the appropriate trash receptacle.
- Masks are easily contaminated. Masks should never dangle around the neck, be placed on the top of the head, or placed into a pocket because they can be contaminated by the area it touches. Many caregivers go in and out of OR rooms and never change their masks. They pull down their masks and let them dangle around their neck, thus contaminating them with their hands and droplets from their mouth and nose. This puts patients at risk for cross-contamination.
- Some caregivers cover only their mouth with their mask. This is unacceptable because it exposes the patient to microorganisms from the nose.
- A mask should be removed by the ties after each procedure to prevent contaminating the hands with droplets from the mouth and nose. Hand hygiene should follow immediately after mask removal.
- PPE should be donned within 3 ft of the patient's head especially when the patient is intubated or extubated. Many caregivers remove their masks, eyewear, and gowns before the patient is awake. This puts them at risk for contamination with bodily fluids.
- The clinical use of masks is so much a part of health care that proper studies are not conducted on their usefulness. Some studies have concluded that staff not directly in the vicinity of a surgical procedure do not pose a risk for infection to the patient.
- Current practices of AORN recommend that masks be worn in restrictive areas at all times. PPE is the responsibility of all health care workers. All staff members should reeducate themselves on their institution's policy.

Personal Protective Equipment

Personnel should be protected from hazardous conditions in the semirestricted and restricted areas. Depending on the exposure that will be encountered, PPE should be worn. The types and characteristics of this attire depend on the task and degree of exposure anticipated. Protective attire does not allow blood or other potentially injurious materials to reach the inner clothing, skin, or eyes. Other considerations concerning protective attire are as follows:

1. Aprons
   a. A decontamination apron worn over the scrub suit protects against liquids and cleaning agents during cleaning procedures. It should be a full-front barrier. These are usually disposable plastic.
   b. When extensive blood loss or irrigation is anticipated, sterile team members wear fluid-proof aprons under their permeable, reusable sterile gowns. They should be lightweight and full front. These are usually disposable plastic.
   c. Lead aprons worn under sterile gowns protect against radiation exposure during procedures performed under fluoroscopy or image intensification or when personnel are exposed to radioactive implants. Lead aprons may be full front, full circumferential body cover, or vest and skirt style.
2. Eyewear and eye protection
   a. Eyewear or a face shield is worn whenever a risk exists of blood or body substances from the patient splashing into the eyes of sterile team members (Fig. 16.4). Bone chips and splatter can be projected from bone-cutting instruments. Several styles of goggles and eyeglasses with top and side shields fit securely against the face. Antifog goggles fit over prescription eyeglasses.

• **Fig. 16.4** Face shield with hood.

A combination surgical mask with a visor eye shield or a chin-length face shield is another option. Care is taken that the lower edge of the face shield does not touch the front of the gown. Side shields applied to spectacles may not be adequate protection for random splashes.

b. Laser eyewear is worn for eye protection from laser beams. Lenses of the proper optical density for each type of laser should be available and worn. An extra pair should be placed on the outer door for personnel who may need to enter the room during the procedure. The color of the glasses has no bearing on which laser light is blocked. Many manufacturers have tried to create clear lenses to minimize visual distortion.

c. Protective eyewear, preferably a face shield, should be worn by personnel handling or washing instruments when this activity could result in a splash, spray, or splatter to the eyes or face. Eyewear should be worn when cleaning the room to avoid splashing chemical germicides into eyes during mopping or cleaning. Surgical hand and arm scrubbing and patient skin prepping can release aerosolized antiseptic solution into the air. Protective eyewear should always be worn when working with detergent-based prep solution.

d. Eyewear or a face shield that becomes contaminated should be decontaminated or discarded promptly.

3. Gloves

a. Nonsterile latex or vinyl gloves are worn to handle any material or items contaminated by blood and body substances. Gloves should be worn only during the period of contact, not continuously. Gloves are never washed between patient contacts; they are discarded. Clean objects and sterile packages should not be handled with contaminated gloves. Avoid opening cupboard doors, using a keyboard, or adjusting monitor settings while wearing soiled gloves.

b. Sterile gloves are worn by sterile team members and for all invasive procedures. Sterile Kevlar-woven glove liners may be worn over or under gloves to protect the hands from cuts caused by heavy instrumentation. Liners can be worn between two layers of gloves and should be a half size larger to prevent constriction. If **double-gloving**, the first pair of gloves can be colored to serve as an **indicator glove**. If the outer glove is punctured, the color shows through to make the perforation visible.

c. Lead and radiation protective gloves may be needed for protection from scatter during ionizing radiation exposure for diagnostic and therapeutic procedures that use real-time imaging. The surgeon may wear natural rubber gloves impregnated with lead for procedures performed under fluoroscopy. The lead is not in direct contact with skin.
When evaluating radiation protective gloves, be sure to note whether they are protective when used in direct radiation beams or if they are intended for use as protection from scatter. Not all radiation protective gloves are intended for use in direct beams. Radiation protective gloves without lead are commercially available.

d. Utility gloves are worn for cleaning and housekeeping duties. Sterile and nonsterile single-use, disposable latex and vinyl gloves are discarded after use. They should not be washed and reused. Soaps and surfactants decrease the surface tension of the gloves and increase the risk for wicking through microscopic holes in the gloves. Hands are washed after gloves are removed.

Surgical Gown

A sterile gown is worn over the scrub suit, a component of **sterile attire** to permit the wearer to enter the sterile field. It prevents contamination between the wearer and the field and differentiates sterile from nonsterile team members (Fig. 16.5). The gown should provide a protective barrier from strike-through (i.e., migration of moisture-borne microorganisms from the skin and scrub suit of the wearer to the sterile field and the patient, and penetration of blood and body substances from the patient to the scrub suit and skin of the wearer).

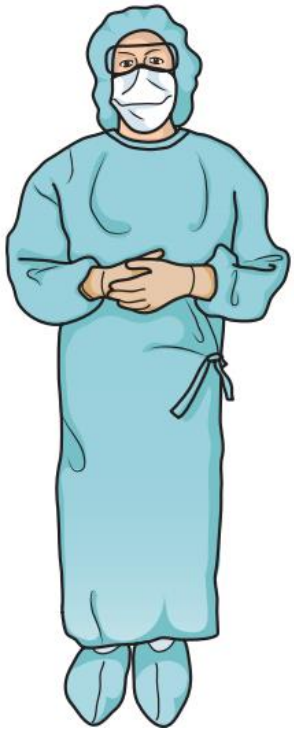
Both reusable and disposable gowns, in a variety of styles, are available. Although the entire gown is sterilized, the back is not considered sterile nor is any area below the level of the sterile field, once the gown is donned. Wraparound sterile gowns that provide coverage to the back by a generous overlap are recommended. These gowns are secured at the neck and waist before the sterile flap is brought over the back and secured by ties at the side or front.

A separate sterile vest put on over the gown covers any exposed back area of scrub attire but does not render the back sterile. The back is never in view of the team, so it cannot be guaranteed to be sterile.

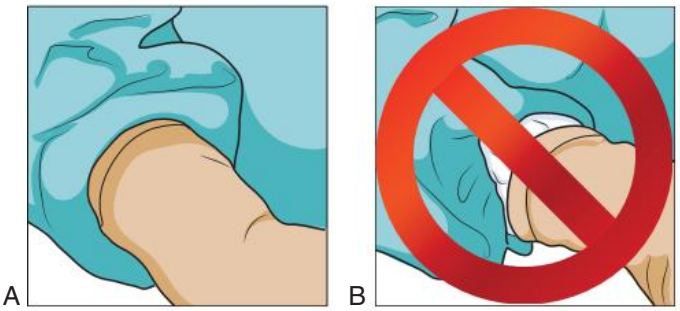
The cuffs of gowns are knitted stockinette to snugly fit wrists and are not fluid impervious. The material and weave absorb the wearer's body sweat, rendering the cuffs contaminated. Sterile gloves must cover the cuffs of the gown completely to prevent contamination of the sterile field (Fig. 16.6).

Changing a contaminated glove by pulling the cuff back down over the hand and employing the closed gloving method to reglove contaminates the fresh glove's sterile surface with the wearer's sweat in the process.

Gowns should be resistant to penetration by fluids and blood and should be comfortable without producing excessive heat buildup. Most single-use disposable gowns are made of spun fibers or nonwoven, moisture-repellent materials. Some of these are reinforced with plastic on the forearms and front.



• **Fig. 16.5** Appropriate Attire for the Sterile Scrubbed Person in the Restricted Area. The gown and gloves are worn over the scrub suit. Hair cover, protective eyewear, and mask are worn.



• **Fig. 16.6** Knitted cuffs are not impervious and should never be pulled back down over the hands to reglove by the closed method. Cuffs must be covered at all times when wearing gloves. **A,** Covered cuffs. **B,** Uncovered cuffs.

Sterile team members may not need a reinforced barrier gown for every procedure; the scrub person usually can safely wear a single-layer impervious gown. The surgeon and first assistant are at greatest risk during procedures when blood loss will be more than 20 mL or when the time will exceed 2 hours. The amount of blood and fluid on the outside of the gown is a critical factor in strike-through by wicking. Bloodborne pathogens can penetrate fabric without visible strike-through. The forearms are the most frequently contaminated areas. Therefore the surgeon and first assistant should wear a gown with at least reinforced or plastic-coated sleeves for these procedures.

Reusable woven textile gowns should be made of a densely woven, moisture-repellent material. Some reusable gowns are a cotton-polyester or Gore-Tex blend. Tightly woven 100% polyester gowns are impervious to moisture. Seams of the gowns should be constructed to prevent penetration of fluids. Monitoring the number of uses and washings is necessary to remove the gown from rotation when it is no longer an effective barrier.

All woven and some nonwoven gowns are not flame retardant. Fire-resistant gowns should be worn for laser surgery and preferably when electrosurgery is used.

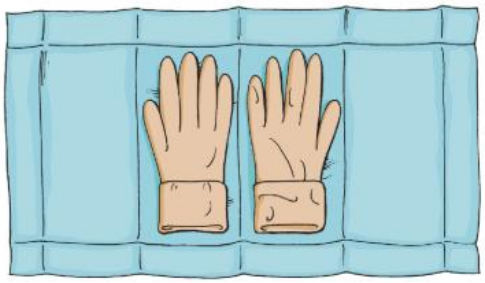
Special attire often is worn with ultraclean laminar airflow systems (Fig. 16.7). (See Chapter 10 for more information concerning laminar airflow systems.) A body exhaust gown with helmet envelops the wearer from the top of the head to within about 16 inches (40 cm) of the floor. If a gown that fits closely at the neck is used, a clear, rigid face shield or helmet is worn. A standard surgical mask is not necessary under this helmet. With both types of gowns, an exhaust system is attached for body cooling and airflow. Powered coolant vests for wear under scrub attire are commercially available.

Surgical Gloves

Sterile gloves complete the attire for sterile team members. They are worn to permit the wearer to handle sterile supplies and tissues of the surgical site. Surgical gloves are made of natural rubber latex, synthetic rubber, thermoplastic elastomers, neoprene, vinyl, or polyethylene. Disposable synthetic gloves are worn most frequently. Latex is a polymeric membrane of natural rubber; most facilities are limiting or not allowing the use of latex gloves for allergic reasons. However, latex provides a better barrier than vinyl, which may allow permeation of blood and fluids over prolonged exposure. Selection of surgical gloves worn during specific procedures depends on the following parameters:

- Length of surgical procedure
- Type of surgical procedure
- Need to double-glove
- Stresses to which the glove is exposed

• **Fig. 16.7** Orthopedic Sterile Scrub Attire Used by Some Orthopedic Surgeons and Teams. No mask is required. The suit has a small air compressor to provide fresh air within the enclosed headgear.



• **Fig. 16.8** Gloves on unfolded open wrapper: right glove to right, and left glove to left, palm sides up.

- Chemical exposure to the gloves during surgical procedure
- Caregiver and patient sensitivity
- Individual preference

Latex gloves of varying thickness, with a minimum of 0.1 mm, can be chosen to meet the needs of the surgeon for tactile sensation. Latex contains protein antigen and is cured with agents that may cause a localized dermatitis or systemic anaphylaxis. Hypoallergenic milled gloves that do not contain these sensitizers are available. However, latex gloves labeled "hypoallergenic" do not always prevent reaction in a highly sensitive person. In 2017 the U.S. Food and Drug Administration (FDA) banned the use of powdered (cornstarch) surgical gloves because of the risks to patients and employees. Risks included airway problems from the inhalation of the powder, formation of granulomas, adhesions, inflammation, and immune reactions.

Several varieties of synthetic nonlatex sterile gloves (e.g., those made of neoprene) are available commercially. Sterile team members should not wear latex gloves if the patient has a known latex sensitivity or allergy.

Gloves are packaged in pairs with an everted cuff on each to protect the sterile outer surface of the glove during donning. The inner sterile paper wrap of the disposable glove package protects the sterility of the gloves when they are removed from the peel-pack outer wrap. Before opening, the package should be inspected for damage or wetness, which indicates contamination. When the inner paper is unfolded, the wearer finds the right glove to the right and the left glove to the left, both with palm sides up and thumbs on the outside edge (Fig. 16.8).

Most health care facilities have replaced latex and powder-containing gloves for safety reasons. Gloves coated on the inside with a hydrogel lubricant allows smooth donning of gloves.

One study demonstrated that surgeons puncture their gloves most often on the index finger of the nondominant hand. Glove puncture and miniscule holes in gloves are hazardous to both patients and team members and can go unnoticed by the wearer. Seepage under the glove poses a threat to a team member if his or her skin is not intact. The risk for blood contamination of the fingers increases the longer the glove is worn. If a sterile glove is punctured or torn, it should be changed immediately to prevent escape of microorganisms from the wearer's skin and seepage of blood and body substances from the patient into the glove.

The scrub person should not be intimidated by politely informing the surgeon or any sterile team member of having a potentially contaminated glove. This is an important part of surgical conscience. The circulating nurse will obtain new gloves and dispense them to the sterile field. The circulator should don nonsterile gloves to remove contaminated gloves from a sterile team member.

Double-gloving is recommended for all sterile team members. The gloves do not need to be of the same variety or composition, but they both need to be sterile. The inner pair of sterile gloves should be applied using the closed-gloving method and should be a half-size larger than the outside glove to create a cushion of air. The outer sterile glove should be the wearer's normal size and can be applied using any sterile method. If available, the inner glove should be colored (i.e., blue or green) to serve as an indicator glove. The rationale is that if the outer glove gets punctured, the hole would be easier to see if color in that area were visible. Wearing two pairs of gloves in the same size can cause compression on the median nerve, resulting in carpal tunnel syndrome in susceptible people.

High-molecular-weight polyethylene orthopedic gloves resist punctures and tears. Some sterile team members wear sterile glove liners for protection from scalpel cuts or instrument tears. These do not protect the hands from needlesticks. Liners are usually worn between two pairs of sterile surgical gloves, usually a half-size larger than normal so they will not cause constriction. The liners may be made of polymer fibers or a Kevlar metal mesh. Some are disposable; others may be reprocessed and sterilized with steam or ethylene oxide.

Petrolatum-based lotions or lubricants should not be used on the hands before donning latex gloves. Hydrocarbons will penetrate latex, causing a change in its physical characteristics, including tear resistance.

Criteria for Surgical Attire

Surgical attire should be as follows:

- An effective barrier to microorganisms. Both reusable woven and disposable nonwoven materials are used. The design and composition should minimize microbial shedding.
- Made of closely woven material void of dangerous electrostatic properties. The garment should meet National Fire Protection Association standards (NFPA-56A), including resistance to flame.
- Resistant to blood, fluids, and abrasion to prevent penetration by microorganisms.
- Designed for maximum skin coverage.
- Hypoallergenic, cool, and comfortable.
- Nongenerative of lint. Lint can increase the particle count of contaminants in the OR.
- Made of a pliable material to permit freedom of movement for the practice of sterile technique.
- Able to transmit heat and water vapor to protect the wearer.
- Colored to reduce glare under lights. Various types of clothes in colorful prints that fulfill the necessary criteria are both attractive and functional.
- Easy to don and remove.

Surgical Hand Hygiene

Surgical hand hygiene (also called the surgical scrub) is the process of removing as many microorganisms as possible from the skin of the hands and arms before donning sterile surgical attire. Despite the antimicrobial component of the hand- and arm-cleansing process, skin is never rendered sterile. Consider that the tap water used in the rinse is from the public water system. This water is not sterile and can in itself grow microbial cultures. The process of surgical scrubbing is not a sterile procedure.

The scrub room is adjacent to the OR for safety and convenience. Scrub sinks with automatic sensor controls or foot- or knee-operated faucets are preferred to eliminate the hazard of contaminating the hands after hand and arm washing. Protective eyewear should be worn when performing a surgical scrub. Aerosolization from the scrub brush can cause chemicals to be dispersed into the user's eyes.

The sink should be deep, wide, and low enough to prevent splashes. Aerated faucets prevent splatter. A sterile gown cannot be donned over damp scrub attire without resultant contamination.

Scrub sinks should be used only for scrubbing or handwashing. They should not be used to clean or rinse contaminated instruments or equipment. Bioburden could inadvertently be transferred to personnel who scrub in the vicinity.

Microbiology of the Skin

The skin is inhabited by the following list of organisms:

- Transient organisms acquired by direct contact. Usually loosely attached to the skin surface, they are almost completely mechanically removed by thorough washing with soap and water.
- Resident organisms below the skin surface in hair follicles and sebaceous and sweat glands. They are more adherent and therefore more resistant to removal. Their growth is inhibited by the chemical phase of the surgical hand-cleansing process. Resident skin flora represents the microorganisms present in the hospital environment. Prolonged exposure of skin to contaminants yields a more pathogenic resident population (i.e., capable of causing infection).

Purpose of Specialized Hand Hygiene

The purpose of surgical hand and arm hygiene is to remove or deactivate soil, debris, natural skin oils, hand lotions, and transient microorganisms from the hands and forearms of sterile team members. More specifically, the purposes are as follows:

- To decrease the number of resident microorganisms on skin to an irreducible minimum
- To keep the population of microorganisms minimal during the surgical procedure by suppression of growth
- To reduce the hazard of microbial contamination of the surgical wound by skin flora

Antimicrobial Skin-Cleansing Agents

Various antimicrobial soaps are used for surgical hand cleansing. The same antiseptic agents are used for the patient's skin prep. The desirable characteristics of **antimicrobial agents** are as follows:

- Broad spectrum
- Fast acting and effective
- Nonirritating and nonsensitizing
- Prolonged action (i.e., leaves an antimicrobial residue on the skin to temporarily prevent growth of microorganisms)
- Independent of cumulative action

Variables in effectiveness of the antimicrobial cleansing process are bioburden, mechanical factors, chemical factors, and individual differences in skin flora. Antiseptics alter the physical or chemical properties of the cell membrane of microorganisms, thus destroying or inhibiting cellular function. More than one FDA-approved antimicrobial agent is available in the scrub room for personnel who are allergic or sensitive to a particular agent.

Chlorhexidine Gluconate

A 4% aqueous concentration of chlorhexidine gluconate (CHG) in a soap base or 0.5% in alcohol exerts an antimicrobial effect against gram-positive and gram-negative, fungal, and viral microorganisms. It reacts poorly against TB microorganisms. Antimicrobial residues bind with the stratum corneum with repeated use and produce a prolonged effect. This agent produces effective, intermediate action and cumulative reductions of resident and transient flora for more than 6 hours.

CHG is rarely irritating to the skin, but it is highly ototoxic and will irritate if splashed in the eye. It can cause permanent corneal damage. Caution should be used when scrubbing with this agent. It is an ingredient in several of the antiseptic hand gels. The alcohol-based chlorhexidine preparation is effective if the hands are coated in the solution for 20 to 30 seconds after mechanical cleansing.[3] The alcohol evaporates rapidly and has minimal odor. Personnel with reactive airway conditions should be aware of minor volatile qualities when using this product. Allow the product to dry thoroughly before donning gowns and gloves.

Iodophors

A povidone-iodine complex in detergent fulfills the criteria for an effective surgical scrub. It is available in concentrations of 10%, 7.5%, 2%, and 0.5%. Iodophors are intermediate-acting antimicrobial agents against gram-positive and gram-negative, TB, fungal, and viral microorganisms. Iodophors have minimal residual effect. Iodophors can be irritating to the skin.

Triclosan

A solution of 1% triclosan is a nonirritating, intermediate antimicrobial agent that inhibits growth of a wide range of gram-positive and gram-negative and TB microorganisms by interruption of hormonal activity within the cell. Triclosan does not work as well against fungi. Antiviral action is unknown. It develops a prolonged cumulative suppressive action when used routinely. The agent is blended with lanolin cholesterols and petrolatum into a creamy, mild detergent. It may be used by personnel sensitive to other antiseptics, although it can be absorbed through intact skin. In 2017 the FDA banned the use of Triclosan for safety reasons.[4]

It was found in many daily use products, such as toothpaste, shampoo, and dish soap, and consequently ends up in the nation's water supply. It may play a role in antibiotic resistance. It has been found in urine and breast milk. Triclosan is no longer available in the health care setting and has been removed from consumer products. More information can be found at www.fda.gov.

Alcohol

Ethyl or isopropyl alcohol (70% to 91.3 %) is rapidly antimicrobial against all microorganisms. It is volatile and does not have residual activity. It is nontoxic but has a drying effect on skin. Alcohol preparations, usually in foam, contain emollients to minimize drying. If other agents cannot be used because of skin sensitivity, mechanical cleansing with soap to remove transient organisms may be followed by cleansing with an alcohol-based skin cleanser.

Parachlorometaxylenol

Used in a concentration of 1% to 3.75%, parachlorometaxylenol (PCMX) does not substantially reduce microorganisms immediately. It does not produce sustained residual activity. Its antimicrobial activity can be altered significantly by the composition of the antiseptic product. Efficacy data should be reviewed before these products are used for surgical scrubs.

Opening the Gown and Gloves

The scrub person wears all the appropriate attire for the restricted area before entering the OR (i.e., scrub suit, head cover, eye protection, and mask). The gown and gloves must be opened before performing surgical hand hygiene. The double-wrapped gown package contains one sterile folded gown and towel. The outer wrap is a peel pouch, and the inner wrap is envelope style. The gown is folded inside out to facilitate donning. The folded gown resembles a thick book with the main fold as its binding. A folded woven fabric or disposable paper towel for drying the hands is packed on top of the gown. The towel is folded into a square or rectangle with one corner turned down for ease of grasping without disturbing the entire gown-towel assembly.

The gown package is opened before the glove package on a separate surface from the main sterile field. The gown inner wrapper is removed from the peel pouch and is used to create a temporary sterile field of its own. It is inappropriate for the scrub person establishing the sterile field to gown and glove off the main sterile field.

The gloves are double-wrapped in a peel pouch and folded paper. The peel pouch is opened and the paper-wrapped gloves can be dispensed to the side of the gown on the inner aspect of the sterile gown wrapper. Do not dispense on top of the towel. The glove wrapper can be contaminated when reaching for the towel with wet hands. Ideally, if another surface is available, the glove wrapper can be opened in its entirety to fashion a temporary sterile area for the purpose of donning the gloves.

Preparations Immediately before Surgical Hand Hygiene

1. The skin and nails should be kept clean and in good condition, and the cuticles should be uncut. If hand lotion is used to protect the skin, a non–oil-based product is recommended. Oil can weaken the integrity of gloves.
2. Fingernails should not reach beyond the fingertips to avoid glove puncture.
3. Fingernail polishes, gels, and ultraviolet cured polishes should not be chipped or cracked. More studies on UV-cured polishes and gels need to be done to determine if they can withstand the surgical scrub. Freshly applied polish may be worn if permitted by facility policy.[5]
4. Artificial nails and decals harbor microorganisms such as bacteria and fungi and are inappropriate for scrub personnel.[5]

5. All jewelry is removed from the fingers, wrists, and neck. Jewelry harbors microorganisms.
6. All hair should be covered by headwear. Pierced-ear studs should be contained by the head cover because they are a potential foreign body in the surgical site. A quick look in the mirror by the scrub sink to be sure all hair is secured helps prevent infection.
7. Adjust the disposable mask snugly and comfortably over the nose and mouth.
8. Clean your spectacles if they are to be worn. Adjust and secure protective eyewear or the face shield comfortably in relation to the mask and spectacles.
9. Adjust water to a comfortable temperature. Cooler water helps minimize dry skin. Hot water can increase chafing by degreasing the skin.

Surgical Hand and Arm Scrub with a Brush

When arriving in the surgical department for the day the first hand cleansing should be a brush scrub, either timed or a counted brushstroke method. When an individual scrubs with a brush and antimicrobial agent the soap decreases the surface tension of the skin, thus permitting the shed cells to be rinsed away with the tap water. Care is taken to avoid scrubbing longer than 3 to 5 minutes, because skin can become abraded and release microorganisms from hair follicles.

In surgical scrubbing with a brush, antiseptic soap, and water the skin is cleansed of microorganisms using the following two properties:

1. *Mechanical:* The mechanical properties remove soil and transient organisms with friction. Nails are cleaned under running water with a nail pick.
2. *Chemical:* The chemical properties reduce resident flora and inactivate microorganisms with an antimicrobial or antiseptic agent.

Debris should be removed from the subungual area of each finger. Single-use disposable products are a brush-sponge combination with an enclosed nail-cleaning pick. Some brushes are individually packaged and impregnated with antiseptic-detergent agents. Additional antiseptic solution is dispensed onto the brush or sponge by a foot pedal from a container adjacent to the sink. Six drops (approximately 2 to 3 mL) of solution is sufficient to generate a lather for the scrub procedure. Waste of antiseptic solution should be avoided.

A timed or counted brushstroke method can be used to scrub the hands and arms. A vigorous 2 to 5-minute scrub with a reliable agent is effective. A counted brushstroke method is equally effective in decreasing the microbial count on the skin. Prolonged scrubbing raises resident microbes from deep dermal layers and is therefore counterproductive. Care should be taken not to abrade the skin during the scrub process. Denuded areas allow the entry of microorganisms. Too short a scrub may be equally ineffectual.

Every member of the surgical team should scrub according to a standardized written procedure. The time required may be based on the manufacturer's recommendations for the agent used and documentation of the product's efficacy in the scientific literature. A copy of the procedure should be posted in every scrub room.

Subsequent scrubs should follow the same procedure as the initial scrub of the day. When gloves are removed at the end of the surgical procedure, the hands are considered contaminated and should be immediately washed with soap and water. Resident microorganisms multiply rapidly in the warm, moist environment under the gloves.

Personnel who scrub should think of their fingers, hands, and arms as having four sides or surfaces. Both methods (timed and counted brushstroke) follow an anatomic pattern of scrubbing: the four surfaces of each finger, beginning with the thumb and moving from one finger to the next, down the outer edge of the fifth finger, over the dorsal (back) surface of the hand, then the palmar (palm) surface of the hand, or vice versa, from the small finger to the thumb, over the wrists and up the arm, in thirds, ending 2 inches (5 cm) above the elbow. Because the hands are in most direct contact with the sterile field, all steps of the scrub procedure begin with cleaning the fingernails and hands and end above the elbows.

During and after scrubbing, keep the hands higher than the elbows to allow water and suds to flow from the cleanest area—the hands—to the marginal area of the upper arms. Take care not to slip in water that may have dripped to the floor during the process. A waterproof mat is suggested in front of the sink.

Surgical Hand Hygiene with Antiseptic Rub

In an antiseptic hand rub method the antimicrobial chemical properties of the agent kill microorganisms. Antiseptic hand gels, lotions, and foams do not use mechanical action or friction. There is no water rinse to physically remove microorganisms; the main action is chemical. The antiseptic does not remove debris from under the nails and hands.

That is why a simple handwashing and drying is recommended by AORN to remove gross soil before using a surgical hand cleansing agent.

Many rub-type surgical skin cleansers have a lasting antimicrobial effect for several hours after application. The coating of the antiseptic agent on the skin should be rubbed in evenly without clumps in the crook of the elbows or between the fingers. The agent is alcohol based and should be completely dry before donning the sterile gown and gloves. The material should not be wiped off the skin, and the hands and arms should not be waved through the air in a drying motion. Air currents cause particulates in the environment to disperse throughout the restricted area.

Most brushless cleansing agents have an alcohol base with an antimicrobial ingredient such as CHG. Care is taken to allow the agent to completely dry before donning the sterile gown and gloves. All products of this nature should be used as directed by the manufacturer. Each product has a specific application process and drying protocol.

Gowning and Gloving

The sterile gown is put on after drying the hands and arms with a sterile towel, immediately after the surgical hand and arm hygiene. The hands and arms must be dry before donning the sterile gown. The sterile gloves are put on immediately after gowning using the closed-glove technique described in the next section.

Purpose

A sterile gown and gloves are worn to exclude skin as a possible contaminant and create a barrier between the sterile and nonsterile areas. The gown protects the patient and the wearer from cross-contamination.

General Considerations

1. The scrub person gowns and gloves from a surface separate from the main sterile field using the closed-gloving method

and then gowns and gloves the surgeon and the rest of the sterile team using the open-assisted or **closed-assisted gloving** method.
2. Gown packages preferably are opened on a separate table from other packages to avoid any chance of contamination from dripping water.
3. Splashing water on scrub attire during the surgical scrub should be avoided because moisture may contaminate the sterile gown.

Drying the Hands and Arms

The hands and arms are dried as follows:
1. Reach down to the opened sterile gown package and pick up the towel with one hand by one corner. Be careful not to drip water onto the pack because contamination may occur. Be sure no one is within arm's reach (Fig. 16.9). Be aware of the environment to prevent contamination.
2. Grasp the opposing corner of the towel with the other hand and open the towel full length. Use one end of the towel to dry one hand and arm. Use a circumferential motion to rub in one direction from hand to upper arm. Do not rub back and forth (Fig. 16.10). Bend slightly forward to avoid letting the towel touch the attire.
3. To dry the second arm, hold the dry, clean end of the towel in the opposite hand and use a circumferential motion to dry the hand and all areas of the arm to the elbow.
4. Discard the towel with the hand that is currently holding it without letting it touch the scrub suit. Do not wad the used towel and toss it across the room to the laundry hamper or trash.

• **Fig. 16.9** Scrub person preparing to gown removes the hand towel on top of gown from open package.

• **Fig. 16.10** Scrub person, holding towel away from body, dries only scrubbed areas, starting with hands. He or she avoids contaminating hands on areas proximal to elbows and then discards towel.

Gowning and Gloving Techniques

The scrub person will don the gown before the gloves. The scrub person may don gloves in one of two ways: by the closed-gloving technique or by the open-gloving technique. The closed-gloving method is preferred for establishing the initial sterile field by the scrub person. Properly executed, the closed-gloving method affords assurance against contamination when donning gloves; no bare skin is exposed in the process because the bare hands do not extend through the cuffs of the gown.

The open-gloving method is used when changing a glove during a surgical procedure or when donning gloves for procedures not requiring gowns. The assisted-open gloving technique is used by the scrub person to help other sterile team members don gowns and gloves before entering the sterile field.

Gowning Self

1. Reach down to the sterile pack and lift the folded gown directly upward (Fig. 16.11). This is like picking up a book by its binding. Take care not to touch the sterile gown wrapper because the sterile gloves will be opened completely on this surface after the gown is donned.
2. Step back and away from the table into an unobstructed area to provide a wide margin of safety while gowning to prevent contamination.
3. Holding the folded gown like a book by its binding, carefully locate the neckline and the armholes.
4. Holding the inside front of the gown just at the armholes with both hands, let the gown unfold, keeping the inside of the gown toward the body and the hands in the armholes. Do not touch the outside of the gown with bare hands. If the top of the gown drops downward inadvertently, discard the gown as contaminated. Never reverse a sterile gown if the wrong end is dropped toward the floor.
5. Extend both arms into the armholes simultaneously as the gown and its sleeves unfold (Fig. 16.12).
6. The circulating nurse, standing behind the scrub, brings the gown over the shoulders by reaching inside to the shoulder and arm seams. The gown is pulled on, leaving the cuffs of the sleeves extended over the hands. Do not push the hands through the cuffs. The back of the gown is securely tied at the

• **Fig. 16.11** Scrub person, picking up gown below neck edge, lifts it directly upward and steps away to avoid touching the edge of the wrapper. Note that inside of wrapper covers the table. Gown is folded inside out.

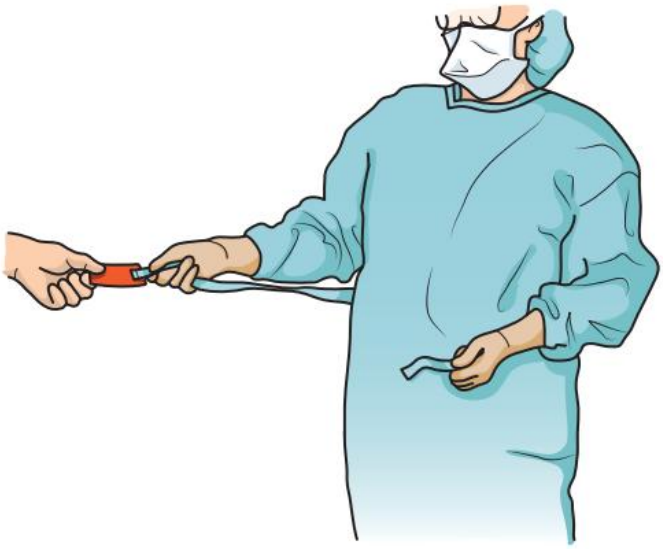
• **Fig. 16.12** Scrub person, putting on gown, gently allows the gown to unfold away from body and then slips arms into sleeves without touching sterile outside of the gown with bare hands.

• **Fig. 16.13** Circulating nurse ties the inner waist ties of the sterile gown.

waist first, followed by the neckline. The circulating nurse takes care not to pull the gown so snug that the cuffs are pulled back and expose the hands (Fig. 16.13).

If the gown is wraparound style, the sterile flap to cover the back is not touched until the scrub person has donned the gloves. A sterile gown may be wrapped around for a "tie-in" in various ways:

1. *Reusable gown:* The wraparound ties are secured to the front of the gown by a single hitch knot. With sterile gloved hands, pull the knot open. Take the longer right tie in the right hand and the shorter left tie in the left hand. Hold on to the left tie. Hand the long right tie to a sterile team member who remains stationary.
   Allowing a margin of safety, turn around toward the left, thereby completely covering the back with the extended flap of the gown. Take the long right tie from the sterile person and tie it to the short left tie on the left side of the gown. Do not place the long right tie under an object on the sterile field to tie yourself in. This causes the back to be turned to the field. It is best to have a sterile person tie you in.
2. *Disposable gown:* The ends of the wraparound ties are covered by a disposable paper tag. Disengage the left short tie from the tag with the left hand. Hold on to the left tie. The tag will remain attached to the long right tie. Hand the tag with the right tie still attached to the circulating nurse, taking care to protect the hands and not disconnect the tag (Fig. 16.14). Turn toward the left, closing the gown flap in the back. Grasp the long right tie about 4 to 6 inches from the tag that the circulating nurse is holding, and pull the tie out of the paper tag. The circulating nurse discards the tag. Tie the long right tie to the short left tie at the side of the gown.
   Do not have the circulating nurse walk in front of the gown to wrap around. Do not turn the back to the sterile field.
3. If either of the ties drops at any time, the circulating nurse retrieves both ties and secures them behind the scrubbed person's back because the dropped tie has fallen below the level of the sterile field and is contaminated.

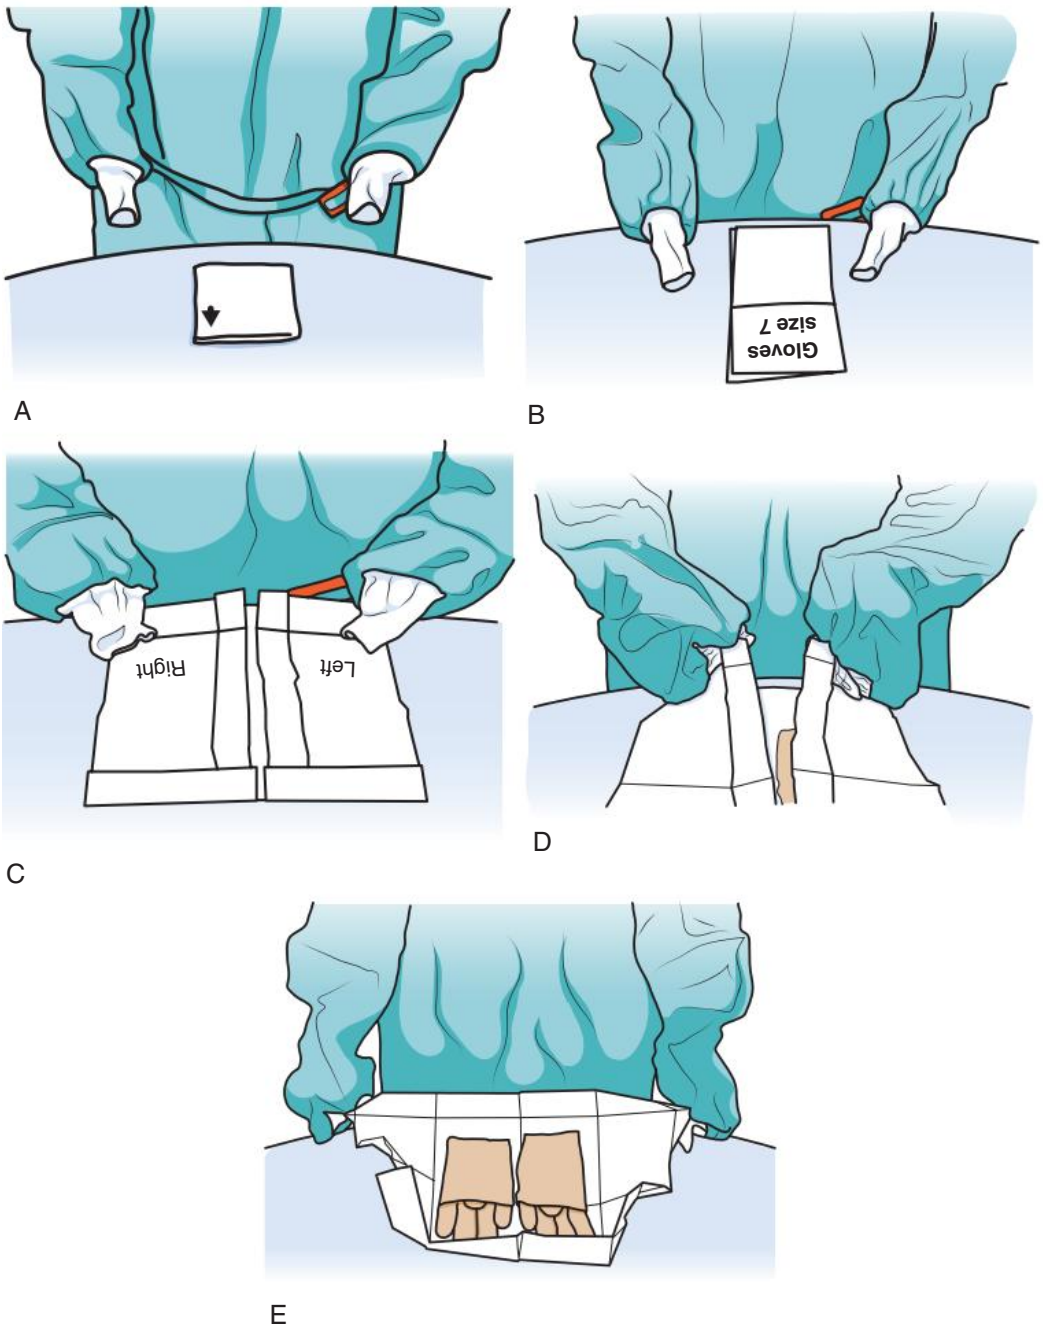


• **Fig. 16.14** The circulating nurse ties in the sterile scrub person. The scrub person hands the paper tag that holds the long right wraparound tie to the circulating nurse while holding the shorter left tie. The nurse walks behind the scrub person and passes the long sterile tie to the scrub person without touching anything but the removable paper tag.

Closed-Gloving Technique

During the **closed-gloving** process the scrub person keeps the hands inside the cuffs of the sterile gown. At first this seems tricky, but with practice the technique will become more refined and quick. Remember to keep the hands inside the cuffs at all times. In this explanation the left hand is gloved first. This is a mirror image of the instructor's demonstration. Either hand can be gloved first when establishing the sterile field.

1. If the gloves are still in the folded inner paper wrapper, they need to be opened. Using the cuff-covered hands, place the wrapper in front of you like a book. Open the two sides. There is an inner fold to the glove wrapper. With two cuff-covered hands grasp the lower inner corners of the bottom fold. Lift both corners open and fold under at the same time. When this method is used the wrapper will remain open and not fall closed during the gloving process (Fig. 16.15).
2. Extend the left forearm with the palm upward (supinated).
3. With the cuff-covered right hand, pick up the left glove from the inner wrap of the glove package by grasping the fingers, lifting straight up, and placing the glove on the left palm thumb side down. The glove fingers will be pointing toward the body (Fig. 16.16, *A*).
4. Grasp the edges of the glove cuff with the cuffed right hand and the opposite edge with the cuffed left hand. Peel the glove over the left cuffed hand, over the end of the left sleeve, and wiggle the fingers to extend them into the glove-covered left hand (Fig. 16.16, *B*). The cuff of the left glove is now over the



• **Fig. 16.15** Closed Gloving. The scrub person opens the glove wrapper on a sterile field with hands contained inside sleeves and cuffs. **A,** Primary one-fourth fold. **B,** Secondary one-half fold. **C,** Open folded wrapper is labeled "right" and "left." Gently pull lower wrapper flap down. **D,** Grasp inner corner of the wrapper and pull open. **E,** Fold bottom flap under the glove wrapper to hold the paper open.

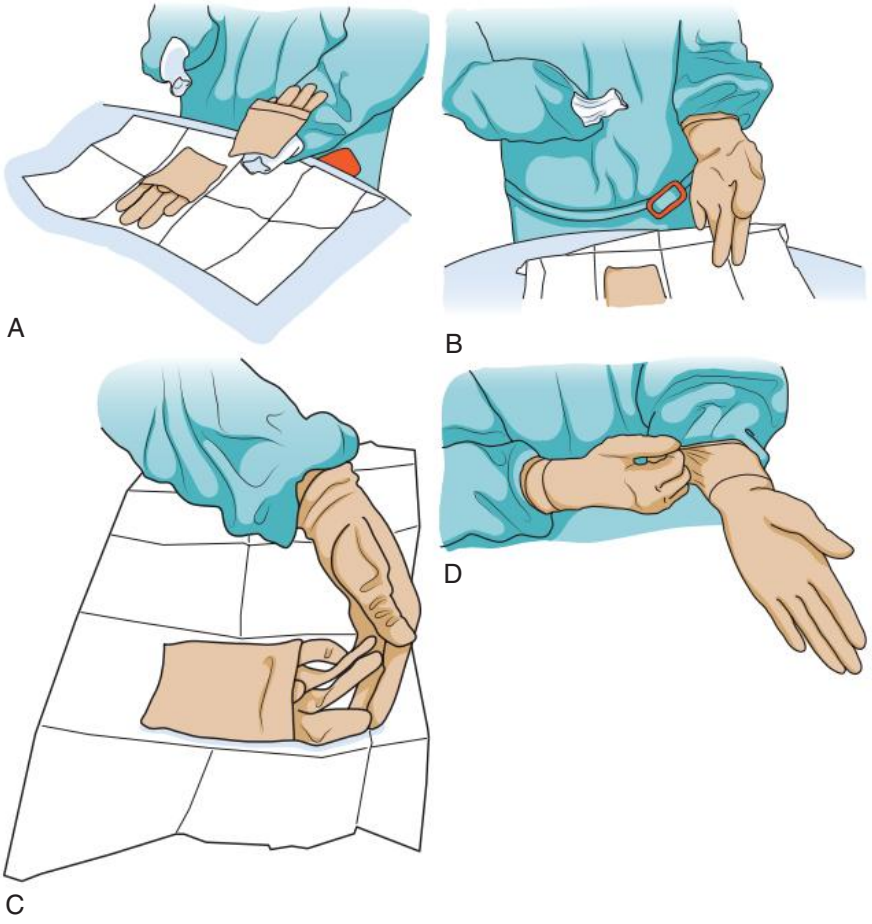
stockinette cuff of the gown, with the hand still inside the sleeve.

5. Grasp the cuff of the left glove and underlying left gown sleeve with the covered right hand. Pull the glove on over the extended left fingers until it completely covers the stockinette cuff.
6. Glove the right hand in the same manner, reversing hands. Use the sterile gloved left hand to grasp the fingers of the right glove and position the glove on the right forearm (Fig. 16.16, *C*). Be sure that the entire cuff of each sleeve is contained within the sterile glove (Fig. 16.16, *D*).

Open-Gloving Technique

Gowning for the open-gloving method is the same as for the closed-gloving method. The only difference is that the scrubbed person extends the hands all the way through the cuffs and sleeves. The hands are totally exposed outside the cuffs (Fig. 16.17). This method is not preferred for the person establishing the sterile field but is used when changing a contaminated glove. In this explanation the left hand is gloved first. This is a mirror image of the instructor's demonstration. Either hand can be gloved first.

The **open-gloving** method uses a skin-to-skin, glove-to-glove technique. The hand, although scrubbed, is not sterile and must



• **Fig. 16.16** Closed Gloving. The hands remain within the cuffs at all times. **A,** Grasp the fingers of the first glove with the opposite cuffed hand and flip directly over onto the wrist of the supinated hand. **B,** Grasp the upper side and undersides of the glove cuff and begin to pull the glove over the first cuffed hand. Work the fingers into the glove until it is fully on the hand. The white part of the first cuff must be completely covered. **C,** With the sterile gloved hand grasp the fingers of the second glove and directly flip it onto the second cuffed hand. **D,** Grasp the upper and undersides of the glove and pull it up and over the second cuff.

• **Fig. 16.17** Open Gloving. The scrub person's hands are exposed through the cuffs. The circulating nurse ties the inner back of the gown.

not contact the exterior of the sterile gloves. The everted cuff on the gloves exposes the inner surfaces. The first glove is put on with the skin-to-skin technique, bare hand to inside cuff. The sterile fingers of that gloved hand then may touch the sterile exterior of the second glove (i.e., glove-to-glove technique).

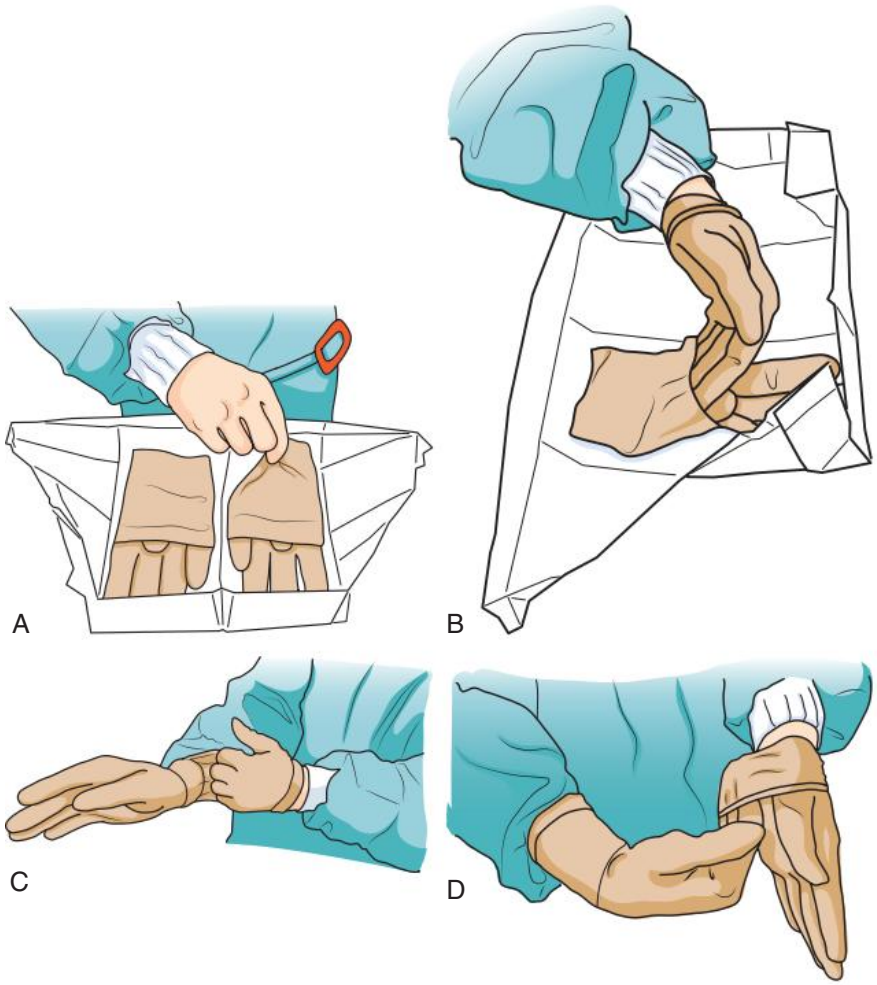
The procedure is as follows:

1. With the right hand, grasp the inner edge of the cuff of the left glove and lift from the wrapper (Fig. 16.18, *A*). Take care not to touch the inner aspect of the wrapper or the sterile exterior portions of the glove.
2. Align the fingers of the left hand and insert the hand into the glove, pulling it on, leaving the cuff turned well down over the hand. Be sure to keep the thumb adducted into the palm of the hand until it is well inside the confines of the glove. Do not adjust the cuff. This will be done as a last step.
3. Slip the fingers of the sterile gloved left hand under the everted right cuff, on the sterile side of the right glove (Fig 16.18, *B*). Pick up the glove, then step back.
4. Align the fingers of the right hand and insert the hand into the right glove, keeping the thumb adducted until well inside the glove. Pull the right glove on all the way, unfolding the cuff, and enclosing the knitted right cuff at the wrist (Fig 16.18, *C*).
5. With the sterile gloved fingers of the right hand, pull the cuff of the left glove up and over the knitted cuff of the sleeve. Avoid touching the bare wrist. Sterile surfaces may touch only sterile surfaces (Fig 16.18, *D*).

Assisted-Gowning and Gloving of a Team Member

A team member in sterile gown and gloves, usually the scrub person, may assist the surgeon or another team member in **gowning** and **gloving** by taking the following steps:

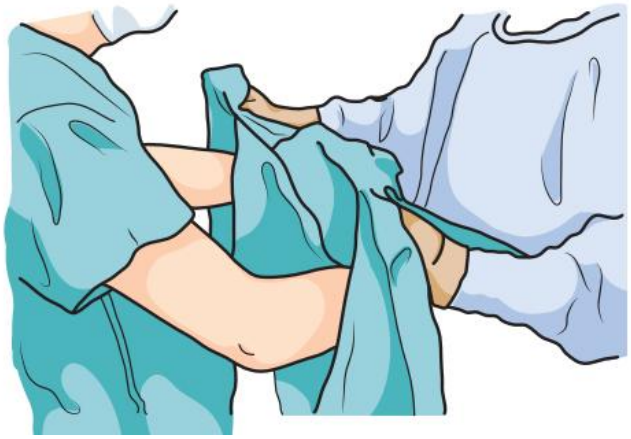
1. Open the hand towel and lay one end on the freshly scrubbed team member's right hand, being careful not to touch the hand.



• **Fig. 16.18** Open Gloving. **A,** The wrapper is opened without touching the inner surface. The first inner glove cuff is grasped without touching the sterile surface and slid over the first hand. The first cuff remains folded. **B,** The first gloved hand is slid into the second cuff on the sterile surface. **C,** The second glove is applied all the way up and over the knitted cuff. **D,** The first cuff is now pulled over the knitted cuff.

Do not hand a towel from a bloody back table or hand a towel with contaminated gloves or any instrument from the active sterile field. The biologic contamination is a hazard. The circulating nurse can open a separate gown and towel package for additional persons who need to enter the sterile field. Each person can pick up his or her own towel from the opened package. The scrub person can help with the remaining gowning and gloving procedure without touching any surface of the gown or gloves that would come in contact with the wearer's skin or clothing.

2. Lift the gown and unfold it carefully with the sterile outside toward you and the unsterile inside toward the person being gowned, holding it open at the shoulders and neckline by cuffing over the hands (Fig. 16.19).
   Do not hand a gown from a back table when the case is in progress. The drapes and gowns on the field in progress are considered biologically contaminated and could contaminate the wearer.
3. Keeping your hands on the sterile side of the gown under a protective cuff of the neck and shoulder area, offer the inside of the gown for the team member to don. He or she slips the arms into the sleeves. Take care not to let the sleeves make contact with unsterile areas.



• **Fig. 16.19** Gowning a team member by holding the armholes open and protecting hands inside sterile surface of the gown.

4. Release the gown when it is secured by the person being gowned. The team member holds arms outstretched while the circulating nurse pulls the gown onto the shoulders and adjusts the sleeves so that the cuffs are properly slid back to expose the hands for **open-assisted gloving**. If the

• **Fig. 16.20** Gloving a team member by open-assisted method.

closed-assisted method is preferred, the person being gowned will keep the hands within the knitted cuffs. The circulating nurse touches only the inside of the gown at the seams and secures the gown at the back.

Gloving a Team Member

1. Offer the right glove first. Pick up the right glove, grasping it firmly with the fingers of both hands under the everted cuff on the sterile side. Hold the palm of the glove toward the person being gloved.
2. Stretch the cuff sufficiently open to allow for passage of the right hand. Avoid touching the hand by holding your thumbs out (abducted) (Fig. 16.20).
3. Exert upward pressure as the person slides the hand into the glove. Do not allow the hand to drop below the level of the sterile field.
4. Pull the glove cuff up and over the knitted cuff of the right sleeve. Enclose the entire cuff.
5. Repeat for the left hand. The person being gloved can facilitate the process by supinating the gloved right hand and flexing the fingers like a hook to hold open the cuff of the glove being donned.
6. If a sterile vest is needed, hold it for the surgeon to slip the hands into the armholes. Be careful not to contaminate the gloves at the neck level. If the gown is a wraparound, assist the person to tie it. Remember that the back of the gown is not considered sterile even if a sterile vest is worn. The back is not considered sterile because it is not in the field of vision of the sterile team.

Removing or Changing Contaminated Gown and Gloves

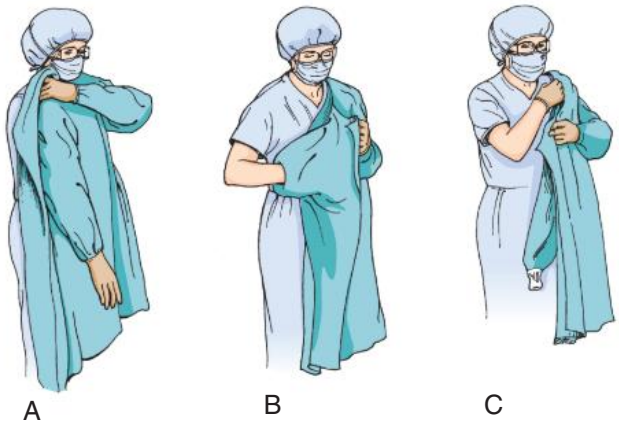
Occasionally a contaminated gown must be changed during a surgical procedure. This means that both gown and gloves must be removed and changed. The circulating nurse obtains sterile gowns and gloves for personnel needing to change. The gown is always removed first, followed by the gloves. The contaminated team member steps away from the field and unties the wrap-around tie, and the circulating nurse unfastens the neck and the inner back tie of the soiled gown. The contaminated person grasps the front of the gown at the shoulders below the neckline (Fig. 16.21, *A*). The gown is pulled off inside out by the wearer and rolled off away from the body (Fig. 16.21, *B* and *C*).

The gloves are removed using a glove-to-glove and then skin-to-skin technique. The cuffs of the gloves usually turn down as the gown is pulled off the arms. A glove-to-glove and then skin-to-skin technique is used to protect the clean hands from the contaminated outside of the gloves, which bear blood and body fluid of the patient (Fig. 16.22). The gloves are removed as follows:

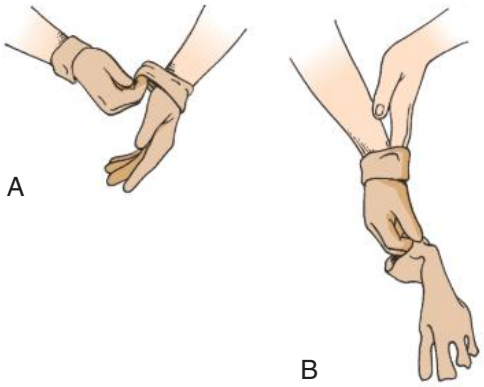
1. Grasp the cuff of the left glove with the gloved fingers of the right hand, and pull it completely off inside out.
2. Slip the ungloved fingers of the left hand under the cuff of the right glove, and slip it off inside out.
3. Both gloves will be inside out to contain the contamination. Discard the gloves in a biohazard trash receptacle.
4. Wash hands. Gloves are never 100% impervious.

This is the same manner in which a gown and gloves are removed at completion of the surgical procedure. Contaminated gowns and gloves are disposed of immediately in the appropriate biohazard receptacle.

When a sterile team member becomes contaminated during a case, rescrubbing is not necessary to regown and reglove to reenter the sterile field. If only a sleeve is contaminated, a sterile sleeve may be put on over the contaminated one. If the person is not planning to reenter the sterile field, he or she should wash the hands immediately after removing the gloves.



• **Fig. 16.21** Sequence of Scrub Person Removing Soiled Gown at End of Surgical Procedure. The gown is removed before the gloves. Clean arms and scrub suit are protected from contamination outside of gown. Do not reach behind the gown to untie the back strings. Have someone untie the back. **A,** With gloves on, grasp the front shoulder of gown and pull forward. **B,** In pulling gown off arms, make sure that gown sleeve is turned inside out to prevent contamination of scrub attire. **C,** The other shoulder is grasped with the other hand, and the gown is removed entirely by pulling it off inside out and rolling it away from body.



• **Fig. 16.22** Scrub person removing the contaminated gloves.

Managing Contaminated Gloves or Objects during the Surgical Procedure

Contamination of the gown and gloves depends on the nature of contamination and whether the scrub person is double gloved. Any puncture of a glove requires a complete glove change, even if double gloved. The puncturing instrument is passed off to the circulating nurse.

Contamination When Wearing Two Sets of Gloves

The contaminated outer glove can be removed, leaving the sterile under glove intact. A new second pair of gloves can be applied over the remaining gloves. If the nature of the contamination is a puncture, both sets of gloves are considered contaminated and must be removed. Regloving is accomplished by the open-gloving method.

Contamination When Wearing a Single Set of Gloves

A second glove can be applied over the top of a superficially contaminated glove by using the open-gloving method. If covering with a second glove is not possible, the contaminated glove must be changed immediately. If stepping away immediately is not feasible, the contaminated hand and any object involved in the contamination should be held away from the sterile field for the circulating nurse to remove.

The glove is changed as follows:

1. Turn away from the sterile field and request a new pair of sterile gloves from the circulating nurse. Regloving should take place on a surface separate from the main sterile field.
2. Extend the contaminated hand to the circulating nurse who, wearing protective gloves, grasps the contaminated objects and sets them aside. The circulating nurse then grasps the outside of the contaminated glove cuff about 2 inches (5 cm) below the top of the glove, closer toward the palm, and pulls the glove off inside out. The scrubbed person can scrunch the palm of the hand to make grabbing the glove easier for the circulating nurse. Care is taken not to snap the glove, creating an aerosol. If the nurse tries to grasp the cuff of the glove, the gown can be contaminated.
3. Preferably, a sterile team member gloves another. If this is not possible, step aside and glove the hand using the open-gloving technique.

The closed-gloving technique is inappropriate for a glove change during a surgical procedure because contamination of the new glove by the porous cuff of a gown in use is inevitable. The hand will be contaminated by the knitted cuff of the gown, which has absorbed body sweat. The contaminated cuff may not be pulled down over the hand because the cuff is contaminated by shed skin cells. Using the cuff to perform closed gloving will contaminate the fresh gloves.

The only way closed gloving is acceptable is for the scrub person to remove both the contaminated gown and gloves and another sterile gown is donned before regloving using the closed-gloving method. The scrub person should change his or her own gloves before gowning and gloving another team member to avoid exposing the team member to contamination.

Decontamination and Disinfection

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Describe the steps in decontamination.
- List Spaulding's classifications of patient care items.
- Compare and contrast the three levels of disinfection.
- Discuss how an instrument is rendered safe for handling.
- Identify three safety issues associated with the use of chemical disinfectants.

KEY TERMS AND DEFINITIONS

Bactericide Kills gram-negative and gram-positive bacteria unless specifically stated to the contrary (adj: bactericidal). Action may be specific to a species of bacteria.
Bacteriostatic Inhibits growth of bacteria.
Bioburden Degree of microbial load on an item before sterilization.
Biofilm Microbial load attached to a surface in a fluid environment. Microbes in slime adhere to surfaces of all kinds of moist material, such as implantable metals, plastics, and tissue, causing antibiotic resistance. Difficult to remove.
Decontamination Process by which chemical or physical agents are used to clean inanimate, noncritical surfaces. A specific contact time is not specified. A low-level disinfectant is commonly used for this purpose. If a known organism, such as hepatitis B virus (HBV), *Mycobacterium tuberculosis* (TB), or human immunodeficiency virus (HIV), is present on the surface, an intermediate-level disinfectant should be used.
Deionized water Water that has been processed through synthetic cation-anion resins to remove the positively or negatively charged ions.
Disinfection Chemical or physical process of destroying most forms of pathogenic microorganisms except bacterial endospores; used for inanimate objects but not on tissue. The degree of disinfection depends primarily on the strength of the agent, the nature of the contamination, and the purpose for the process.
Distilled water The process of evaporating water and creating condensation from the steam that is collected for future use.
Endospore Protective capsule that forms inside specific bacterial species (class Clostridia and genus *bacillus*) to protect the genetic matter from destructive forces, such as disinfection or sterilization.
Enzymatic cleaner Protease product used to remove organic protein material from surgical instruments before disinfection.
Fungicide Kills fungi.
High-level disinfection Process that destroys all microorganisms except high numbers of bacterial endospores.
Intermediate-level disinfection Process that inactivates vegetative bacteria, including *M. tuberculosis,* and most fungi and viruses but does not kill bacterial endospores.
Low-level disinfection Process that kills most bacteria, some viruses, and some fungi but does not destroy resistant microorganisms such as *M. tuberculosis* or bacterial endospores.
Pasteurization Not a method of sterilization. This heating process kills many pathogenic microorganisms that are found in biosubstances such as milk or wine.
Sporicide Kills endospores.
Virucide Kills viruses.

Central Processing Department

Workflow in the Processing Areas

The central service (CS) personnel work within confined areas in a specialized department. Each CS worker has a specified set of duties based on infection control parameters of the facility. The surgical services central processing department (CPD or SPD) is located in close proximity to the main surgical suite to minimize the potential for cross-contamination between soiled and clean instruments and supplies. The CPD is composed of the **decontamination** area, set assembly room, sterile processing, sterile storage, and case cart packing room.

The CPD is set up to receive soiled instruments through one entrance, the decontamination room. The soiled instruments are delivered by the surgical personnel to the CPD covered and

contained to prevent dispersal of microorganisms along the traffic pattern. Some facilities use elevators or dumbwaiters to transport soiled instrumentation.

CS personnel, wearing the appropriate personal protective equipment (PPE), are responsible for cleaning instruments and equipment in the decontamination area and do not enter areas where cleaned instruments are stored, packaged, or sterilized. Care is taken to ensure that sharps and contaminated disposables are discarded into the proper puncture-proof containers per facility policy.

The CS decontamination personnel have specialized training in cleaning many types of instruments using several methods, as described later in this chapter. The decontamination process renders soiled instruments safe for handling, but not safe for patient use. After decontamination the cleaned instruments are transferred via a pass-through door to the instrument set assembly room. Some facilities have a conveyor system that automatically sends the cleaned items to the clean assembly area after passing through the washer.

The CS personnel in the clean set assembly room organize the instruments into standardized trays according to tray inventory sheets. Some assembly rooms have computerized scanning equipment to track instruments through bar codes and validate set contents. Most facilities have computerized instrument count sheets that correspond to the contents of the tray. A copy of the count sheet accompanies the assembled tray as it is wrapped or packed into a closed container for sterilization. CS personnel in the clean area also operate the sterilizers and place the sterilized trays in the sterile storage area until they are needed for use.

When a tray is needed for a surgical procedure other CS personnel in the sterile storage area pack a case cart with the necessary sterile tray and supplies for the surgical team. The case cart exits the CPD through a separate door that has no communication with the decontamination area. Detailed information concerning sterilization is found in Chapter 18.

Central Service Personnel

CS personnel entrusted with the care, cleaning, assembly, and processing of patient care equipment to the appropriate degree of safety require specific training and credentialing. Training entails learning about thousands of surgical instruments and their care. CS personnel need to know and understand all methods of instrument processing such as decontamination, **disinfection**, and sterilization. The role of the CS technician requires attention to detail.

Credentialing of Central Service Personnel

New Jersey, New York, Connecticut, and Tennessee require certification for CS personnel. Personnel currently holding positions in CS are required to become certified. New hires will have 2 years from the date of hire to attain the credential as recommended by the Association for the Advancement of Medical Instrumentation (AAMI). Training programs take between 6 and 12 months to complete. There are two recognized organizations for CS certification. AAMI sets the standards for instrument processing in the United States and recognizes both certifying bodies.

The International Association of Healthcare Central Service Materiel Management (IAHCSMM) is driving the effort to require mandatory standardization of education and certification of all CS personnel. Information about CS certification requirements via IAHCSMM can be found at www.iahcsmm.org.[1]

Certification signifies that an individual professional has attained specific knowledge and skill in a specific professional practice. It sets a standard for performance and raises the bar for expectations in the profession. Successful passage of the certification examination is represented by the certified registered central service technician (CRCST) designation after the name of the CS employee. IAHCSMM offers short-term 1-year certification at four levels: (1) technician, (2) instrument processing, (3) leadership, and (4) vendor certification.[1]

The Certification Board of Sterile Processing and Distribution (CBSPD) is an international sterile processing certification examination program accredited by the National Commission for Certifying Agencies (NCCA) offered four times per year. The examination is offered only in English. CBSPD offers five levels of certification: (1) technician, (2) supervisor and manager, (3) flexible endoscope reprocessor, (4) surgical instrument processor, and (5) ambulatory surgery.

CBSPD certification eligibility requires one of the following: 12 months of employment in the role or completion of a formal central processing course with a passing grade of 70% or higher. Successful candidates earn the certified sterile processing and distribution technician (CSPDT) credential. Certification is valid for 5 years and can be renewed through reexamination or by continuing education, attaining 100 to 150 points through education or work experience. Information about certification of CS personnel can be found at www.sterileprocessing.org.

Becoming certified encourages individuals to seek additional training that exemplifies certification-level knowledge. Periodic competency testing should be incorporated into performance assessment. (An example of CS personnel competency testing can be found at www.apic.org.)

Coordination of Central Service Staff and Operating Room Staff

The relationship between CS staff and operating room (OR) staff is complex and synergistic. The OR staff relies on the CS staff to provide complete instrumentation processed to the appropriate degree of safety for patient use. The CS staff relies on the OR staff to return used sets in a safe-to-process condition without concealed blades or other sharps that pose a risk for injury during preparation for processing. Each person has a stake in the intricate coordination of preparing for a surgical procedure. Mutual respect and cooperation between the two specialty areas is in the best interest of safe and efficient patient care.

Instrument Cleaning and Decontamination

Decontamination of instrumentation is performed in a designated area by specially trained personnel immediately after completion of the surgical procedure. The scrub person can facilitate the instrument decontamination process by wiping instruments as they are used on the sterile field and then opening the instruments completely before placing in a tray for return to the processing area. This is referred to as *point-of-use cleaning.* An **enzymatic cleaner** such as a foam or solution can be applied to the instruments to prevent debris drying during transport to the CS area. All instruments on the table during a surgical procedure require decontamination before processing to the required level of safety for patient use. The processing of endoscopes is discussed in Chapter 32.

Decontamination combines mechanical or manual cleaning and a physical or chemical microbicidal process. Prerinsing, washing, rinsing, and disinfecting/sterilizing is done in the processing department to render the instrumentation safe for handling by CS personnel. This part of the process is referred to as *thorough cleaning* or *return-to-use cleaning.*

After the formal decontamination process, instrumentation is assembled into sets by the CS technician and processed either by sterilization or disinfection (high level, intermediate level, or low level) for use by the OR staff in patient care. Methods and procedures for decontamination and disinfection vary according to the item to be processed and the recommended agent used in processing. Personal protective equipment (PPE) should be worn while using chemical disinfecting agents.

Prerinsing/Presoaking

The purpose of prerinsing or presoaking is to prevent blood and debris from drying on instruments or to soften and remove dried blood and debris. The circulating nurse can prepare a basin or plastic bin (with a cover) of enzymatic solution for the scrub person. For a short immersion period, instruments may be presoaked in the following list of agents and solutions:

- A triple proteolytic enzymatic detergent. Proteolytic enzymes dissolve blood and debris, and the detergent removes dissolved particulate from the surfaces of instruments, including otherwise inaccessible areas such as lumens.
- An enzymatic agent diluted per manufacturer's instructions.
- Water with a low-sudsing, near-neutral detergent. The detergent should be compatible with the local water supply.
- Plain, clean, demineralized distilled water.
- Sodium hypochlorite (chlorine bleach) is corrosive; however, it is used as a presoak in suspected or potential prion disease such as transmissible spongiform encephalopathy (TSE). Instruments should not be soaked in any chlorine compound for more than 1 hour and should not be autoclaved with chlorine solution because of the formation of toxic chlorine gas.
- Soaking in a phenolic, or sodium hydroxide is an alternative, but chlorine bleach is the most reliable in reducing the prion titer within 1 hour. These chemicals are extremely corrosive and are not appropriate for use on endoscopes.

Prerinsing or presoaking instruments with an enzymatic solution in the OR can make further processing more efficient. The soaking solution should be disposed of if possible before transport to eliminate the possibility of spillage and contamination. Instruments should not be cleaned in scrub sinks or utility sinks in the substerile room. Instruments transported in an enzymatic soak solution should be transported to the processing department in a covered container that is leak and puncture proof. The container should be labeled biohazard and easily identified.

Manual Cleaning

If a washer-sterilizer or washer-decontaminator is not available, instruments are washed by hand in the processing area. The purpose of manual cleaning is to remove residual blood and debris before terminal sterilization or high-level disinfection.

Delicate and sharp instruments should be handled separately and processed according to the manufacturer's instructions. Complex instruments require complete disassembly before cleaning. Other instruments require special care. For example, the outside surfaces of powered instruments must be cleaned, but these instruments cannot be immersed in liquid. Some powered equipment requires lubrication as part of the cleaning process.

Personnel in the processing area wear PPE such as caps, gloves, waterproof aprons, and face shields to prevent accidental spray from contaminated body fluids and chemical cleaning solutions.

The following steps should be observed when cleaning instruments manually:

1. Fill the washing sink with clean, warm water to which a noncorrosive, neutral pH, low-sudsing, free-rinsing detergent has been added.
   a. Detergent should be compatible with the local water supply. The mineral content of water varies from one region to another; a water softener may be used in the system routinely to minimize mineral deposits. Regardless of the water content, the detergent should be anionic or nonionic and have a pH as close to neutral as possible. An alkaline detergent (pH more than 8.5) can stain instruments; an acidic detergent (pH less than 6) can corrode or pit them.
   b. Proteolytic enzymatic detergents dissolve blood and protein and remove dissolved debris from crevices. These detergents are effective in a wide range of water qualities.
   c. Liquid detergents are preferable because they disperse more completely than do solids. Dilute the concentration before contact with instruments to avoid corrosion and staining. Do not pour liquid or put solid detergents directly on instruments.
2. Wash instruments carefully to guard against splashing and creating aerosols.
   a. Use a soft brush to clean serrations and box locks. A soft-bristle toothbrush may be used to clean ophthalmic, microsurgical, and other delicate instruments. Keep instruments totally submerged while brushing to minimize aerosolizing microorganisms and chemicals.
   b. Use a soft cloth to wipe surfaces. A nonfibrous cellulose sponge will prevent damage to delicate tips.
   c. Remove bone, tissue, and other debris from cutting instruments.
   d. Never scrub surfaces with abrasive agents such as steel wool, wire brushes, scouring pads, or powders. These agents will scratch and may remove the protective finish on metal, thus increasing the likelihood of corrosion. The finish on stainless steel instruments protects the base metal from oxidation.
   e. Instruments that contain lumens should be soaked vertically in solution, brushed inside, and flushed with cleaning solution. Some lumens can be flushed with 70% to 90% alcohol before processing.
3. Rinse instruments thoroughly in **distilled water** or **deionized water** at the temperature recommended by the manufacturer. Some enzymes can be inactivated by extreme temperatures. The water should not exceed 140° F (60° C) to prevent burns of the skin. Inadequate rinsing can leave a surface residue that can stain instruments.
4. Load instruments into the appropriate trays for terminal sterilization or containers for high-level disinfection.
   a. Put instruments back into sterilization racks or replace the protective guards as appropriate.
   b. Arrange instruments that can be steam-sterilized in sterilizer trays for the washer-sterilizer or washer-decontaminator. The unwrapped tray is terminally steam-sterilized to make it safe for handling.
   c. Unless an automatic cleaning, disinfecting, and sterilizing machine is available, immerse lensed instruments that are heat sensitive in a high-level disinfectant after manual cleaning.
   d. Follow the manufacturer's instructions for the proper decontamination, cleaning, lubrication, and terminal sterilization of powered instruments.

Washer-Sterilizer/Washer-Decontaminator

Mechanical cleaning and terminal sterilization/decontamination can be accomplished in an automated washer-sterilizer or washer-decontaminator. Precleaning takes place before instruments are placed in any automated machine.

A washer-sterilizer requires instruments to be prewashed by hand in germicidal solution at 110° F (43.3° C) before being placed in the machine. All **bioburden** must be removed for the washer-sterilizer cycle to be effective. The temperature of the washer-sterilizer ranges from 250° F to 280° F (121° C to 138° C) and would cause coagulation and crusting of protein. The instruments should be thoroughly rinsed. At the end of the cycle the instruments may be safely handled without gloves. The sets can be assembled and prepared for routine sterilization. A cycle in a washer-sterilizer makes the instruments safe to handle with the bare hands, but it does not render instruments safe for immediate patient use or sterile storage.

A washer-decontaminator cleans with a spray-force action. It is comparable to the washer-sterilizer in that the cycle includes a cold-water prerinse to loosen blood and protein, an alkaline low-sudsing detergent wash, a neutral rinse, and finally, steam and heat. A washer-decontaminator does not reach the same temperature as a washer-sterilizer. It cleans at a maximum temperature of 140° F to 180° F (60° C to 82° C), rendering the instrument safe to handle without gloves at the end of the cycle. Some models incorporate ultrasonic capabilities and lubrication for select loads. The sets can be assembled and prepared for routine sterilization when the process is complete.

An indexed washer-decontaminator has several chambers. The instrument tray automatically passes from chamber to chamber like a car wash. It is indexed for the prerinse, ultrasonic cleaning, wash, rinse and lubrication, and drying cycles. The multiple chambers of the indexed washer-decontaminator can process several trays simultaneously.

Instruments should be arranged in perforated trays for processing in the washer-sterilizer or washer-decontaminator. The following steps should be observed when arranging the instruments:

1. Place heavy instruments in a separate tray or in the bottom of a tray, with smaller, lightweight instruments on top.
2. Turn instruments with concave surfaces, such as curettes and rongeurs, with the bowl side down; this facilitates drainage of the concave surface. Be certain that bone and tissue are removed from these surfaces during precleaning.
3. Open the box locks and pivots of hinged instruments to expose maximum surface area.
4. Disassemble complex instruments that can be taken apart without tools (e.g., stapling devices).
5. Position sharp or pointed instruments carefully on top of other instruments to prevent contacts that could damage the cutting edges or surfaces of other instruments. An alternative is to either place sharp instruments in a separate tray or terminally sterilize them after manual cleaning. Fine, delicate instruments should be put in a washer-sterilizer or washer-decontaminator according to the manufacturer's instructions.
6. Always arrange instruments neatly. They should not be randomly piled on top of one another.

Ultrasonic Cleaning

Surgical instruments vary in configuration from smooth surfaces, which respond to most types of cleaning, to complicated devices that contain box locks, serrations, grooves, blind holes, and interstices that are difficult to clean. Using high-frequency sound waves, ultrasonic energy thoroughly cleans by a process of *cavitation.* These sound waves generate tiny bubbles in the solution of the ultrasonic cleaner. The bubbles are small enough to get into the serrations, box locks, and crevices of instruments that are impossible to clean by other methods. The bubbles expand until they become unstable and collapse in on themselves. This implosion generates minute vacuum areas that dislodge, dissolve, or disperse soil.

For ultrasonic cleaning, precleaned and decontaminated instruments are completely immersed in the cleaning solution. The tank should be filled to a level of 1 inch (2.5 cm) above the top of the instrument tray. Suitable detergent, as specified by the manufacturer, is added. The temperature of the water should be between 100° F and 140° F (37.7° C to 60° C) to enhance the effectiveness of the detergent, but it should not be extremely hot, which would coagulate protein material on instruments. Instrument trays should be designed for maximum transmission of sonic energy. An important relationship exists among wire gauge, opening size, and sonic frequency. A large mesh of small wire size transmits more energy than heavy wire with narrow spacing.

The solution is degassed by the ultrasonic energy. Gas, which is present in most tap water, impedes the transmission of sonic energy. An electrical generator supplies electrical energy to a transducer. The transducer converts the electrical energy into mechanical energy in the form of vibrating sound waves of such high frequency that they are not audible to the human ear. The presence of excess gas prevents the cleaning process from being fully effective, because the cavitation bubbles fill with gas and the energy released during implosion is reduced. Tap water should be degassed for 5 minutes or longer each time it is changed. The solution should be changed at least once per shift and whenever the detergent solution is visibly soiled. The inside of the tank should be cleaned between fillings.

An ultrasonic cleaner is not a sterilizer like the washer-sterilizer. The ultrasonic process uses mechanical and chemical action to process the instrumentation, but the instrument does not go through a sterilization process that renders the item safe for handling. The terminal sterilization function is performed separately in a different machine after rinsing the cleaning solution from the instruments.

Most surgical instruments, including ophthalmic instruments, microinstruments, glassware, rubber goods, and thermoplastics, can be definitively cleaned by this method to remove the tiniest particles of debris from crevices. The manufacturer's instructions must be carefully followed. In general, these instructions include:

1. Arrange heavy instruments at the bottom of the tray and lightweight instruments on top.
2. Open the box locks and pivots of hinged instruments. Disassemble instruments as appropriate.
3. Protect cutting edges from other instruments. Fine, delicate microsurgical and ophthalmic instruments may be damaged by vibrations or contact with each other. Some small units may be suitable for delicate instruments.
4. Separate dissimilar metals. Do not mix stainless steel instruments with other metals because electrolysis with resultant etching may occur.
5. Do not clean plated instruments in an ultrasonic cleaner. Cavitation will accelerate the rupture and flaking of plating. Plated instruments are not suitable for use in surgery. The surface coating of the instrument could potentially flake or peel during use and leave particles in the patient's tissues. Plated instruments will rust if the coating is removed.
6. Rinse instruments thoroughly in hot deionized water after the cleaning cycle to remove any surface debris and detergent residue.

7. Dry instruments promptly and completely before reassembling or storing. Instruments will corrode, spot, or stain if they are stored with trapped moisture.

Lubrication

All instruments with moving parts should be lubricated after cleaning. This is particularly important after ultrasonic cleaning, because the sonic energy removes all lubricant. Instruments are immersed in steam-penetrable antimicrobial water-soluble lubricant that is sometimes referred to as *instrument milk.* The antimicrobial properties help prevent microbial growth in the lubricant bath, which can be reused for up to 7 days. A water-soluble lubricant deposits a thin film deep in box locks, hinges, and crevices but does not interfere with sterilization. Some lubricants also contain a rust inhibitor to prevent electrolytic mineral deposits.

Mineral oil, silicones, and machine oils are not used to lubricate instruments because they leave a residue that interferes with steam or ethylene oxide sterilization. Oiling any surgical instrument constitutes a break in technique by introducing a nonsterile item into a sterile field during its use in patient care. Oil deposits can be left in a patient's tissues.

The lubricant should be used according to the manufacturer's instructions for dilution, effectiveness, and exposure. To use most lubricants, instruments are completely immersed for 30 to 45 seconds; they are dipped and then allowed to drain dry. The solution is not rinsed or wiped off; excess solution can be shaken off. The thin film will evaporate during steam sterilization. This process is sometimes referred to as *milking* the instrument, because the solution is white and opaque like milk.

Inspecting and Testing

Each instrument must be critically inspected after each cleaning. Instruments with movable parts should be inspected and tested after lubrication. Each instrument should be completely clean to ensure effective sterilization, and each should be inspected for proper function. The following essential points should be observed when inspecting an instrument after cleaning:

- Check hinged instruments for stiffness. Box locks and joints should work smoothly. Stiff joints are usually caused by inadequate cleaning. Lubrication eases stiffness temporarily. If box locks are frozen, leave the instruments in a water-soluble lubricant bath overnight, then gently work the jaws back and forth. Reinspect the instrument for cleanliness and function.
- Test forceps for alignment. A forceps that is out of alignment can break during use. Close the jaws of the forceps slightly; if they overlap, they are out of alignment. The teeth of forceps with serrated jaws should mesh perfectly. Hold the shanks in each hand with the forceps open and try to wiggle them. If the box lock has considerable play or is very loose, the forceps will not hold tissue securely. If a surgeon continues to use it, jaw misalignment will occur and impair the effectiveness of the forceps.
- Check the ratchet teeth. Ratchet teeth are subject to friction and metal-to-metal wear by the constant strain of closing and opening. Ratchets should close easily and hold firmly. To check this, clamp the forceps on the first tooth only. Hold the instrument at the box lock and tap the ratchet teeth lightly against a solid object. If the forceps springs open, it is faulty and should be repaired. A forceps that springs open when clamped on a blood vessel or duct is hazardous to the patient and is an annoyance to the surgeon. The ratchets must hold.
- Check the tension between the shanks. When the jaws touch, a clearance of 1/16th to 1/8th inch (1.5 to 3 mm) should be visible between the ratchet teeth of each shank. This clearance provides adequate tension at the jaws when closed. The misalignment of hinged instruments is a common problem that occurs primarily as a result of misuse. The instrument needs to be repaired or replaced if the teeth or serrations do not mesh perfectly or the jaws overlap.
- Test needle holders for needle security and precision. Clamp an appropriate-size needle in the jaws of the needle holder and lock it on the second tooth of the ratchet. If the needle can be turned easily by hand, the needle holder needs repair or replacement. Using a needle holder for placement of a blade on a scalpel handle can cause the jaws of a needle holder to loosen. Needle holders are designed for holding needles and should not be used for any other purpose.
- Test scissors for correctly ground and properly set blades. The blades should cut on the tips and glide over each other smoothly. Use tissue/operating scissors to cut through four layers of gauze at the tip of the blades (or through two layers if the scissors are less than 4 inches [10 cm] long). The scissors should cut with a fine, smooth feel and a minimum of pressure. Tissue scissors should not be used to cut dressings or tape.
- Electrical insulation should be intact on all reusable electrosurgical equipment. Split insulation can cause inadvertent tissue damage during use.
- Inspect the edges of sharp and semisharp instruments such as trocars, needles, chisels, osteotomes, rongeurs, and adenotomes for sharpness, chips or dents, and alignment. Remove any questionable items from service, and send for repair or replacement. Shards of metal could be deposited in the patient's tissue during use.
- Inspect microsurgical instruments under a magnifying glass or microscope to check alignment and detect burrs on tips and nicks on cutting edges. The exact alignment of teeth on fine-tooth forceps is an absolute necessity. Microscopic teeth are very easily bent. Be certain that these instruments are thoroughly dry. A chamois is useful for drying delicate tips.
- Check pins and screws of reusable staplers to be sure they are secure and intact. They can become loose or fall out during ultrasonic cleaning as a result of vibration.
- Flatten or straighten malleable instruments such as retractors and probes. Weakened or cracked items should be immediately replaced.
- Self-retaining retractors should provide free motion and sliding of the retracting blades. They should attach, slide, and detach easily. The tilts and ratchets should slide and hold as appropriate. All screws, wing nuts, and removable parts should be inspected for stripped threads.
- Demagnetize instruments by passing them back through a magnetic field. Although this is not a common occurrence, instruments can become magnetized when magnetic sheets are used in the OR.
- Unclean or questionable instruments should be returned to the cleaning area for ultrasonic cleaning. Instruments in poor working condition should be removed from the processing area. A place is usually designated in the OR suite or the CS department for the collection of instruments for repair. A defective instrument should be tagged as unsafe for use and not be allowed to remain in circulation. These instruments are good for use in a teaching environment.

Instrument Marking for Identification

New instruments may be marked for identification before they are put in service. Some manufacturers will imprint identification numbers or bar codes with a laser when their instruments are purchased. The surface of the instrument should not be etched or engraved by personnel in the department. Etching and engraving cause destruction of the instrument surface that permits trapped microorganisms and **endospores**.

Some facilities affix specialized heat-stable tape to instruments to color code them by sets or specialty. These tapes must withstand cleaning and sterilizing without peeling. They must be replaced if they loosen. The tape is wrapped around the circumference of the handle but should not overlap. The edges should just meet. The presence of marking tape allows debris to accumulate in the folds. Worn or peeling tape leaves an adhesive residue on the instrument that is hard to remove and attracts debris. The tape manufacturers have commercial tape-removal systems available for purchase. The kits include a tape cutter and solvent that is safe for use on instruments.

Instrument processing departments may find that a loose-leaf binder containing pictures and descriptions of each instrument is useful for the identification of specialty set contents. This process can be cumbersome and time consuming because manufacturers use different numbers and names for like devices.

Repairing or Restoring versus Replacing Instruments

Instruments in poor working condition inhibit the surgeon and create a serious hazard for the patient. Instruments should be repaired at the first sign of damage or malfunction. If an instrument breaks during a procedure, all pieces should be accounted for in their entirety. A lighted magnifying lens is a useful CS tool for examining instrumentation.

Repair

Even with normal usage the blades of scissors and the edges of other cutting instruments become dull over time, just as kitchen knives do at home. Steam sterilization causes the softening of the metal that in turn dulls the edge. Cutting instruments must be sharp. For this reason, scalpel blades are disposed of after a single patient use. Osteotomes, chisels, gouges, and meniscotomes can be sharpened by specialty companies that use handheld hones or a honing machine designed for this purpose. Some specialty instrument repair companies will come to the facility in a mobile van fully equipped with all the machines and tools needed to recondition and repair surgical instruments. Scissors, curettes, rongeurs, and reamers should be frequently rotated for sharpening. OR and CS personnel are not qualified to sharpen or repair surgical instruments.

Drill bits and saw blades should be single-use items. Reuse and processing cause the cutting edges to rip tissue instead of cutting. Stiff joints or frozen box locks are the result of inadequate cleaning or corrosion caused by trapped moisture or a corrosive substance. The instrument should be repaired before the box lock cracks and the instrument must be replaced.

After repeated use, instruments eventually wear, misalign, and stiffen. Parts such as inserts, screws, or springs may need to be replaced. The life of many instruments can be extended by preventive maintenance or prompt repair.

Restoration and Resurfacing

Instruments may become spotted, stained, corroded, pitted, or rusted. Some surface discoloration will appear with normal use, but the unusual or severe buildup of deposits may impair function or sterilization. The color of a stain may help identify a problem that needs to be corrected, such as the following examples:

- Light or dark water spots (from mineral content in tap water or condensate in sterilizer; caused by inadequate drying)
- Rust-colored film (from iron content or softening agents in steam pipes)
- Bluish-gray stain (from some chemical sterilizing or disinfecting solutions)
- Brownish stain (from polyphosphate cleaning compounds that are incompatible with local water supply, leaving a chromic oxide film on instruments)
- Purplish-black stain (from detergents that contain ammonia or from amines in steam lines)
- Rust deposits (from inadequate cleaning or drying, agents not thoroughly rinsed, electrolytic deposits from exposed metal under chipped chrome plating onto stainless steel, or residues in textile wrappers; avoid the use of plated instruments in surgery; these are not surgical grade instruments)

Blood, saline solution, and detergents that contain chloride can cause pitting if they are not rinsed promptly and thoroughly. Detergents with high or low pH can destroy the protective chromium oxide layer on stainless steel.

If an instrument has been damaged, the surface can be repolished and passivated by the manufacturer to restore the integrity of the finish.

Replacement

Broken instruments must be replaced if they are beyond repair or restoration. With normal use, good-quality surgical instruments have an expected life of at least 10 years. Using these precise tools for only their intended purpose cannot be overemphasized. Misuse and abuse are the most common causes of instrument breakage. Use of a lightweight instrument on heavy tissue causes the jaws to bend or "spring." Using a needle holder to load and disarm knife blades can damage the jaws. A heavier clamp should be used for this purpose.

Instrument counts and accountability activities in the OR help prevent instruments from being discarded into the trash or sent to the laundry. Replacing instruments that have been needlessly damaged is an unnecessary expense for the OR. Repairing the laundry equipment can be an additional expense. Personnel could be injured by instruments that protrude through trash bags and puncture the skin. Some facilities, having had extreme instrument losses, have installed metal detectors in the trash room. These are valid reinforcements for accountability for instrumentation in the OR.

Disinfection of Items Used in Patient Care

Disinfection differs from sterilization by its lack of sporicidal power. Theoretically, all items used in the sterile field must be sterilized. Surfaces of items that will penetrate or separate tissue or invade the intravascular system must be sterile to prevent the introduction of potentially harmful microorganisms into the patient's body. Items that cannot be sterilized by conventional sterilization methods discussed in Chapter 18 are disinfected to eliminate as many microorganisms as possible.

Some specialized instruments and equipment cannot be sterilized between each patient use or will not withstand a sterilization

process. Disinfection may be the only alternative. Disinfection can be accomplished with chemical and physical agents. The application and selection of disinfecting agents depend on the level of importance of the item as used in patient care, risk for exposure to biologic material, or environmental contamination.

Chemical agents used for disinfection of the environment or instrumentation are prepared and maintained for use according to the manufacturer's recommendations. Care is taken not to overdilute the solution by immersing wet items. Anything placed into the solution must be absolutely dry to prevent inactivity of the chemical properties.[2] Dip sticks are commercially available to test the concentration and efficacy of the solution before use.

Care is taken to note the correct use and shelf life of mixed solutions. A reconstituted chemical container should be labeled with the date of mixing and date of expiration. It should remain covered at all times to minimize evaporation, and PPE should be worn any time the solution is used. Disposal of used or expired solution may be subject to special handling to meet federal environmental guidelines.

Spaulding's Classification of Patient Care Items

Earle H. Spaulding, a well-known microbiologist, developed a classification system in 1968 to determine the appropriate method to attain the desired level of processing required for safety in patient care items. This system was adopted and later modified by the Centers for Disease Control and Prevention (CDC). Spaulding's classifications of the importance of patient care items are still applicable in the twenty-first century.

- *Critical items* must be sterile because they enter sterile tissue, break the mucosal barrier, or come into contact with the vascular system. Examples include surgical instruments, endoscopes, endoscopic accessories that cut tissue, catheters, implants, and needles.[3] Sterilization is required for all critical items. High-level chemical disinfection should not be confused with chemical sterilization. Some of the same chemicals used for disinfection are used for longer times in higher concentrations to cause sterilization.
- *Semicritical items* come into contact with intact skin and mucous membranes and require high-level disinfection, although they also may be sterilized. Examples include respiratory therapy equipment, anesthesia equipment, and vaginal probes.
- *Noncritical items* are used in contact only with intact skin. Intermediate- or low-level disinfection is adequate. Examples include blood pressure cuffs, furniture, linens, bedpans, and eating utensils.

Levels of Disinfection

Disinfection is the process of destroying or inhibiting growth of pathogenic microorganisms on inanimate objects. It reduces the risk for microbial contamination but does not provide the same level of assurance as sterilization because all endospores are not killed. Disinfection levels are classified by the effectiveness of the process (i.e., the ability of the agent to kill microorganisms) as follows:

- **High-level disinfection**: Kills all bacteria, viruses, and fungi. The process may kill endospores if contact time is sufficient and other conditions are met. A high-level disinfectant should be used if a semicritical item is disinfected rather than sterilized. Some chemicals used in high-level disinfection can produce sterilization if they are allowed to remain in contact with the surface of the item for the time specified by the manufacturer. Chemicals used in the high-level disinfection process must be approved by the U.S. Food and Drug Administration (FDA) and disposed of according to local, state, and federal agencies.

  Note: High-level disinfection is not effective against Creutzfeldt-Jakob disease (CJD; also including new variant CJD, which is a transmissible spongiform encephalopathy (TSE). The biologic material that causes CJD is not a living microorganism like a bacteria or virus. It is a protein, referred to as a prion, that is extremely difficult to remove and inactivate. Prions and other specific microorganisms are discussed in detail in Chapter 14.
- **Intermediate-level disinfection**: Kills most bacteria, viruses, and fungi on noncritical items. The process does not attack endospores. It inactivates tuberculosis (TB).
- **Low-level disinfection**: Kills most vegetative bacteria **(bactericide,** bacteriocidal), fungi, and the least resistant viruses on noncritical items, including human immunodeficiency virus (HIV).

A record of the agent, concentration, and time of exposure should be maintained for semicritical items that have undergone high-level disinfection (Fig. 17.1). The level of disinfection that can be achieved depends on the type and concentration of the agent, contact time, and bioburden. Items that are disinfected are patient safe for their intended uses to minimize risks for infection for the patient. An all-purpose disinfectant does not exist. The best housekeeping agents are not the best disinfectants and vice versa.

Methods of Disinfection

Methods of disinfection include manual wiping with a chemical-impregnated cloth or sponge, soaking by total immersion, and processing by flush-through machinery. The method used depends on the desired level of disinfection.

Chemical Disinfectants

Chemical agents for disinfection are registered with the Pesticide Regulation Division of the Environmental Protection Agency (EPA) to be sold in interstate commerce. An EPA registration

number is granted only when requirements of laboratory test data, toxicity data, product formula, and label copy are approved. Any chemical agent accepted for use by a facility must be FDA approved and have a copy of the safety data sheet (SDS) readily available in the event of a spill or exposure as required by the Occupational Safety and Health Administration (OSHA).

Disinfectants are labeled with the chemical properties and appropriate warnings of precautions. The labels must be read, and directions for dilution and/or use must be followed. The product label should indicate several salient points important to the selection of the appropriate agent for the desired task. The user should read the label before use. Sample labeling information is listed in Box 17.1. Isopropyl alcohol, sodium hypochlorite, formaldehyde, glutaraldehyde, and phenol are considered hazardous chemicals. Some other chemicals can cause contact dermatitis. Gloves should be worn when handling all chemical agents. Avoid neoprene and polyvinylchloride gloves because they can absorb some chemicals.

To be labeled for hospital use a chemical disinfectant should be proved effective against *Staphylococcus aureus* (gram-positive), *Salmonella choleraesuis* (gram-negative), and *Pseudomonas aeruginosa* (gram-negative); these are the most resistant gram-positive and gram-negative organisms. The agent can be classified as a hospital disinfectant without being pseudomonacidal, but the label is required to say whether it is effective against *Pseudomonas* organisms. Influences on efficacy of the solution can be found in Box 17.2.

The EPA defines a disinfectant as an agent that kills growing or vegetative forms of bacteria. The terms *germicide* and *bactericide* may be used synonymously with the term *disinfectant* according to this definition. However, *Mycobacterium tuberculosis* has a waxy envelope that makes it comparatively resistant to aqueous germicides. Effective agents against *M. tuberculosis* should be labeled "tuberculocidal." Agents also are labeled regarding whether they kill fungi (**fungicide**), viruses (**virucide**), and/or endospores (**sporicide**).

Agents effective enough to be labeled as tuberculocidal will kill HIV. Those that meet the EPA testing requirements may be labeled specifically as HIV virucides. HBV cannot be adapted to laboratory testing, but it is known to survive exposure to many disinfectants.

The most common liquid chemical disinfectants used in the perioperative environment are listed in Table 17.1. With few exceptions, most liquid chemical disinfectants are not sporicides. Analysis of the label statements helps determine whether a product is appropriate for a specific purpose in the OR. Items disinfected by chemical agents for patient care require removal of the agent before the item is safe for use on a patient. Items need to be rinsed with clear water until the chemical is removed. The sterility of the rinse water depends on the intended use of the item. Sterile and high-level disinfected items will require the use of sterile water as a rinse. Noncritical items can be rinsed with tap water.

Factors to be considered in the selection of an agent include the following:

1. Microorganisms, particularly endospore-forming bacteria and certain viruses, differ markedly in their resistance to liquid chemical disinfectants. Factors influencing the microbial response include the structure and design of the item to be disinfected, the active ingredient of the chemical, pH, hardness of the water, exposure time, and extent of precleaning before processing. Resistance levels of select microorganisms are described in Table 17.2.
2. Disinfectants differ widely in the level of microbicidal action they produce and mechanisms involved. All are protoplasmic poisons that can coagulate or denature cell protein, oxidize or bind enzymes, or alter cell membranes. In-use culture testing must determine the number of viable microorganisms after an agent is used for the intended purpose.
3. The nature of the microbial contamination influences the results of chemical disinfection. Bacteria, spores, fungi, and viruses are present in air and on surfaces throughout the environment. However, organic soil such as blood, plasma, pus, feces, and tissue absorbs germicidal molecules and inactivates some chemicals. Therefore good physical precleaning before disinfection helps reduce the number of microorganisms and maintain the effectiveness of the disinfectant.

• BOX 17.1 Information to Look for on a Disinfectant Label

Information about Active Ingredient
- Trade and generic name
- Concentration or strength
- Environmental Protection Agency (EPA) registration number

Warnings
- Toxicity alert
- Cautionary statement
- Treatment for untoward exposure
- Poison control listing
- Hotline number

Instructions for Use
- Dilution information
- Personal protective equipment (PPE) requirements
- Intended use
- Surfaces safe for use
- Method of application
- Duration of necessary contact

Intended Action
- Antimicrobial activity
- Residual action (if any)

Aftercare
- Of equipment
- Of treated surface
- Of cleaning supplies
- Disposal or storage of unused product
- Biodegradability and effects in the natural environment

• BOX 17.2 Influences on the Efficacy of Disinfectants on Patient Care Items

- Concentration of the solution
- Temperature of the solution
- Shelf life and storage of the solution
- Compounded agents in the solution
- Precleaning and drying of item before immersion
- Degree of bioburden and **biofilm** on the surface of the item
- Composition and surface texture of the item
- Duration of contact with the agent
- Humidity of the environment
- Temperature of the environment
- pH and mineral content of the diluent

TABLE 17.1 Common Liquid Chemical Disinfectants

Disinfectant Agent	Level of Disinfection	Timing	Virucidal	Fungicidal	Sporicidal	Mycobacterium (Tuberculocidal)	Hazards	Notes
Alcohol, 70%-95%								
Ethyl	Intermediate level	10-30 min for both	Yes, but not all lipid viruses, HAV	Yes	No	Yes	All forms are flammable.	Bactericidal but not bacteriostatic. Ineffective against spores. Noncorrosive.
Isopropyl	Intermediate level		Yes, but not enteroviruses	Yes	No	Yes		Denatures proteins. Harms rubber and plastic. Combined with other disinfectants to form a tincture that can extend the bactericidal action. Rapid evaporation. Used in skin antisepsis.
Aldehyde								
							Toxic: skin, eye, and respirator irritant.	
Aqueous acidic 2%	High level	20-90 min at 68°-77° F (20°-25° C)	Yes	Yes	No	Yes; very slow	OSHA exposure limit is 0.05 ppm. Can cause respiratory irritation. Carcinogenic.	Excellent materials compatibility. Local regulations may restrict disposal of used product. Inexpensive to use. Use in well-ventilated area. Reduced effect in detergent.
Glutaraldehyde								
Banicide 3.5%	Sterile	10 hr at 77° F (25° C)	Yes	Yes	Yes	Yes		30-day reuse period. Absorbed by neoprene or PVC gloves.
	High level	45 min at 77° F (25° C)						
Cidex activated alkaline 2.4% dialdehyde	Sterile	10 hr at 77° F (25° C)	Yes	Yes	Yes	Yes		Coagulates blood and tissue. Activated alkaline form has shelf life of 14-30 days.
	High level	45 min at 77° F (25° C)	Yes	Yes	Some	Yes		Concentration level must be monitored.
Cidex OPA (0.55%) orthophthalaldehyde	High level	12 min at 68° F (20° C)	Yes	Yes	Some, but improves when the pH is increased to 8	Yes; superior action	No known irritations.	Requires no activation and remains more stable over a wide range of pH (3-9). Stains protein gray; 14-day reuse period.

					Scopes pass sporicidal test at 32 hr at 20° C			Concentration level must be monitored
Cidex OPA (5.75%) ortho-phthalaldehyde concentrate	High level	5 min at 122° F (50° C)			Scopes pass sporicidal test at 32 hr at 122° F (50° C)			Used in an automated endoscope high-level disinfector.
Phenol Compound								
1.64% with 0.95% glutaraldehyde (Sporicidin)	Sterile	12 hr at 77° F (25° C)	Yes	Yes	Yes	Yes	Skin and eye irritant. Carcinogenic. Toxic to animals.	Effective in presence of organic matter. Leaves an active residue. Effective in detergents.
	High level	20 min at 77° F (25° C)	Yes, but limited	Yes	No	Yes		Maximum reuse period of 7 days.
Quaternary Ammonium Compounds (Quats)								
C0.1%-2% concentration	Low	10 min	Limited; lipophilic only	Yes	No	No	No odor and low toxicity.	Easily inactivated by organic debris. Effective in temperatures up to 212° F (100° C). Most effective in alkaline solution. Neutralized by detergents and hard water. Nonirritating and noncorrosive. Inexpensive. Inactivated by use with gauze pads. Surface disinfection.
Halogens								
Chlorine and chlorine compounds such as sodium hypochlorite	Low to high based on concentration and pH	10-30 min	Yes	Yes	Limited	Yes	Toxic and corrosive. Do not autoclave chlorine solutions; will vaporize and cause free chlorine gas inhalation hazard. Dangerous gas forms if mixed with ammonia.	Ethyl alcohol 60% can be added to increase kill potential. Oxidizes metallic objects. 1:10 dilution of 6% chlorine bleach (household bleach) contains 6000 ppm available chlorine. Combines with protein and decreases in effectiveness. Premixed solution can be stored in cool place in a light-proof container.

Continued

TABLE 17.1 Common Liquid Chemical Disinfectants—cont'd

Disinfectant Agent	Level of Disinfection	Timing	Virucidal	Fungicidal	Sporicidal	Mycobacterium (Tuberculocidal)	Hazards	Notes
Iodophors (Wescodyne)	Low at a wide range of pH	10-30 min	Yes	Yes	No	Yes		Alcohol can be added to extend effectiveness in a solution of 1:10 in 50% ethyl alcohol. Vaporizes in hot water (120° F-125° F [48° C-51.6° C]). Reduced action in presence of protein. Inactivated iodophor loses brown-yellow color. Becomes clear when deactivated.
Peracetic Acid								
STERIS 0.2%	Sterile	12-30 min at 122° F-133° F (50° C-56° C)	Yes	Yes	Yes	Yes, even at low temperatures. Can be a fire hazard at high temperatures when dry.	Wear PPE if risk for contact to skin, eyes, or mucous membranes.	Used in STERIS processing as a single-use liquid chemical sterilant. No residue. Uses filtered tap water for rinse. Can corrode metallics. Approximately $6 per cycle. No special disposal requirements. Protect from light and heat.
Sporox Hydrogen Peroxide								
7.5%	Sterile	6 hr at 68° F (20° C)	Yes	Yes	Yes	Yes	Wear PPE to protect eyes.	Requires no activation. Has no special disposal instructions.
	High level	30 min at 68° F (20° C)	Yes	Yes	Some	Yes		Must monitor minimal effective concentration. Maximum reuse period of 21 days. May enhance removal of organic debris. Not effective as a disinfectant in presence of organic matter.

HAV, Hepatitis A virus; *OSHA,* Occupational Safety and Health Administration; *PPE,* personal protective equipment; *ppm,* parts per million.

TABLE 17.2 Resistance Levels of Select Microorganisms

MINIMAL-RESISTANCE	INTERMEDIATE-RESISTANCE	HIGH-RESISTANCE
Lipid Viruses	**Nonlipid Viruses (Hydrophilic)**	**Bacterial Endospores**
Influenza	Echovirus	Gram positive
Rubeola	Parvovirus	*Bacillus subtilis*
Cytomegalovirus (CMV)	Hepatitis A virus	*Bacillus stearothermophilus*
Human immunodeficiency virus (HIV)	Rhinovirus	*Clostridium tetani*
Herpes simplex virus types 1 and 2 (HSV)	Poliovirus	*Bacillus anthracis*
Hepatitis B virus (HBV)	Coxsackievirus	*Clostridium botulinum*
Hepatitis C virus (HCV)	*Clostridium perfringens*	
Respiratory syncytial virus (RSV)	*Clostridium difficile*	
Epstein-Barr virus (EBV)	Gram negative	
	Coxiella burnetii	
Vegetative Lipid-Coated Bacteria	**Fungi**	**Mycobacteria**
Non–Endospore Forming		
Gram Positive	*Trichophyton* species	*Mycobacterium bovis*
Staphylococcus aureus	*Cryptococcus* species	*Mycobacterium tuberculosis*
Staphylococcus epidermidis	*Candida* species	*Mycobacterium leprae*
Streptococcus groups A and B		
Pseudomonas aeruginosa		
Salmonella choleraesuis		
Corynebacterium diphtheriae		
Gram Negative		
Haemophilus influenzae		
Helicobacter pylori		

Knowledge of microbial resistance to decontamination, disinfection, and sterilization is important in selecting which method to use during reprocessing.

4. Requirements of the chemical agent vary.
   a. Housekeeping products should be detergent-disinfectants that meet the following requirements for both cleaning and disinfection:
      (1) They must be effective against a broad spectrum of microorganisms, including *P. aeruginosa* and *M. tuberculosis,* preferably in the presence of organic soil.
      (2) They must be compatible with tap water for dilution.
      (3) They must be low-foaming and prevent waterborne deposits.
      (4) They must rinse easily and not leave a residual film that could affect electrical conductivity or transfer to the patient.
      (5) They should be nontoxic and nonirritating to patients and personnel.
      (6) They should be virtually odorless.
   b. Instrument and equipment disinfectants should be registered by the EPA and should kill as many species of microorganisms as possible to decontaminate items effectively for handling by personnel or for preparing items for patient use, such as stethoscopes and monitors.
5. The kill time is correlated with the concentration of the agent and the number of microorganisms present. Most disinfectant chemicals are used in aqueous solution. Water brings the chemical and microorganisms together. Without this water reaction, the process stops. Increasing the concentration of the chemical may shorten exposure time but not necessarily.
   a. All tap water contains *Pseudomonas* bacteria. The pH, calcium, and magnesium in hard tap water can inactivate disinfectants. Therefore deionized water may be recommended for use in dilution.
   b. The temperature of hot water may make chemical agents unstable.
   c. Disinfectants should be premixed in required concentrations and stored in properly labeled containers to ensure personnel use the product in the correct concentration.
   d. Instruments are completely submerged for the maximum time recommended by the manufacturer of the product used.
   e. All instruments should be clean and dry when put into solution. Wet items will dilute the solution and change the concentration of the chemical agent.

6. The composition of items to be disinfected varies. Nonporous items, such as metal instruments, are more easily disinfected than are porous materials. Items must be stable in a wet environment.
7. The method of application influences the effectiveness of the chemical agent.
   a. Direct application of a liquid disinfectant, either by mechanical action for housekeeping purposes or immersion for instrument disinfection, is the most effective method of applying chemicals to the surface of inanimate objects.
   b. Aerosol spray from a pressurized container is an effective method of spot disinfection on smooth surfaces and into crevices not otherwise accessible. Care is taken not to disperse the aerosol in the room environment. Spray bottles are not appropriate for surface disinfection in the OR.
8. Disinfection should be done immediately before and after use or contamination. All patients are considered to be potential carriers of microbial contamination. Therefore adequate bactericidal and virucidal disinfection is needed before and after every invasive procedure.
9. The shelf life and safe storage after reconstitution are other factors to be considered. Room temperature and exposure to lighting may be factors in efficacy. The chemical manufacturer provides information about storage methods and duration of efficacy.

Alcohol

Ethyl or isopropyl alcohol, 70% to 95%, kills microorganisms by coagulation of cell proteins.

Effectiveness

- It may be used as a housekeeping disinfectant for damp-dusting furniture and lights or wiping electrical cords without leaving a residue on treated surfaces. It is nonstaining.
- It can disinfect semicritical instruments. To prevent corrosion of metal, 0.2% sodium nitrite is added.
- It is bactericidal, pseudomonacidal, and fungicidal in a minimum of 10 minutes' exposure by total immersion. It is not sporicidal.
- It is tuberculocidal and virucidal for most viruses (except hydrophilic viruses), including HIV, in a minimum of 15 minutes' exposure. It is effective against HBV.

Precautions

- The pattern of effectiveness of 95% isopropyl alcohol on HBV is irregular because it evaporates rapidly and does not have prolonged moist contact with the microorganism. It should not be used for cleaning up blood or body fluid spills because it is inactivated in the presence of biologic matter.
- It is volatile; it will act only as long as it is in solution. Alcohol becomes ineffective as soon as it evaporates, and it loses its microbicidal activity in concentrations below 50%; it should be discarded at frequent intervals.
- It is inactive in the presence of organic soil. It does not penetrate skin oil that lodges on instruments through handling.
- It will blanch asphalt floor tiles.
- It cannot be used on lensed instruments with cement mountings because it dissolves cement.
- With long exposure, it will harden and swell plastic tubing and items, including polyethylene.
- It is flammable, so it is stored in a cool, well-ventilated area. Many ORs are banning alcohol-based products because of increased fire risk.
- It is a skin irritant.

Chlorine Compounds

Inorganic chlorine is valuable for the disinfection of water. Chlorine compounds kill microorganisms by the oxidation of enzymes. Sodium hypochlorite (household bleach), 1:10 dilution of 5.25%, is a low-level disinfectant. Concentration may range up to 1:100, or 500 parts per million (ppm). Sodium dichloroisocyanurate (Precept disinfectant tablet) has a lowered pH, which enhances its microbicidal action.

Effectiveness

- Chlorine compounds are housekeeping disinfectants for spot cleaning of blood and body fluid spills and for cleaning of floors and furniture.
- They are bactericidal, fungicidal, and tuberculocidal and have a virucidal effect on HIV, HBV, and other viruses.

Precautions

- Sodium hypochlorite is unstable and dissipates rapidly in the presence of organic soil. A dilution is prepared daily.
- The odor may be objectionable. It can be a respiratory irritant.
- Chlorine is corrosive to metal; it cannot be used for instrument disinfection and decontamination.
- Chlorine compounds are potentially carcinogenic if combined with formaldehyde.
- Do not combine with ammonia because a toxic gas is emitted.
- Do not autoclave instruments saturated in a chlorine compound because a toxic gas is released.

Formaldehyde

Formaldehyde kills microorganisms by coagulation of protein in cells. The solution may be 37% formaldehyde in water (Formalin) or 8% formaldehyde in 70% isopropyl alcohol. Formaldehyde is not commonly used for housekeeping purposes as a surface disinfectant.

Precautions

- Formaldehyde fumes are irritating to the eyes and mucous membranes.
- Fumes are potentially carcinogenic; it is toxic to tissue.
- Formalin 10% may be used for permanent section specimens.
- Formaldehyde should be stored in an area with adequate ventilation.
- PPE is required when handling.
- Exposure protocols should be followed for medical monitoring.

Glutaraldehyde

An aqueous solution of glutaraldehyde kills microorganisms by denaturation of protein. It is most commonly used in an activated 2.0% to 2.4% solution that can be reused for the specified period of activation. Both alkaline and acid solutions are available for high-level disinfection of critical and semicritical items that cannot be steam-sterilized. A 1:16 dilution is not considered a high-level disinfectant; a 2% solution is. Glutaraldehyde is not used for housekeeping purposes.

Effectiveness

- It is a noncorrosive high-level disinfectant for endoscopes and lensed instruments.
- It is safe as a high-level disinfectant for most plastic, rubber, and heat-sensitive items.
- It is bactericidal, pseudomonacidal, fungicidal, and virucidal, including against HIV and HBV, in a minimum of 10 minutes' exposure at a temperature between 68° F and 86° F (20° C to 30° C).

- It is tuberculocidal. Variations in formulations of products available affect the exposure time and temperature of the solution, especially after reuse. A 2% solution at 77° F or 86° F (25° C or 30° C) may be 100% tuberculocidal in 45 to 90 minutes, depending on the formulation. Label instructions of the manufacturer should be followed.
- Most of the products labeled as cold sterilants are sporicidal in a minimum of 10 hours' exposure at room temperature.
- Some products can be reused in closed containers or in an automatic machine for a period of activation specified by the manufacturer.
- It remains active in the presence of organic matter; it does not coagulate protein material.

Precautions
- Thorough and careful cleaning in a mild detergent is essential to remove organic debris and reduce microbial contamination. Detergent is rinsed off, and the item is dried before immersion.
- Items are completely immersed and lumens are filled with glutaraldehyde solution for no longer than 24 hours.
- Items are thoroughly rinsed before use.
- Odor and fumes may be irritating to the eyes, throat, and nasal passages. The solution should be kept covered and used in a well-ventilated area.
- Shelf life of glutaraldehyde is limited after activation.
- Proper training, PPE, and knowledge are required before handing.

Iodophors

A complex of free iodine with detergent kills microorganisms through a process of oxidation of essential enzymes. An iodophor is an effective low- to intermediate-level disinfectant. The iodine-detergent complex enhances the microbicidal activity of free iodine and renders it nontoxic, nonirritating, and nonstaining when used as directed. The concentration varies among the products available. The manufacturer's instructions for use should be followed.

Effectiveness
- Iodophors are commonly used as surgical scrubs and preoperative skin preps in the surgical setting. Iodine is effective as long as it is wet. An aqueous solution is more effective for cleaning than is an alcohol solution because it dries more slowly.
- An iodophor can be used as an instrument disinfectant if no other agent is available. To prevent corrosion of metal, 0.2% sodium nitrite is added.
- Iodophors are bactericidal, pseudomonacidal, and fungicidal in a minimum of 10 minutes' exposure in a concentration of 450 ppm of iodine or a minimum of 20 minutes' exposure in a concentration of 100 ppm of iodine.
- They are tuberculocidal and virucidal, including against HIV and HBV, in a minimum of 20 minutes' exposure with a minimum concentration of 450 ppm of iodine. They are not sporicidal.

Precautions
- Some iodophors are unstable in the presence of hard water or heat and are inactivated by organic soil.
- Iodine stains fabrics and tissue; however, this is reduced or is temporary when iodine is used as an iodophor.

Phenolic Compounds

Derivatives of pure phenol kill microorganisms mainly by coagulation of protein. Depending on the phenol coefficient and species of organisms, phenolic compounds may cause rapid lysis of cells, leakage of cell constituents without lysis, or death by denaturing enzymes. Pure phenol, obtained from coal tar, is an extremely caustic agent and dangerous to tissue, causing painless burns and blanching. Derivatives are used as low-level disinfectants, usually with a minimum of a 2% phenolic compound in an aqueous or detergent solution. Phenolic compounds are used primarily for housekeeping purposes.

Effectiveness
- Phenolic compounds may be used as housekeeping disinfectants for cleaning surfaces such as floors, furniture, and walls. Phenolics retain a safe level of activity in the presence of heavy organic soil.
- They are the disinfectants of choice when dealing with fecal contamination. They have good stability and remain active after mild heating and prolonged drying. Subsequent application of moisture to dry surfaces can redissolve the chemical so that it becomes bactericidal again.
- They are tuberculocidal.

Precautions
- Tissue irritation precludes use for semicritical instruments that will come into contact with skin and mucous membranes (e.g., anesthesia equipment).
- Personnel should wear gloves when cleaning with these products to avoid skin irritation.
- Rubber and plastics may absorb phenol derivatives.
- The product may have an unpleasant odor.
- Pure phenol is inactivated by the application of alcohol. Phenol is solid at room temperature and liquefies when warm.

Quaternary Ammonium Compounds

"Quats," as these compounds are often called, cause gradual alteration of cell membranes to produce leakage of protoplasm of some microorganisms, primarily vegetative bacteria. These compounds possess detergent properties and are used to sanitize noncritical surfaces. Benzalkonium chloride, one of the most widely used of these compounds, should be used in a concentration of 1:750.

Effectiveness
- They are rarely used as housekeeping disinfectants for surfaces such as floors, furniture, and walls.
- For low-level, noncritical instrument disinfection, 0.2% sodium nitrite is added to the solution to prevent corrosion of metal.
- They are bactericidal, pseudomonacidal, fungicidal, and lipid virucidal in a minimum of 10 minutes' exposure. They are nonirritating to skin.
- There is no buildup on surfaces. They are not inactivated by hard water.

Precautions
- The microbicidal effect can be reversed by adding a neutralizer such as soap.
- They are not effective against TB or hydrophilic viruses, such as poliovirus.
- The active agent can be selectively absorbed by fabrics, thus reducing the strength perhaps to an ineffectively low level. Gauze or a towel must not be put in the basin used for immersing instruments.
- Compounds are inactivated in the presence of organic soil.

Hydrogen Peroxide

Effectiveness

- It is rapidly bactericidal, virucidal, fungicidal, and tuberculocidal.
- It is useful for disinfection of noncritical items.
- Hydrogen peroxide is used in some room fogging devices for disinfection of surfaces.
- Hydrogen peroxide can be used for sterilization when turned into a gas or vapor (see Chapter 18).

Precaution

- It is inactivated by blood.

Physical Disinfectants

Boiling Water

Boiling water cannot be depended on to kill endospores. Heat-resistant bacterial endospores will withstand water boiling at 212° F (100° C) for many hours of continuous exposure. Inactivation of some viruses, such as those associated with hepatitis, is uncertain.

If no other method of sterilization or disinfection is available, boiling water can be rendered more effective by adding sodium carbonate to make a 2% solution, which reduces the hydrogen-ion concentration. At sea level the recommended boiling time for disinfection is 15 minutes. Rubber goods and glassware must not be boiled in sodium carbonate because it is destructive to both. If sodium carbonate is not used, the minimum boiling period is 30 minutes. At high altitudes the boiling time is increased to compensate for the lower temperature of boiling water.

Pasteurization

A high-level disinfection process, sometimes referred to as **pasteurization**, can be used for items such as reusable respiratory devices and anesthesia breathing circuits to render them safe for patient use.

Pasteurization is a method of hot water decontamination/disinfection performed with chlorine detergents at low temperatures. Although not a sterilization process, exposure to hot water (140° F to 180° F [60° C to 82° C]) for 30 minutes kills microorganisms without killing endospores.

Anesthesia hoses, masks, and fluted breathing bags are positioned in the pasteurization unit on special pegs and hooks that permit total immersion and full-surface contact of the sprayer arms. Time and temperature are closely monitored to provide high-level disinfection. The pasteurization process takes approximately 1 hour to complete, followed by air-drying in a specially filtered cabinet. The items must be completely dry before being placed in storage. The average pasteurization unit can process up to 10 complete anesthesia circuits in one cycle.

Ultraviolet Irradiation

Ultraviolet (UV) rays at wavelengths of 240 to 480 nm photochemically transform nucleic acid bases to denature DNA and proteins. Generated by low-pressure mercury vapor bulbs, UV lights produce nonionizing radiant energy in sufficient wavelengths and intensity for low-level disinfection. The rays can kill select vegetative bacteria, fungi, and lipoprotein viruses on contact in air or water.

The practical usefulness of UV irradiation is still being studied, however, because the rays must make direct contact with the organisms and may actually support life for some varieties. Current studies show promise in effectiveness of killing 99.8% of *Clostridium difficile*.[4] Microorganisms are in a constant state of motion in the air currents of the ventilating system and in water. Moving across the ray of UV light, pathogens may be exposed for too short a time for effective contact with the radiant energy.

Three types of UV systems are used: UV rays with mercury lamps, UV light emitting diodes or UV-C machines with wavelengths between 250 and 280 nm, and pulsed xenon lights with wavelengths around 230 nm.[4] Effectiveness is determined on how close the light is to an object, size of the area, time setting, and placement of the machine.

UV lights are used to augment surface disinfection after terminal cleaning in some surgical environments. Only surfaces in contact with the UV system are disinfected.

UV rays can cause skin burns, comparable to sunburn, and conjunctivitis. These lights may be turned on only when the room is unoccupied to reduce airborne and surface contamination.

UV irradiation is used in conjunction with activated carbon 5-micron filters for water purification. UV irradiation kills bacteria but does not remove impurities. The filtration process is followed by exposing water flowing at a constant rate and temperature to a 5-watt UV lamp. This produces purified, not sterile, water. UV irradiation is not sporicidal, and HBV can survive exposure.

Disposable Products

Disposable products can be useful in the OR. It is sometimes easier to discard a contaminated item after use than to clean and process it. The use of disposable products has become popular, but consideration of the logistics of using them includes determination of the benefits and/or consequences of their use and their reuse.

The production of disposable products often involves the use of natural resources and potential industrial damage to the earth's environment. Disposal of the contaminated item by incineration or in landfills can pose comparable problems. Many issues concerning economy, including labor costs, storage, and delivery, need to be evaluated on an individual basis. Economy may be shown with the use of disposable products.

Considerations for the Use of Disposable Products

A disposable product is used once with reasonable assurance of safety and effectiveness. Most disposables are patient charge items (i.e., the cost of these items is added to the patient's bill). Use of patient-charge items requires specific and accurate recordkeeping.

Most surgical computer systems send all the estimated items into a case cart system with an estimated charge sheet. The case cart usually contains only the items needed for a routine procedure. If the total complement of items is used during the procedure, the disposables are already charged in the system. This saves personnel time and money by having much of the paperwork done in advance. This process facilitates flat-rate costing by procedure.

If a disposable item remains completely intact (is not opened or contaminated in any way), it can be returned to stock. The cost of the item is then removed from the patient's charge sheet in the computer, using a process referred to as *charging by exception.* The cost is removed by personnel in the stock room, and the patient is not charged. The item is then electronically credited to stock for future use in the departmental inventory.

Bar code technology is very useful for inventory tracking. Many manufacturers have included a bar code on their packaging. Items can be scanned as used and the computer automatically charges it to the patient. Examples include staplers, single-use instrumentation, and implants.

Conversely, taking an item from the stock room without accounting for it in the computer system will leave an inaccurate number of items available for actual use. Planning for other cases depends on having correct numbers of disposables available for use. The system will know when an item is really available only if the records are complete and up-to-date.

Advantages

- When a sterile item is required, proper packaging and sterility must be ensured. Sterility is guaranteed by reliable manufacturers as long as the integrity of their packages is maintained. Industry conforms to far more rigid standards of quality control than onsite conditions permit. All sterilized products are tested for sterility before they are distributed to purchasers.
- Single-use items, such as urinary and suction catheters, are esthetically more acceptable to patients. More important, disposable products eliminate a potential source of cross-contamination.
- Items such as needles and disposable trocars ensure more comfort for the patient because they are always new and sharp. Proper function is thus ensured.
- Standardized service at reduced cost per unit may be provided. Sponges are precounted and sterilized, for example. Packs and trays become standardized and can be customized.
- Loss and breakage in reprocessing reusable items are eliminated.
- Labor costs of processing supplies are reduced, particularly in the tedious, meticulous cleaning and packaging.
- The need for expensive mechanical cleaning equipment is eliminated.
- Contaminated used items can be contained for safe disposal. Handling is minimal, and processing is eliminated.

Disadvantages

- Costly waste occurs if sterile items are contaminated by carelessness or are unnecessarily opened. Extreme care is needed in opening packages to maintain sterility. Handling should not compromise the integrity of wrappings and pose a threat to the maintenance of sterility.
- Flexibility in complying with requests of individual physicians for special setups can be complicated. No allowance is made for deviation from custom packs. Procedures need to be standardized to conform to available items and sets.
- If a defect is found in one package, it may extend throughout the total lot, requiring replacement of the total supply on hand. Each lot is numbered for identification and recall if a problem arises.
- The circulating nurse may have to open an increased number of individually packaged items if the custom pack is not adequate.
- In the event of a sudden increase in use, adequate inventory may not be readily available.
- Potentially unstable products, such as some disposable trays containing medications, may carry an expiration date. Unless oldest products are used first, unnecessary costs are incurred if a product must be discarded because its time of reliability has expired. All dated products should be routinely checked for expiration.
- Environmental ecology may be affected by incineration or disposal in landfills. Some medical waste is regulated by local and federal laws.

Other Considerations

Other considerations regarding the use of disposable products include the following:

- Some hospitals have saved money by reducing their labor force through conversion to as many totally disposable systems as possible, such as intravenous therapy, drapes, and special procedure trays. In some geographic areas where efficient labor may be readily available at minimum wage, disposable products are more costly than labor. However, if professional personnel are being used for reprocessing supplies, use of disposable products will enable them to spend more time giving more care to patients and less time on processing supplies.
- Proper and safe storage facilities should be provided. More storage space or more frequent deliveries may be required to maintain adequate inventories of disposable products.
- Disposal may be an ecologic problem. Used items are taken to an incinerator, compactor, or other safe waste-disposal area. Waste should not be allowed to accumulate in the OR suite or in other hospital areas.
- Disposables opened but unused or exposed to patients in any way can be set aside for orientation or practice sessions or donated to nursing schools. Care is taken not to use anything from a sterile field that has been used in a surgical procedure. Cases that are set up and immediately canceled are ideal for salvaging items for learning situations.

Reusing/Reprocessing Disposable Single-Use Products/Devices

Manufacturers use extensive controls and testing procedures to ensure cleanliness, nontoxicity, nonpyrogenicity, biocompatibility, sterility, and function of disposable products. All items must be safe and effective for their intended patient uses. The manufacturer guarantees product stability and sterility for a single use only.

In this era of cost containment, salvage of undamaged disposable items may be attempted. The risks of salvaging items should be evaluated seriously. The health care facility assumes legal responsibility for items it chooses to reuse, reprocess, and resterilize. The manufacturer cannot be held liable for the efficacy of a disposable product or one intended for single use if the user chooses to reprocess it. The burden of liability rests with the processor.

Reuse

A used, disposable, single-use item requires cleaning, packaging, and sterilizing if it will be reused as a sterile item. Some products degrade with use. Many manufacturers have not tested their products for more than one use. For a product to be reused, it should be tested to validate patient safety. Patients have the right to know they are being treated with a reused single-use product. They should not be charged the cost of a new item.

Reprocessing

Repackaging and resterilizing unused sterile disposable items may be hazardous. These are items that were opened and not needed, or they are clean but have been contaminated in some way (i.e., the original packaging is not intact). Many of these items are very expensive, and salvage seems to be an acceptable alternative.

The manufacturer must provide written instructions for resterilization of unused but contaminated items by onsite personnel. Many of these items are heat sensitive. Services that reprocess and resterilize some types of clean, unused, and undamaged products are available. Such services must guarantee product stability and sterility. The FDA regulates reprocessing and requires specific guidelines and tracking of reprocessed items.[5]

Resterilization

The sterilization process must not alter the characteristics of any part of the product, regardless of whether it is intended to be disposable or reusable. Some products are labeled "do not resterilize." This instruction means that the product will be damaged or rendered ineffective in the process of resterilization. The manufacturer's recommendations should be followed if any reprocessing is performed.

Safety Considerations

Patient safety should be the prime concern in the decision to reuse, reprocess, or resterilize a disposable item. The following questions should be answered:

- Is the item a noncritical/noninvasive device? Critical items, particularly those that will enter or be in contact with the bloodstream or mucous membranes, present the greatest risks for adverse effects. Disposables of this type should not be reprocessed.
- Is the item really clean? Many porous materials cannot be thoroughly cleaned after use. If these are not adequately cleaned, microbial growth can predispose patients to infection. Lumens of catheters and tubing are especially difficult to clean. Biologic debris interferes with the sterilization process. Many items cannot be disassembled for adequate cleaning.
- Is the item nontoxic or nonpyrogenic after cleaning and reprocessing? Residues from some cleaning compounds and sterilizing processes are toxic. Chemicals can be retained by the item during reprocessing.
- Is the item truly sterile? The sterilization method should be appropriate for materials in the item and in the packaging. The packaging material should allow penetration of the sterilant to all surfaces of the item and should prevent contamination during storage. Sterility should be verified by biologic testing for each type of product that is resterilized.
- Is the integrity of the product maintained? Physical and/or chemical characteristics may be altered by cleaning agents, the cleaning process, or resterilization. Some materials deteriorate or become brittle, which can affect function.
- Is the number of times an item has been reprocessed tracked and controlled? The manufacturer's written instructions should include the number of times the product may safely be reused or sterilized if the item can be reprocessed. The user should ensure that this number is not exceeded. The manufacturer has no control after a product leaves the factory. If the item is not in its original package, pertinent product information may not be immediately available.
- Is the item traceable? Reprocessing of any implantable item, such as synthetic mesh or graft material, should be controlled by lot numbers. The lot number on the product when first obtained from the manufacturer corresponds only with the processes at the point of controlled production.

  If the product is reprocessed onsite, the lot number is no longer valid because the same controls are not in place for subsequent sterilization. Many variables can alter the safety of the product for reuse. Any patient receiving this implantable material after reprocessing is not getting the same level of care as the first patient for whom it was opened.
- Is the item being charged for twice? How are charges determined? Charging full price for a used item is not ethical.

If in doubt about the appropriateness of a reprocessed item, it should not be reused. With or without written instructions from the manufacturer, the health care facility is liable for product safety, stability, and sterility of any item it processes and sterilizes.

Sterilization

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Define the term *sterilization.*
- List three methods of sterilization.
- Describe the process for preparing an item for sterilization.
- Identify the primary hazards associated with each type of sterilization.
- Discuss sterilization process monitors.
- Discuss the use of a case cart system.

KEY TERMS AND DEFINITIONS

Aeration Warm circulating air is used to remove ethylene oxide sterilant gas from packages in a special chamber for a specified period of time.

Bowie-Dick test Class 2 chemical indicator used in a prevacuum sterilizer to test the efficacy of the air removal cycle.

Capillary action Moisture penetrates through a permeable surface and carries with it microbial material.

Case cart System of gathering and delivering instruments and supplies to the perioperative environment. Some models include provision for the return of instruments and contaminated items to the appropriate decontamination area after the surgical or interventional procedure.

Custom packs Prepackaged collections of disposable supplies, drapes, sponges, and containers prepared by the manufacturer or the distributor according to specific instructions and requests by a particular service at a facility.

Flash sterilization A rapid method of steam sterilizing properly prepared instruments for immediate use. These instruments are not wrapped. Flash sterilization is not the preferred method of sterilization.

Gravity displacement sterilizer A steam sterilizer that uses steam in a downward motion to remove air from the sterilizing chamber. Air exits near front lower drain. Can be high speed or pulsing.

Indicator Devices inserted into a packed set and attached to the outside of the wrapper/container used by health care personnel to monitor sterilization exposure conditions. Biologic indicators are the best indicators that parameters are adequate to kill microorganisms. Chemical indicators are not proof of sterility, but they signify that the item was exposed to the parameters necessary for sterilization. Autoclave tape is a class 1 type indicator.

Integrator A chemical device inserted into a packed set that changes in response to the time, temperature, and steam penetration to demonstrate visually that parameters necessary for sterilization have been met. An integrator mimics the conditions required of a biologic monitor.

Prevacuum sterilizer A faster steam sterilizer that removes air by a vacuum before filling the chamber with steam. Also known as dynamic air removal steam sterilization.

Process challenge pack/process challenge device (PCD) A prepackaged unit consisting of dense materials and sterilization indicators or integrators used to test the effectiveness of the sterilization process.

Rigid container An instrument case that seals and locks. Instruments are placed in a rigid container for sterilization.

Sterile Microorganisms are at an irreducible minimum. No viable microbes.

Sterilization Processes by which all pathogenic and nonpathogenic microorganisms, including endospores, are killed. This term refers only to a validated process capable of destroying all forms of microbial life, including endospores. The sterilizer is a piece of equipment used to attain either physical or chemical sterilization. The agent used must be capable of killing all forms of microorganisms.

Strike-through Moisture or other substance penetrates through a sterile drape or wrapper to an unsterile surface. Strike-through provides a pathway for capillary action.

Terminal cleaning Thorough cleaning and disinfection of the perioperative environment at the end of use.

Terminal sterilization Procedures carried out for the destruction of pathogens on instruments at the end of the surgical procedure in the operating room or in other areas of patient contact (e.g., postanesthesia care unit [PACU], intensive care unit [ICU], patient care unit).

Turnover Activity geared toward cleaning and preparation of the operating room between cases for the next patient's arrival.

Wet pack Internal aspect of the sterile package remains moist or damp after passing through all sterilization parameters. Indicates a nonsterile item.

Wicking Passage of fluids through a material by passive action. Also referred to as capillary action or strike-through.

Sterilization versus Disinfection

Pathogenic microorganisms, as well as those that do not normally invade healthy tissue, are capable of causing infection if introduced mechanically into the body. Standardized procedures that are based on accepted principles and practices are necessary for the **sterilization** or disinfection of all supplies and equipment used for patient care in the perioperative environment.[1] Following established protocols for instrument processing helps minimize the patient's risk for infection of the surgical site.

A **sterile** item has been exposed to a sterilization process to render it free of all living microorganisms, including endospores. As long as sterility is maintained, this process renders items safe for contact with nonintact tissue and for exposure to the vascular system without transmitting infection. The sterilization process should provide assurance that an item can be expected to be free of known viable pathogenic and nonpathogenic microorganisms, including endospores. For items and materials that cannot be sterilized, disinfectants are used to kill as many microorganisms in the environment as possible. (Decontamination and disinfection are described in Chapter 17.)

Sterilization

Bacterial endospores (e.g., *Clostridia* and *Bacillus*) are the most resistant of all living organisms because of their capacity to withstand external destructive agents. Although the physical or chemical process by which all pathogenic and nonpathogenic microorganisms (including endospores) are destroyed is not absolute, supplies and equipment are considered sterile when all parameters have been met during a sterilization process.

Reliability Parameters for Sterilization

Two types of parameters are considered for the reliability of sterilizing methods: product-associated parameters and process-associated parameters.

Product-Associated Parameters

- *Bioburden:* The degree of contamination with microorganisms and organic debris
- *Bioresistance:* Factors such as heat and/or moisture sensitivities and product stability
- *Biostate:* The nutritional, physical, and/or reproductive phase of microorganisms
- *Bioshielding:* Characteristics of the packaging materials
- *Density:* Factors affecting penetration and evacuation of the agent

Process-Associated Parameters

- Temperature
- Humidity/moisture/hydration
- Time
- Purity of the agent and air, and the residual effects or residues
- Saturation/penetration
- Capacity of the sterilizer and the position of items within the chamber

Methods of Sterilization

Reliable sterilization depends on the contact of the sterilizing agent with all surfaces of the item to be sterilized. Selection of the agent used to achieve sterility depends primarily on the nature of the item to be sterilized. The time required to kill endospores in the available equipment then becomes critical. Sterilization processes are either physical or chemical, and each method has its advantages and disadvantages. The following are available sterilizing agents (sterilants)[2]:

1. Thermal (physical)
   a. Steam under pressure/moist heat
   b. Hot air/dry heat
2. Chemical
   a. Ethylene oxide gas
   b. Hydrogen peroxide plasma/vapor
   c. Ozone gas
   d. Acetic acid solution
   e. Glutaraldehyde solution
   f. Peracetic acid 0.2% solution
   g. Hypochlorous acid (electrochemical conversion process)
3. Radiation (physical)
   a. Microwave (nonionizing)
   b. X-ray (ionizing)

Sterilization Cycle

The time required to achieve sterilization is referred to as the process cycle, which includes the following:

- Heat up and/or penetration of the agent
- Kill time (i.e., exposure to the agent)
- Safety factor for bioburden
- Evacuation or dissipation of the agent

Monitoring the Sterilization Cycle

To ensure that instruments and supplies are sterile when used, it is essential that the sterilization process be monitored. Care is taken to assure that testing products such as chemical and biologic **indicator** strips and packs have not expired before use. The accuracy of monitoring depends on the systems in place for the task. Appropriate care and maintenance of mechanical equipment plays a large part in accurate read-outs and documentation of processing cycles performed. The general considerations are mentioned in the following sections. Specific tests are discussed later in this chapter with each method of sterilization.

Administrative Monitoring

Work practices are supervised. Written policies and procedures are strictly followed by all personnel responsible for sterilizing and handling sterile supplies. If sterility cannot be achieved or maintained, the system has failed. Policies and procedures pertain to the following:

- Decontaminating, terminally sterilizing, and cleaning all reusable items; disposing of disposable items in the appropriate manner
- Packaging and labeling items
- Loading and unloading the sterilizer
- Operating the sterilizer and checking its efficacy
- Monitoring and maintaining the records of each cycle
- Adhering to safety precautions and preventive maintenance (PM) protocol
- Transporting sterile packages to the sterile storage room. Cart should be enclosed and have a solid bottom
- Storing sterile items
- Handling sterile items ready for use
- Making a sterile transfer to a sterile field at the point of use
- Tracking and recalling items if an item in a particular load is not safe for use

Mechanical Indicators

Sterilizers have gauges, thermometers, timers, recorders, and/or other devices that monitor their functions. Most sterilizers have automatic controls and locking devices, and some have alarm systems that are activated if the sterilizer fails to operate correctly. Records are reviewed and maintained for each cycle. Test packs or special diagnostics are run at least daily, as appropriate for the type of sterilizer, to monitor the functions of each sterilizer. Such tests can identify processing errors.

The manufacturer of the sterilizer provides a manual for the comprehensive care and maintenance of the sterilizing device. Reliable operation depends on the following:

- Routine maintenance that consists of daily inspections and scheduled cleanings per the manufacturer's recommendation. All gaskets, gauges, graph pens, drain screens, paper rolls, ink cartridges, and charting devices should be repaired or replaced by qualified personnel as needed.
- PM that includes periodic calibration, lubrication, and function checks by qualified personnel on a scheduled basis should be documented.

Chemical Indicators

External indicator tape, labels, or paper strips should be clearly visible on the outside of every package to differentiate between sterilized and unsterilized items. The indicator helps monitor the physical conditions within the sterilizer to alert personnel to malfunctions, human errors in packaging, or improper loading of the sterilizer.

An internal indicator/**integrator** is placed inside a package in a position most likely to be difficult for the sterilant to penetrate. If a chemical reaction of the indicator does not show the expected results, the item should not be used. Indicators do not establish the sterility of an item; they indicate only that process parameters have been met.

Chemical indicators are categorized into classes according to the type of process measurement they perform.

- *Class 1:* Immediate visual indicator on the exterior of the processed pack, such as striped tape or a tab that changes color in response to the sterilizer.
- *Class 2:* Autoclave test packs used to test for air removal during the cycle.
- *Class 3:* Single-variable indicator of one of the parameters of sterilization.
- *Class 4:* Multivariable monitor strip that displays two or more changes in response to sterilization. Commonly used in a dry heat cycle.
- *Class 5:* Chemical integrator strip that reacts in the same way as a biologic indicator in the presence of time, temperature, and steam penetration.
- *Class 6:* Emulating indicator responds to all critical variables during the use of a sterilization **process challenge pack/process challenge device (PCD)**.

Biologic Indicators

Positive assurance that sterilization conditions have been achieved can be obtained only through a biologic control test. A biologic indicator is a preparation of living endospores that are resistant to the sterilizing agent. The preparation may be supplied in a self-contained system (e.g., dry endospore strips) or in sealed vials or ampules of endospores in suspension.

To perform the test, a biologic unit that has been exposed to the sterilant and an unprocessed biologic unit (control) from the same lot number are incubated for the same period of time. If sterilization has occurred, the processed biologic unit will not grow any microorganisms. The unprocessed biologic control unit will grow microorganisms and display a change in color. If the unprocessed biologic unit fails to grow microorganisms, its endospores have been inactivated. In such a case, the processed unit also may have been inactive before processing; thus the biologic test is rendered invalid. The entire load is considered unsterile when either the test indicator or the control is in question. Test indicators and controls should be interpreted by qualified personnel.

Each sterilization process requires biologic testing at regular intervals. Consecutive biologic monitors should be run each time the sterilizer is calibrated, repaired, or relocated. Biologic testing involves incubation according to the manufacturer's recommendations. The gram-positive bacterial endospores used for biologic monitoring and testing intervals include the following:

- *Geobacillus stearothermophilus* at 131° F to 140° F (55° C to 60° C) tests steam under pressure daily and with each load of implants.
- *Bacillus atrophaeus* at 95° F to 98.6° F (35° C to 37° C) tests dry heat and ethylene oxide (EO) with every load.
- *B. atrophaeus* testing is performed daily for low-temperature hydrogen peroxide plasma.
- Peracetic acid sterilizers are tested according to the manufacturer's recommendations. The user can employ commercial endospore strips for use during the cycle but may want to test rinse water as a secondary measure.

A rapid-readout biologic indicator specifically for monitoring a high-speed pressure steam sterilizer with a gravity displacement cycle is based on the fluorometric detection of a *G. stearothermophilus*–bound enzyme rather than on endospore growth. The enzyme becomes fluorescent yellow within 60 minutes as the endospores are killed.

Biologic indicators need to conform to the testing standards of the United States Pharmacopeia (USP). A control test is performed at least weekly in each sterilizer (Table 18.1). Many hospitals monitor on a daily basis; others test each cycle. Every load of implantable devices is monitored, and the implant should not

TABLE 18.1 Guidelines for the Use of Chemical and Biologic Indicators[a]

AAMI	AHA	AORN	CDC	TJC
Chemical				
Purpose: To indicate items exposed to the sterilization process; to monitor one or more sterilization parameters; to detect failures in packaging, loading, or sterilizer function. Indicators do not verify sterility.				
Placement				
External: on all packages except if internal indicator is visible	With each package; can be used inside or on outside	External: visible on every package	External: attached to each package	With each package, no designation to inside or outside
Internal: in center or area least accessible to sterilant within each package		Internal: inside each package	Internal: inside large pack	
Biologic				
Purpose: To document efficacy of sterilization process by killing resistant endospores; to ensure that all process parameters are met; to detect nonsterilizing conditions in sterilizer.				
Steam				
Frequency: at least weekly, preferably daily	Frequency: once a day	Frequency: at least once a week, preferably daily, and with each load of implants	Frequency: at least once a week, and with each load of implants	Frequency: at least weekly (daily is recommended), or with each load if sterilization activities are performed less frequently or if load contains implantable or intravascular material
Placement: positioned in cold point in process challenge test pack, normally bottom front of sterilizer				
Ethylene Oxide				
Frequency: every load	Frequency: every load	Frequency: every load	Frequency: at least once a week, and with each load of implants	Frequency: at least weekly (daily is recommended), or with each load if sterilization activities are performed less frequently or if load contains implantable or intravascular material
Placement: inside pack in geometric center of load				

[a]All organizations require that indicators and integrators be used routinely.

be used until negative test results are known. All test results are filed in a permanent record for each sterilizer.

Assembly of Instrument Sets

The weight of instruments and density of metal mass are distributed in the tray to allow steam penetration for sterilizing and revaporization for drying. A large tray distributes instruments so they make minimum contact with one another.

The size, design, and density of instruments are more important than their weight. The conditions necessary for steam sterilization are difficult to achieve in exceedingly heavy sets. Trays should not be overloaded. Closed container instrument sets should not weigh more than 25 pounds. Consideration is given to the personnel who must lift and move the packed sets when determining the presterilization weight. To assemble instrument sets for sterilization, the following steps should be performed:

1. Make sure the instruments are thoroughly dry. All instruments belonging to each set must have passed through **terminal cleaning** and **terminal sterilization** before they are safe to handle.
2. Unless contraindicated, place an absorbent towel or foam in the bottom of the tray to absorb condensate, as for a **rigid container** with vacuum valves. Include a biologic indicator or chemical integrator in the tray.
3. Count instruments as they are placed in the tray, and record the number of each type. A preprinted form is often used for this purpose. This form might be placed in the tray before wrapping and sterilization so the circulating nurse and scrub person can verify the baseline count. The form can be folded in half and placed in a paper peel pouch without a

plastic coating to prevent printer toner from transferring to the instruments during processing. Concerns for toner particulate transfer to the instruments during the cycle are under study. The best choice may be to affix the tray inventory count sheet to the outside of the package.

4. Arrange the instruments in a definite pattern to protect them from damage and to facilitate their removal for counting and use. Follow the instrument book or other listing of instruments to be included.
5. Place heavy instruments, such as retractors, in the bottom of the tray.
6. Open the hinges and box locks on all hinged instruments.
7. Place ring-handled instruments on stringers or holders designed for this purpose. The curved jaws of hemostatic forceps and clamps should point in the same direction from smallest to largest. Instruments should be grouped by style and classification (e.g., six straight hemostats, six curved hemostats). Do not band with rubber bands. The metal under the band will not sterilize adequately.
8. Place sharp and delicate instruments on top of other instruments. They can be separated with an absorbent material or left in a sterilizing rack with the blades and tips suspended. The blades of scissors, other cutting edges, and delicate tips should not touch other instruments. If the instrument has a protective guard, leave it on. Tip-protecting covers or instrument-protecting plastic sleeves should be made of material that is steam-permeable and does not melt or deform with heat.
9. Place concave or cupped instruments with the cupped surfaces down so that water condensate does not collect in them during steam sterilization and drying.
10. Disassemble all detachable parts. Some parts, such as screws and springs, can be put in a peel pouch that is left open. Sealed pouches may not process correctly during the sterilization process.
11. Separate dissimilar metals. For example, brass knife handles and malleable retractors should be separated from stainless steel instruments. Preferably, put each metal in a separate tray, or separate metals with absorbent material.
12. Place instruments with a lumen, such as a suction tip, in as near a horizontal position as possible. These instruments should be tilted as little as possible to prevent trapped air or the pooling of water condensate.
13. Distribute weight as evenly as possible in the tray. Some trays have dividers, clips, and pins that attach to the bottom, which help prevent instruments from shifting and keep them in alignment.
14. Wrap the tray, or place it in a rigid container. Check woven textile wrappers for holes or abrasion. Sequentially double-wrap in a woven or nonwoven material, or use a double-thickness wrap in a single-fold configuration.
15. Place a chemical indicator tab or tape on the outside wrapper or container for proof that the package has been through the parameters necessary for sterilization.
16. Label the sets appropriately with their intended use (e.g., basic set), the date sterilized, and the process lot control number.

Packaging Instruments and Other Items for Sterilization

To be effective, the sterilizing agent must come into direct contact with all surfaces of every instrument. Therefore instruments must be packaged (individually or in sets) in such a way to allow adequate exposure to the sterilant, prevent air from being trapped and moisture from being retained during the sterilization process, and ensure sterile transfer to the sterile field.

The majority of surgical instruments are made of stainless steel and can be sterilized by steam under pressure. Effective steam sterilization involves the direct contact of all surfaces with steam and the revaporization of water condensate to produce a dry, sterile instrument.

Instrument Packaging

For sterilizing and transporting, instruments are put in a closed container or wrapped individually. Instruments placed in open trays are wrapped as sets. Instruments may be prepared in advance as for a **case cart** or may be retained in sterile core storage until needed.

Packaging Considerations

The packaging materials for all methods of sterilization should do the following:

- Permit penetration of the sterilizing agent to achieve sterilization of all items in the package.
- Allow the release of the sterilizing agent at the end of the exposure period and allow adequate drying or aerating.
- Withstand the physical conditions of the sterilizing process.
- Maintain integrity of the package at varying atmospheric and humidity levels. In dry climates or at high altitudes, some packaging materials are susceptible to rupture during sterilization or dry out and crack in storage.
- Provide an impermeable barrier to microorganisms, dust particles, and moisture after sterilization. Items must remain sterile from the time they are removed from the sterilizer until they are used.
- Cover items completely and easily and fasten securely with adhesive strip or a heat seal that cannot be resealed after opening. Seal integrity should be tamperproof. A margin of at least 1 inch (2.5 cm) is considered a standard for safety on all sealed packages. Scissors should not be used to cut off the end of a package. Contents cannot be drawn out over this cut end because the contents would be contaminated by the edge of the packaging material. For the same reason, packages are never torn open below a seal.
- Resist tears and punctures in handling. If accidental tears and holes do occur, they must be visible.
- Identification of the contents and the chemical indicator evidence of exposure to a sterilizing agent should be placed on a label that is visible on the outside of the package.
- Be free of toxic ingredients and nonfast dyes.
- Be lint-free or low-linting.
- Protect the contents from physical damage.
- Permit easy removal of the contents with transfer to the sterile field without contamination or delamination (separation into layers).
- Be economical.

Packages should be wrapped far enough away from sterile storage areas so that mixing sterile and nonsterile packages is not possible. Cabinets that contain nonsterile items should be labeled conspicuously. A procedure for sending items to and receiving items from the sterilizer should be set up so sterile and nonsterile packages can never be confused en route. This procedure must be understood by everyone.

Packages may be wrapped with nonwoven or woven materials sequentially in two layers. Double-thickness wrapping in one layer without using the sequential method is also acceptable. The wrappers can be stitched around the edges or bonded/fused together. Aseptic presentation to the sterile field is the prime consideration. Each facility should determine which method and material is best suited to the clinical environment.

Items are enclosed with all corners of the wrapper folded in. Either a square or an envelope fold may be used (Figs. 18.1 and 18.2).

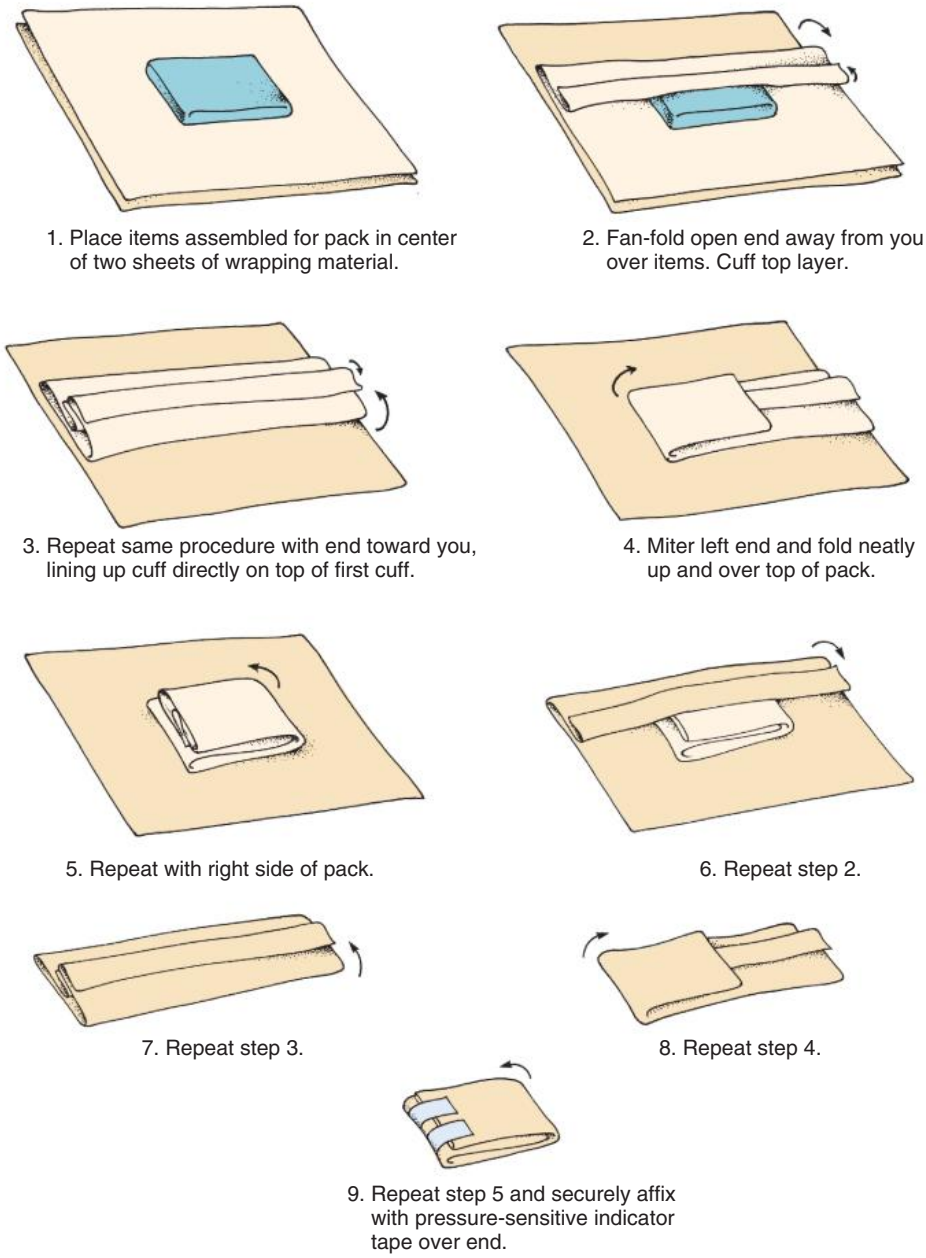
- *Sequential wrapping with two wrappers:* An item is wrapped in one wrapper; the package is wrapped in a second wrapper. A cuff turned back on the first fold of each wrapper provides a margin of safety to prevent contamination when opening after sterilization. Packages can be fastened securely with chemical indicator tape.
- *Single wrap:* An item is wrapped in a single wrap that is of double thickness. The package is sealed with chemical indicator tape.

Packaging Materials and Methods

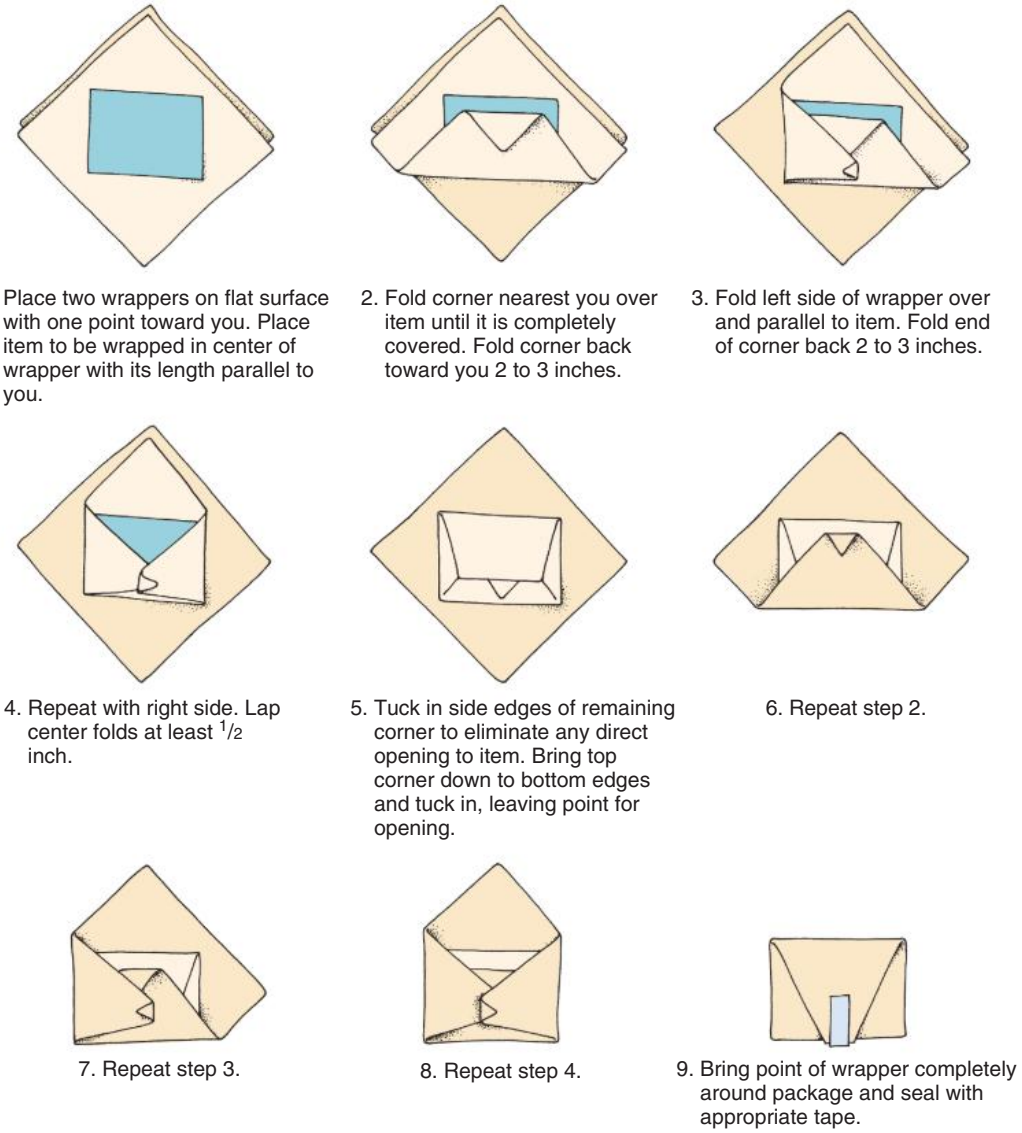
Packaging materials must be compatible with the sterilization process. The following materials may be safely used to wrap items for steam sterilization because they permit steam penetration, adequate air removal, and adequate drying.

Woven Fabrics

Reusable woven fabrics are commonly referred to as *muslin* or *linen.* When no other alternative is available, a 140-thread count,



• **Fig. 18.1** Square fold for wrapping item for sterilization. Single-layer (double-thickness) heavy wrap may be applied in a nonsequential manner. (Modified from the Association for the Advancement of Medical Instrumentation: Good hospital practice: steam sterilization and sterility assurance, ANSI/AAMI ST46, Arlington, VA, 2009, American National Standards Institute.)



• **Fig. 18.2** Envelope fold for wrapping item for sterilization. Single-layer (double-thickness) heavy wrap may be applied in a nonsequential manner. (Modified from the Association for the Advancement of Medical Instrumentation: Good hospital practice: steam sterilization and sterility assurance, ANSI/AAMI ST46, Arlington, VA, 2009, American National Standards Institute.)

carded, 100% cotton muslin is used. Steam sterilizer cycles are based on a time-temperature profile of 140-thread count muslin. This type of fabric is not moisture resistant and is used in a double thickness. Two pieces are sewn together on the edges only, with a blind hem and without cross-stitching, so the wrapper is free of holes.

This wrapper should withstand between 50 and 75 launderings before becoming too worn to be a microbial barrier. A laundering mark-off system is helpful to monitor the number of times a wrapper has been used. The manufacturer should provide information about the number of launderings and sterilization cycles the wrapper can withstand.

Before resterilization, woven fabrics are laundered to rehydrate them. The moisture content of the woven material affects steam penetration and prevents superheating during the sterilization process. The fabric should be stored in an area with controlled room temperature and humidity, according to the manufacturer's instructions. Before use, the woven fabric is inspected for holes and patched with vulcanized patches if necessary. Check manufacturer's recommendation with the use of vulcanized patches because some sterilants may not penetrate the patches. Fabric may create free-floating lint in the OR.

Nonwoven Fabrics

Nonwoven fabrics are a combination of cellulose and rayon with strands of nylon randomly oriented through it, or they are a combination of other natural and synthetic fibers bonded by a method other than weaving. These fabrics have the flexibility and handling qualities of woven materials and are available in several weights. Lightweight is used in four thicknesses; medium weight is the most economical for wrapping items in two thicknesses; and heavy-duty weight is used when a single wrap is used for wrapping supplies for sterilization.

Packages are wrapped in the same manner as woven fabrics. Nonwoven fabrics provide an excellent barrier against microorganisms and moisture during storage after sterilization. They are disposable and virtually lint free. Some manufacturers provide a recycling service for nonwoven wrappers.

Peel Packs or Pouches

Peel pouches and tubes made of a combination of paper on one side and clear plastic film on the other are satisfactory for wrapping single instruments, odd-shaped items, and small items. Double-sided paper pouches are commercially available. For sterile presentation, a peel-open seal may be preformed on one end. The open end is either heat sealed or closed with indicator tape after the item is inserted. All air is expressed from the package before sealing. Self-sealing pouches with adhesive flaps that do not require heat sealing also are available.

The sequential packaging of supplies in a smaller pouch into a larger pouch is not routinely necessary. However, this method may be useful for keeping multiple small items together, such as a set of bone screws. The aseptic presentation of tiny parts to the sterile field without dropping items on the floor can be accomplished with sequential packaging. The manufacturer's instructions should be consulted if sequential peel pouches will be used.[3]

A peel pouch should not be processed flat, but positioned on its side. The plastic side of the pouch can impede the flow of steam penetration through the package. Inclusion of plastic-sided pouches within an instrument set can impair the process of steam through a tray. Obstruction of the steam flow can compromise the entire load. After processing, the peel pouch should be stored on its side to maintain integrity of the packaging.

Sealants and Labeling

Chemical indicator tape is used to seal packages such as peel pouches and wrapped items. Steam-sensitive tape resembles tan masking tape and reveals dark stripes when exposed to steam sterilizing conditions. Gas-sensitive tape is light green and reveals dark stripes after exposure to gas sterilizing conditions.

Peel pouches are usually heat-sealed or self-sealing and have an indicator area or dot that changes color in response to steam or gas exposure.[3] They may be sealed with steam- or gas-sensitive tape. These sealants are not indicators of sterility but are a visual means by which to validate exposure to sterilant conditions. Labels or writing should be applied on the plastic side of the peel pouch to allow the sterilant to penetrate the paper side without transferring the ink to the instrument.

The sealing tape on the outside of the package should be labeled with a dark marker that is nontoxic and resistant to moisture, bleed through, or smearing. Preprinted labels may be used instead. The date of processing and a load number should be attached to each package. These forms of identification are helpful in tracking and locating items that have been processed in batches. A recall of items may be necessary if the sterility of a particular load is in doubt.

Wrapped Trays

To allow steam penetration around instruments and prevent air from being trapped in the tray, trays cannot be solid. Therefore instruments are placed in open trays with mesh or perforated bottoms. Absorbent towels or foam may be placed in the bottom of the tray and over instruments to absorb condensate and protect instruments from snagging in the perforations. Trays are sequentially double-wrapped in woven or nonwoven wrappers. They must be allowed to cool and dry at the end of the sterilizing cycle before they are handled. Hot packages should not be placed on cool surfaces. Condensation under the tray can generate **strike-through**, promoting capillary action of moisture between the warm sterilized tray and the shelving. The moisture can carry microorganisms to the inside of the package.

Rigid Closed Containers

A metal or plastic rigid closed container system may be used for sterilizing instruments singly or in sets. A stainless steel mesh or perforated basket lined with foam porous padding nests in the rigid container. The lid is affixed to the container base by metal snap locks. Plastic breakaway shrink bands secure the flip locks and act as chemical external indicators by changing color. The body of the container is labeled with the contents. A load-identifying label is affixed to the container before processing.

Most styles of closed containers have single-use unidirectional air filters in the lid and bottom. These filters are changed each time the container is processed. The closed container is placed into the steam sterilizer so the steam can penetrate through the bottom and lid. Some containers do not have vents in the bottom. The manufacturer of the closed container system should establish the processing temperature and time.

After the sterilization process is complete, the container is placed on a firm, dry surface adjacent to the sterile table. The circulating nurse breaks the shrink band seal by flipping open the locks and then lifts the lid toward him or her. The outer rigid container is not considered sterile. The scrub person carefully reaches into the container without touching it and grasps the handles of the sterile inner basket, lifting it straight up and out. The sterile basket containing the instruments can be placed on the sterile back table.

Sterile supplies are not to be opened into the rigid container, because the edges are not considered sterile. Condensate in the bottom of the nonvented closed container is considered sterile because it is not permeable to the capillary action associated with other packaging methods.

Specialized Tray Sets

A manufacturer may supply a fitted case or rack for a set of instruments or implants, such as orthopedic devices. These cases or racks help protect the instruments and keep them separated for sterilization and use. These cases or racks are double-wrapped before sterilization; they are not the same as rigid closed containers.

Count Sheets

Count sheets are sometimes packed inside the instrument set for use in counting instruments in the OR. The inks and toner pose a questionable risk for depositing foreign matter inside the patient during the surgical procedure. Toner in the printer cartridge is fused to the paper by heat. The transfer of the toner from the paper to the instruments is of concern during thermal sterilization. Although no data exist to demonstrate harm from toner on count sheets, no data are available to prove that toner is harmless. It may contribute to the formation of adhesions in the same way any foreign body can stimulate an inflammatory response.

Some facilities place the count sheet in a peel pouch. The plastic side of the pouch can obstruct the flow of steam if placed flat in the tray. A paper peel pouch is preferred. Another option is to place the count sheet in a separate labeled peel pouch and process it separately from the packed tray.

Thermal Sterilization

Heat is a dependable physical agent for the destruction of all forms of microbial life, including endospores. It may be used moist or dry. The most reliable and commonly used method of sterilization is steam under pressure.

Steam Under Pressure (Moist Heat Sterilization)

Heat destroys microorganisms, and this process is hastened by the addition of moisture. Steam in itself is inadequate for sterilization. Pressure that is greater than atmospheric pressure is necessary to increase the temperature of steam for the thermal destruction of microbial life. Moist heat in the form of steam under pressure causes the denaturation and coagulation of protein or the enzyme-protein system within cells.

Direct saturated steam contact is the basis of the steam sterilization process. For a specified time and at a required temperature, the steam must penetrate every fiber and reach every surface of the items to be sterilized. When steam enters the sterilizer chamber under pressure, it condenses on contact with cold items. This condensation liberates heat, simultaneously heating and wetting all items in the load and thereby providing the two requisites: moisture and heat. This sterilization process is spoken of in terms of degrees of temperature and time of exposure—not in terms of pounds of pressure. Pressure increases the boiling temperature of water but in itself has no significant effect on microorganisms or steam penetration.

Exposure time depends on the size and contents of the load and the temperature within the sterilizer. At the end of the cycle, reevaporation of water condensate must effectively dry contents of the load to maintain sterility; the water is dried from the sterilized pack or item.

The vegetative forms of most microorganisms are killed in a few minutes at temperatures ranging from 130° F to 150° F (54° C to 65° C); however, bacterial endospores will withstand a temperature of 240° F (115° C) for more than 3 hours. No living thing can survive direct exposure to saturated steam at 250° F (121° C) for longer than 15 minutes. As the temperature of the steam is increased, the time of exposure may be decreased. A minimum temperature-time relationship is maintained throughout all portions of the load to accomplish effective sterilization.

Special Circumstances

Prions (pronounced pree-ons) such as those that cause Creutzfeldt-Jakob disease (CJD) are not a living plant, animal, or virus. They are infectious protein material, and the instruments used must be steam-sterilized for a minimum of 1 hour at 270° F (132° C) after soaking in sodium hydroxide (bleach) or sodium hypochlorite at room temperature for 1 hour, then rinsed. This solution should be solidified and incinerated after use.

If a **prevacuum sterilizer** is used, the item can be safe to handle if processed for 18 minutes at 274° F (134° C) after the 1-hour exposure to sodium hydroxide. If a **gravity displacement sterilizer** is used, the processing time increases to 1 hour. After the soaking and steam sterilizing procedures, the instruments can be processed through the routine washer-sterilizer procedure like other instruments.

Prion material becomes resistant to removal methods if left to dry. Instruments should be kept moist until they can be decontaminated and processed. Drapes and gowns should be disposable and incinerated because prions are not deactivated by laundry procedures used on woven material. The use of disposable instruments and supplies is highly recommended.

Eye instrumentation that is improperly cleaned and processed can subject the patient to toxic anterior segment syndrome (TASS). An inflammatory response in the anterior chamber of the eye causes permanent damage to intraocular tissues and predisposes the patient to secondary glaucoma. Eye instruments should be cleaned separately from other instruments and sterilized according to the manufacturer's instructions.[4]

Advantages of Steam Sterilization

- Steam sterilization is the easiest, safest, and surest method of onsite sterilization. Heat- and moisture-stable items that can be steam-sterilized without damage should be processed with this method.
- Steam is the fastest method; its total time cycle is the shortest.
- Steam is the least expensive and most easily supplied agent. It is piped in from the facility's boiler room. An automatic, electrically powered steam generator can be mounted beneath the sterilizer for emergency standby when steam pressure is low.
- Most sterilizers have automatic controls and recording devices that eliminate the human factor from the sterilization process as much as possible when operated and cared for according to the recommendations of the manufacturer.
- Steam leaves no harmful residue. Many items such as stainless steel instruments withstand repeated processing without damage.

Disadvantages of Steam Sterilization

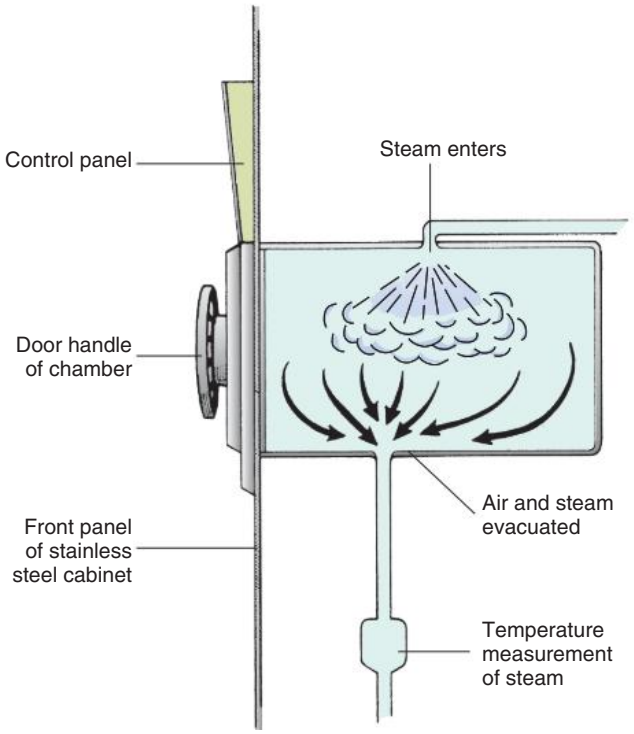
- Precautions must be used in preparing and packaging items, loading and operating the sterilizer, and drying the load.
- Items need to be clean, free of grease and oil, and not sensitive to heat.
- Steam must have direct contact with all areas of an item. It must be able to penetrate packaging material, but the material must be able to maintain sterility.
- The timing of the cycle is adjusted for differences in materials and sizes of loads; these variables are subject to human error.
- Steam may not be pure. Steam purity refers to the amount of solid, liquid, or vapor contamination in steam. Impurities can cause wet or stained packs and stained instruments.

Types of Steam Sterilizers

Sterilizers that are designed to use steam under pressure are often referred to as *autoclaves* to distinguish them from sterilizers that use other agents. Personnel charged with the responsibility of operating steam sterilizers must fully understand the principles and operation of each type. They must be aware of the problems that cause malfunction, which include attaining the sterilization temperature and maintaining it for the required period of time, trapped air, and dirty traps.

Gravity Displacement Sterilizer

The metal construction of the gravity displacement sterilizer contains two shells that form a jacket and a chamber. Steam fills the jacket that surrounds the chamber. After the door is tightly closed, steam enters the chamber at the back, near the top, and is deflected upward. Air is more than twice as heavy as steam. Thus, by gravity, air goes to the bottom and steam floats on top. Steam entering under pressure and remaining above the air displaces air downward (both in the chamber and in the wrapped items) and forces it out through a discharge outlet at the bottom front. The air passes through a filtering screen to a waste line.



• **Fig. 18.3** Schematic cross-section of steam-under-pressure sterilizer. Steam enters at top of chamber to displace air or enters after air is withdrawn by vacuum. Air and steam are evacuated at bottom of chamber. Temperature of steam is measured in air-steam drain line near vent.

A thermometer located at this outlet below the screen measures the temperature in the chamber. When steam has filled the chamber, it begins to flow past the thermometer (Fig. 18.3). The timing of the sterilizing period starts only when the thermometer reaches the desired temperature.

When air is trapped in the chamber or in wrapped items, the killing power of steam is decreased in direct proportion to the amount of air present. Because the vital discharge of air from the load always occurs in a downward direction, never sideways, all supplies are prepared and arranged to present the least possible resistance to the passage of steam downward through the load from the top of the chamber. Air and steam discharge lines are kept free of dirt, sediment, and lint.

Many gravity displacement steam sterilizers operate on a standard cycle of 250° F to 254° F (121° C to 123° C) at a pressure of 15 to 18 pounds per square inch (psi). The size and contents of the chamber determine the exposure period; the average exposure time is 30 minutes for wrapped instruments. Exposure time may vary if a closed sterilization container system is used. Some air-powered instruments may require longer exposure periods at different temperatures. The manufacturer's instructions included with the instrumentation should be consulted for the recommended times and settings for steam sterilization.

Prevacuum Sterilizer (Dynamic air removal)

In this high-vacuum sterilizer, air is almost completely evacuated from the chamber before the sterilizing steam is admitted. The desired degree of vacuum is achieved by means of a pump and a steam-injector system.

A prevacuum period of 8 to 10 minutes effectively removes the air to minimize the steam penetration time. The steam injector preconditions the load and helps eliminate air from the packages. As a result, the sterilizing steam almost instantly penetrates to the center of the packages when admitted to the chamber, because the air has been vacuum-pumped out. If the items in the load are easily penetrable and the sterilizer is functioning properly, there is no demonstrable time difference between complete steam penetration of large or small and tight or loose packages. Therefore the maximum capacity of the sterilizer can be used.

A postvacuum cycle draws moisture from the load to shorten the drying time. The **Bowie-Dick test** is performed daily to ensure that the air vacuum pump is functioning properly.

Temperatures in the prevacuum sterilizer are controlled at 270° F to 276° F (132° C to 135.5° C) at a pressure of 27 psi. Some prevacuum sterilizers with computer-controlled pulsing air evacuation systems reach temperatures between 275° F and 286° F (135° C to 141° C). All items are exposed to a temperature of at least 270° F (132° C) for a minimum of 4 minutes. A complete cycle takes approximately 15 to 30 minutes, depending on sterilizer capacity.

Immediate Use/"Flash" Sterilization

A flash/high-speed pressure sterilizer may have either a gravity displacement or a prevacuum cycle for immediate use sterilization (IUSS), formerly referred to as **flash sterilization** (Table 18.2). The high-speed pressure sterilizer operates at a pressure of 27 psi at sea level (or a maximum of 22 psi at 5000 feet above sea level) to increase the temperature in the chamber to between 270° F and 275° F (132° C to 135° C).

The minimum exposure time at this temperature is 3 minutes for unwrapped, nonporous, uncomplicated stainless steel items without lumens. When porous items or instruments with instrument marking tape or lumens are included in the load, timing is increased to 4 minutes or longer in a prevacuum sterilizer and to 10 minutes or longer in a gravity displacement sterilizer.

With these cycles, the entire time for starting, sterilizing, and opening the sterilizer is a minimum of 6 to 7 minutes. The process should be documented for the record (Box 18.1). Steam should be maintained in the jacket at all times.

IUSS should not be used for routine sterilization of complete instrument sets and should be used only in urgent, unplanned, or emergency situations (e.g., individual items inadvertently dropped or forgotten) for which no alternative method exists.

AORN indicates that one or more steps in the decontamination and sterilization processes may be skipped when IUSS is used, leading to surgical site infection, and that all instruments should be thoroughly washed and dried before processing. Closed container IUSS pans/trays should be used if flashing is unavoidable.

Specially designed surgical suites with in-room sterilizers may provide an emergency form of IUSS sterilization if needed. Items to be permanently implanted in the body are not sterilized for immediate use unless the results of biologic monitoring are immediately available. Sterility is not ensured without the results of biologic test indicators.

Closed container systems are available for flash sterilization to protect items during transfer from the sterilizer to the sterile field. The manufacturer of the container should provide scientific evidence of its suitability for the sterilizer in use.

A high-speed pressure sterilizer used for the flash sterilization of unwrapped instruments is physically located in or immediately adjacent to the OR (e.g., the substerile room). A sterile transfer is made from the sterilizer to the sterile field. Transferring the sterilized item to the sterile field without contaminating it is difficult.

TABLE 18.2 IUSS Unwrapped Instruments for Immediate Use after Cleaning with Approved Instrument Cleanser

Item	Gravity Displacement	Prevacuum	Notes
Stainless steel	3 minutes at 270° F (132° C)	3 minutes at 270° F (132°C)	Items must be clean, disassembled, open box locks; 30 psi
Nonporous			Use chemical indicator
No lumens			
Porous lumens	10 minutes at 270° F (132° C)	4 minutes at 270° F (132° C)	Items must be clean, disassembled, open box locks; 30 psi
Mixed loads			Lumen should be flushed with water and sterilized wet Use chemical indicator
Complex device	Follow steam and dry times	Follow steam and dry times	Refer to manufacturer's recommendations
Saws or drills	Most require longer times at temperatures between 120° F and 132° F (48.9° C and 55.6° C)	Most require shorter steam exposure and longer dry times at temperatures between 120° F and 132° F (48.9° C and 55.6° C)	Use chemical indicator

• BOX 18.1 Content of Flash Sterilization Record

- Date
- Time
- Patient name or number
- Load contents
- Sterilizer identification number
- Cycle parameters (time, temperature, pressure)
- Indicator verification (chemical and/or biologic)

Closed varieties are commercially available that allow an item to be flash-sterilized in a covered container. The outside is considered contaminated, but the inside is considered sterile. The circulating nurse removes the lid toward him or her, touching only the edges. The scrub person reaches inside to remove the sterile item without touching the sides of the outer container.

Precautions

With all types of steam sterilizers, the following precautions are taken to ensure safe operation:

Note: Most steam sterilizers are automatically ready for immediate use. Older models are described for facilities that need additional instruction.

1. Turn on the valve for steam in the jacket before use. Steam may be kept in the jacket throughout the day. (It may be turned off at the end of the surgical schedule if departmental policy indicates this practice.) The jacket maintains heat, so do not touch the inside of the chamber when loading. Check the sterilizer; not all of them have a steam jacket.
2. Never put heat-sensitive items into a steam sterilizer of any type; they will be destroyed.
3. Close the door tightly before activating either the automatic or the manual controls.
4. Unless it is an automatically controlled device, do not set a manually operated timer until the desired temperature registers on the thermometer and recording graphic chart. Thermometers, not pressure gauges, are the guides for sterilization.
5. Open the door only when the exhaust valve registers zero. Stand behind the door and open it slowly to avoid the steam that may escape around the door.
6. Wash the inside of the chamber according to the manufacturer's directions and with manufacturer-approved solution, rinse it with tap water, and dry it with a lint-free cloth every day. Remove and clean the filtering screen daily. Flush the discharge lines weekly with a hot solution of trisodium phosphate: 1 ounce (30 mL) to 1 quart (1000 mL) of hot water. Follow the flush with a rinse of 1 quart (1000 mL) of tap water.
7. Wipe the gasket daily with a lint-free cloth, and check for signs of wear and defects.
8. Provide routine PM, including the evaluation of steam and air purity. The amount of solid, liquid, or vapor contamination in the steam is minimal. An ineffective air filter may contaminate a load when air is drawn into the chamber at the end of the cycle. A defective steam trap or clogged exhaust line can cause malfunction. Make sure the thermometer is correctly calibrated.

Preparing Surgical Instruments for Steam Sterilization

Most instruments are made of metal, but many are difficult to clean. For effective steam sterilization, organic material and debris are first removed. Items that come apart should be totally disassembled and all instruments with box locks opened. Heavy instruments should be placed on the bottom levels of the tray, with lighter instruments on top. The tray contents should be evenly distributed and not exceed the weight set forth by the manufacturer. Items are thoroughly rinsed and dried after cleaning and before sterilization.

Manuals (which often contain photographs) or index file cards are available in the room in which supplies are packaged; these materials provide ready reference during preparation and for wrapping single items, packs, or trays. Instructions are strictly followed to ensure safety in sterilizing items.

Powered Equipment

Powered equipment should be placed in the cases provided by the manufacturer after appropriate decontamination and lubrication. Powered equipment require special cleaning, decontamination, and sterilization. Follow the manufacturer's instructions for sterilization to prevent damage to the equipment.

Basin Sets

If they are nested (placed one inside another), basins and solid utensils are separated ½ inch by porous material, such as toweling. This permits the permeation of steam via **wicking** around all surfaces and the condensation of steam from the inside during sterilization. Sponges and drapes are not packaged in basins because steam could be deflected from penetrating fabrics. Basin sets should not exceed 7 pounds (3.15 kg).

Drape Packs

Freshly laundered woven fabric drapes and gowns are fan-folded or rolled loosely to provide the least possible resistance to the penetration of steam through each layer of material. Packs must not exceed a maximum size of 12 × 12 × 20 inches (30 × 30 × 50 cm) and must not weigh more than 12 pounds (5.5 kg).

Drapes are loosely crisscrossed so they do not form a dense, impermeable mass. Pack density should not exceed 7.2 lb/ft (see Box 18.2 for the calculation of density). The inner aspect of the outside wrapper becomes the temporary sterile field when the pack is opened. An impervious sterile barrier drape should be placed on the instrument table before the sterile field is established for the procedure. The drapes are transferred to the table covered with the impervious barrier drape.

Rubber Goods and Thermoplastics

A rubber or Silastic sheet or any other impervious material should not be folded for sterilization because steam can neither penetrate it nor displace air from the folds. It should be covered with a piece of gauze fabric or toweling of the same size, loosely rolled, and then wrapped. For example, a layer of roller gauze is rolled between layers of an Esmarch bandage.

The mechanical cleaning of tubing, including catheters and drains, is a factor in reducing the microbial count inside the lumen. A residual of distilled water should be left in the lumen of any tubing that is to be steam-sterilized by gravity displacement. The residual becomes steam as the temperature rises, which helps displace air in the lumen and increase the temperature within it. (This is not necessary in a prevacuum sterilizer.) The tubing should be coiled without kinks. Keep in mind that disposable tubing is generally preferred because of the complexities associated with cleaning tubing.

Detachable rubber or plastic parts should be removed from instruments and syringes for cleaning and sterilizing. Rubber surfaces should not touch metal, glassware, or each other during sterilization; this prevents melting or sticking and permits steam to reach all surfaces. Rubber bands should not be used around solid items because steam cannot penetrate through or under rubber.

Wood Products

During sterilization, lignocellulose resin (lignin) is driven out of wood by heat. This resin may condense onto other items in the sterilizer and cause reactions if it gets into the tissues of a patient. Therefore wooden items are individually wrapped and separated from other items in the sterilizer.

Repeated sterilization dries wood so that during sterilization it absorbs moisture from the saturated steam. Cracks in the wood could harbor microorganisms. As the water content of the saturated steam decreases, the steam becomes superheated and loses some of its sterilizing power. Because of this problem, the use of wood products that require steam sterilization should be minimized and their repeated sterilization is avoided.

Loading the Sterilizer

All packages are positioned in the chamber to allow free circulation, steam penetration, and prevent the entrapment of air or water. A gravity displacement sterilizer is loaded so steam can displace air downward and out through the discharge line. Wire mesh or perforated metal shelves separate layers of packages. Shelves may be contained within the chamber on sliding racks or a transfer carriage. The shelves are loaded and rolled into the sterilizer. Floor loaders are easier to manage than off-floor carriage racks. Steam sterilizers should be loaded as follows:

1. Flat packages of textiles are placed on the shelf on edge so flat surfaces are vertical, as shown in Fig. 18.4. Instrument trays and closed container systems with perforated bottoms may be laid flat.
2. Large packs are placed 2 to 4 inches apart in one layer only on a shelf. Small packages may be placed on the shelf above with 1 or 2 inches between them. If small packages are placed one on top of another, they should be crisscrossed.

• BOX 18.2 Calculation of Density of Drape Pack

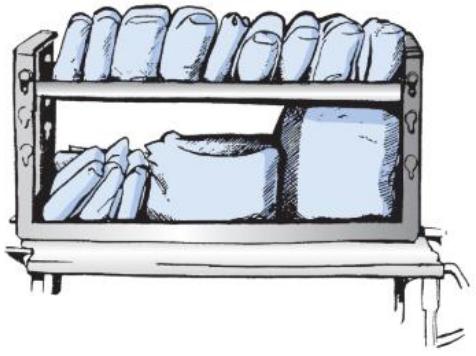
$$\frac{\text{Size of pack (inches)}}{1728\ (\text{in/ft}^2)} = \text{Cubic feet of pack}$$

$$\frac{\text{Weight of pack (lb)}}{\text{Cubic feet of pack}} = \text{Density factor}\ (\text{lb/ft}^3)$$

Example:

$$\frac{12" \times 12" \times 20"}{1728\ (\text{in/ft}^2)} = 1.666\ \text{ft}^3$$

$$\frac{12\ \text{lb}}{1.666\ \text{ft}^3} = 7.2\ \text{lb/ft}^3\ \text{(maximum density)}$$



• **Fig. 18.4** Proper loading of gravity displacement steam sterilizer; packs should be placed on edge, and the rack should not be overloaded. Steam must completely surround and penetrate every package in all sterilizers.

3. Packages must not touch the chamber walls, floor, or ceiling.
4. Rubber goods are placed on edge, loosely arranged and in one layer to a shelf; this allows free steam circulation and penetration. No other articles should be with the rubber goods.
5. Basins and solid containers are placed on their sides to allow air to flow out of them. They should be placed so that if they contained water all of it would flow out. If being sterilized in a combined load with fabrics, basins and containers should be placed on the lowest shelf.

Timing the Load

The timing of a sterilization cycle begins when the desired temperature is reached throughout the chamber. Materials that need different lengths of exposure to ensure sterilization in a gravity displacement sterilizer should not be combined in the same load if the maximum time needed will be destructive to some items. The minimum time standards, which are calculated after effective steam penetration of porous materials and the rate of heat transfer through wrapping materials, are listed in Table 18.3.

Most sterilizers are equipped with a graphic recorder and automatic electromechanical or microcomputer time-temperature controls. Some sterilizers print out a computer record to document each load. The time and temperature for each load are recorded for a 24-hour period. The record of each load should be checked before unloading to be certain that the desired temperature was achieved. Also, the temperature being recorded should be checked daily against the thermometer to see that the recording arm is working properly.

Drying the Load

After the sterilizer door is opened, the load of wrapped packages is left untouched to dry for 15 to 60 minutes. The time required for drying depends on the type of sterilizer and the types of supplies in a load. Large packages require a longer time than small ones. The packages are then unloaded onto a table or cart containing wire mesh shelves padded with absorbent material. Warm packages laid on a solid, cold surface become damp from steam condensation and thus contaminated by strike-through (**capillary action**).

TABLE 18.3 Minimum Exposure Time Standards for Steam Sterilization after Effective Steam Penetration and Heat Transfer

	GRAVITY DISPLACEMENT		PREVACUUM
Materials	**250° F (121° C)**	**270° F (132° C)**	**270° F (132° C)**
Basin sets, wrapped	20 minutes	Not applicable	4 minutes
Basins, glassware, and utensils, unwrapped	15 minutes	Not recommended	3 minutes
Instruments, with or without other items, wrapped as set in double-thickness wrappers	30 minutes	Not applicable	4 minutes
Instruments, unwrapped but with other items, including towel in bottom of tray or cover over them	20 minutes	10 minutes	4 minutes
Instruments, completely unwrapped	15 minutes	3 minutes	3 minutes
Drape packs, 12 × 12 × 20 inches (30 × 30 × 50 cm) maximum size, 12 lb (5.5 kg) maximum weight	30 minutes[a]	Not applicable	4 minutes
Fabrics, single items wrapped	30 minutes[a]	Not applicable	4 minutes
Rubber and thermoplastics, including small items and gloves but excluding tubing, wrapped	20 minutes[a]	Not applicable	4 minutes
Tubing, wrapped	30 minutes	Not applicable	4 minutes
Tubing, unwrapped	20 minutes	Not applicable	4 minutes
Sponges and dressings, wrapped	30 minutes	Not applicable	4 minutes
Solutions, flask	(Slow exhaust)	Not applicable	Automatic selector determines correct temperature and exposure period for solutions
75-mL flask	20 minutes		
250-mL flask	25 minutes		
500-mL flask	30 minutes		
1000-mL flask	35 minutes		
1500-mL flask	45 minutes		
2000-mL flask	45 minutes		

[a]Fabrics and rubber deteriorate more rapidly with repeated sterilization for prolonged periods in gravity displacement sterilizer.

Packages are observed for water droplets on the exterior or interior and for absorbed moisture in the package. Packs wrapped in moisture-permeable materials that have water droplets on the outside or inside are unsafe for use because the moisture can be a pathway for microbial migration into the package via capillary action. A package should be considered contaminated if it is wet when opened for use. Packages should be completely dry after cooling at a room temperature of 68° F to 75° F (20° C to 24° C) for a minimum of 1 hour.

Biologic Testing of the Steam Sterilizer

Biologic test packs with *Geobacillus stearothermophilus* for steam sterilizers vary according to the type of sterilizer being tested. Each steam sterilizer is tested at least weekly for routine monitoring and as needed for a process challenge test. Many hospitals test sterilizers daily. Because of the variations in sterilizers, the appropriate test is used for each type of sterilizer.

Gravity Displacement Sterilizer

With a gravity displacement sterilizer, the test pack/PCD is placed on edge in the lower front of the load. This is the coldest area and therefore represents the greatest challenge in sterilization. The chamber is fully loaded. The contents of the test pack may be any of the following:

- The equivalent of three woven fabric gowns, 12 towels, 30 gauze sponges (4 × 4 inches), 5 laparotomy tapes/sponges (12 × 12 inches), and 1 woven fabric drape sheet. Two biologic indicators are placed in the center of the pack, with a chemical indicator placed one towel above or below them. The pack is double-wrapped. It should be approximately 12 × 12 × 20 inches (30 × 30 × 50 cm) and should weigh 10 to 12 pounds.
- The equivalent of 16 freshly laundered reusable huck towels or absorbent towels in good condition, each approximately 16 × 26 inches (40 × 66 cm), folded 9 × 9 inches (23 × 23 cm), and stacked with a biologic indicator in the center. The pack is taped to provide a density of 12 lb/ft^3, and it should weigh 3 pounds.
- An equivalent commercial test pack.

Prevacuum Sterilizer

With a prevacuum sterilizer, the contents of the test pack/PCD with biologic indicators can be the same as for a gravity displacement sterilizer. In addition, a Bowie-Dick test is conducted daily, usually on the first run of the day, to check for air entrapment in the prevacuum sterilizer. A biologic indicator may be put into this test pack. The test pack is placed horizontally on the bottom shelf at the front, near the door, and over the drain of an empty prevacuum chamber. The test pack consists of the following:

- Between 24 and 44 absorbent towels folded in a stack no smaller than 9 × 12 × 11 inches (23 × 30 × 28 cm)
- One Bowie-Dick test sheet placed in the center of the stack
- One double-thickness wrapper

Dry Heat Sterilization

Dry heat in the form of hot air is used primarily to sterilize anhydrous oils, petroleum products, and talc, which steam and EO gas cannot penetrate. The destruction of microbial life by dry heat is a physical oxidation or slow burning process that involves coagulating the protein in cells. Higher temperatures are required in the absence of moisture because the microorganisms are destroyed through a very slow process of heat absorption by conduction. Dry heat sterilizers are not commonly found in the OR processing areas. Dry heat is commonly used in dental suites.

Advantages of Dry Heat Sterilization

- Hot air penetrates certain substances that cannot be sterilized by steam sterilization or another method.
- Dry heat is a protective method of sterilizing some delicate, sharp, or cutting-edge instruments. Steam may erode or corrode cutting edges.

Disadvantages of Dry Heat Sterilization

- A long exposure period is required, because hot air penetrates slowly and possibly unevenly.
- The time and temperature required will vary for different substances.
- Overexposure may ruin some substances.

Types of Dry Heat Sterilizers

Mechanical Convection Oven

The most efficient and reliable dry heat sterilizer is an electrically heated, mechanical convection hot air oven. A blower forces hot air in motion around items in the load to hasten the heating of substances and ensure a uniform temperature in all areas of the oven.

Early models operated at 320° F to 340° F (160° C to 171° C) for 1 to 2 hours. Faster portable tabletop models are available; these run at 375° F to 400° F (190.5° C to 204° C), with total cycle times of 6 minutes for unwrapped items and 12 minutes for wrapped ones. Optional cooling chambers are also available.

Gravity Convection Oven

A conventional gravity displacement steam sterilizer chamber can be used for dry heat sterilization. Heat is provided by steam in the jacket only; this heat may not be evenly distributed throughout the chamber. The hot air rises initially and by gravity displaces cooler air at the bottom of the chamber. The maximum temperature that can be obtained is 250° F (121° C) or 270° F (132° C) in a high-pressure gravity displacement sterilizer. To ensure adequate heat conduction through all items, the exposure period is a minimum of 6 hours and preferably overnight.

Preparing Items for Dry Heat Sterilization

Oils

The amount of oil—including mineral oil and lubricating oil for electrically powered or air-powered instruments—put into a container should not exceed 1 ounce (30 mL). The depth of the oil is preferably not more than ¼ inch (6.35 mm). The greater the depth, the longer the exposure period.

Talc

A maximum of 5 g to 1 ounce of talc may be spread out in a glass container so the depth of the layer does not exceed ¼ inch (6.25 mm). The lid is secured, with the cap screwed tightly on the bottle or jar, and a dry heat process chemical indicator is affixed to the bottle. The sterilizing cycle for a gravity convection oven (steam sterilizer with steam in the jacket only) should be a minimum of 9 hours at 250° F (121° C) or 6 hours at 270° F (132° C).

An average quantity of 2 to 3 g of talc is usually needed as an intrapleural sclerosing agent for poudrage. This smaller quantity may be evenly distributed inside a sealed glassine envelope or peel

pouch, which is then inserted into a second envelope or pouch. The talc should not accumulate into a mass exceeding ¼ inch (6.25 mm); the package should lie flat in the sterilizer. Prepackaged sterile talc is commercially available and is preferred.

Packaging Materials for Dry Heat Sterilization

Glass

Petri dishes, ointment jars, flasks, small bottles, or test tubes can be used for dry heat sterilization. Caps or lids are affixed or screwed tightly onto containers.

Stainless Steel Boats or Trays

Covers must fit tightly. They can be held in place with indicator tape. The heat causes the adhesive to stick to the surface of the container and is hard to remove.

Aluminum Foil

Foil conducts heat rapidly.

Woven Fabric and Peel Pouches

These materials can be used for wrapping instruments if the temperature in the chamber will not exceed 400° F (204° C). Powders and talc can be put in double glassine envelopes.

Loading the Sterilizer

When loading a dry heat sterilizer, it is necessary to allow space between the items and along the chamber walls so the hot air can circulate freely. The chamber is never loaded to full capacity.

Timing the Load

The time of exposure in a dry heat sterilizer varies depending on the characteristics of individual items, the layer depth in containers, and the temperature in the sterilizer. The timing of exposure begins when the thermometer registers the desired temperature. Items are exposed for the following minimum periods, assuming the amount in each container is kept to a minimum and the sterilizer is loaded according to the manufacturer's recommendations:

- 6 minutes at 400° F (204° C), unwrapped
- 12 minutes at 375° F (190.5° C), wrapped
- 1 hour at 340° F (171° C), wrapped or unwrapped
- 2 hours at 320° F (160° C), wrapped or unwrapped
- 3 hours at 285° F (140.5° C), wrapped or unwrapped
- 6 hours at 250° F (121° C), wrapped or unwrapped

Biologic Testing of the Dry Heat Sterilizer

Biologic indicators with endospores of *Bacillus atrophaeus* are used to monitor the dry heat process. Commercially prepared endospore strips in glassine envelopes should be used. Each load should be tested and the items quarantined until negative results are confirmed.

Chemical Sterilization

The only chemicals used for sterilization are those that are registered as a sterilant by the Environmental Protection Agency (EPA). They may be approved for use in a gaseous, plasma, or liquid state.

Ethylene Oxide Gas Sterilization

EO gas is used to sterilize items that are sensitive to heat or moisture. EO or EtO is a chemical alkylating agent that kills microorganisms (including endospores) by interfering with the normal metabolism of protein and reproductive processes, resulting in cell death. Used in the gaseous state, EO must have direct contact with microorganisms on or in the items to be sterilized. EO is the most regulated sterilization process in the United States.

EO is highly flammable and explosive in air and therefore must be used in an explosion-proof sterilizing chamber in a controlled environment. The machine is equipped with alarms and will automatically lock if a malfunction occurs.

When handled properly, EO is reliable and safe for sterilization, but the toxic emissions and residues of EO present health hazards to personnel and patients. Therefore the environment in which EO is used is constantly monitored for unsafe exposure levels. Employee exposure records are required by law to be retained for 30 years.

EO gas sterilization depends on four parameters, each of which may be varied. Consequently EO sterilization is a complex, multiparameter process. Each variable affects the other dependent parameters:

1. *Concentration of EO gas:* Liquefied EO is supplied in high-pressure metal cylinders, tanks, and disposable cartridges. In the sterilization process, air is withdrawn from the chamber and the EO enters as gas under pressure. The only means for controlling EO concentration is to operate the sterilizer according to the manufacturer's instructions. The operating pressure of the cycle influences the rate of gas diffusion through the items to be sterilized. The absorbency of the items and packaging materials influences the concentration of the gas. EO gas may be diluted or used in pure form:
   a. *100% EO:* Unit-dose cartridges of 67 g or 134 g pure EO are used in small self-contained sterilizers. Because pure EO is highly flammable, only a small number of cartridges are kept in inventory.
   b. *EO/CO_2, referred to as 10/90:* This is a mixture of 10% EO in 90% carbon dioxide. Because of the great pressure differential between EO and carbon dioxide, maintaining a uniform mix is difficult. A high-pressure cycle must be used; therefore not all devices can be sterilized safely in this mixture.
2. *Temperature:* Temperature influences the destruction of microorganisms and affects the permeability of EO through cell walls and packaging materials. Higher density items and loads require a longer heat-up time. As temperature is increased, exposure time can be decreased. Gas sterilizers operate at temperatures ranging from 85° F to 145° F (29° C to 63° C). The uppermost limit for many heat-sensitive plastic materials is 140° F (60° C). The temperature in the chamber is raised by the injection of saturated steam.
3. *Humidity:* Moisture is essential in achieving sterility with EO gas. Desiccated or highly dried bacterial endospores are resistant to EO gas; they must be hydrated. The moisture content of the immediately surrounding atmosphere and the water content within organisms are important to the action of EO gas. Therefore to hydrate the items during preparation, the relative humidity of the room in which the items are packaged and held for sterilization should be at least 50% and must not be less than 30%. The ability of the item and packaging material to absorb moisture affects the humidification and diffusion of gas during the sterilization process. A humidity level of 30% to 80% is maintained throughout the cycle; excessive moisture will inhibit sterilization. Saturated steam provides the necessary humidity.

4. *Time.* The time required for the complete destruction of microorganisms is related primarily to the concentration and temperature of the gas. The cleanliness of items, types of materials, arrangement of load, and rate of penetration also influence exposure time. Drawing an initial vacuum at the start of the cycle aids in penetration of the gas.

Advantages of EO Gas Sterilization

1. EO gas is an effective substitute agent to use with most items that cannot be sterilized by heat, such as plastics with low melting points.
2. EO gas provides an effective method of sterilization for items that steam and moisture may erode; it is noncorrosive and does not damage items.
3. EO gas completely permeates all porous materials; it does not penetrate metal, glass, and petroleum-based lubricants. EO gas sterilization is not recommended for oils, liquids, and powder (including talc).

   Solutions in glass ampules can be sterilized in EO because the gas does not penetrate glass. But a glass vial with a rubber stopper must not be put in the sterilizer because the gas will penetrate the rubber and may react with the drugs in solution, causing a potentially harmful chemical reaction.
4. Automatic controls preclude human error by establishing proper levels of pressure, temperature, humidity, and gas concentration. The sterilizer is operated according to the manufacturer's instructions.
5. EO gas leaves no film on items.
6. EO gas sterilization is used extensively in the preparation of commercially available, packaged, presterilized items because packaging materials that prolong storage life can be used.

Disadvantages of EO Gas Sterilization

1. EO gas sterilization is a complicated and long process that is carefully monitored.
   a. An item that can be safely steam-sterilized should never be gas-sterilized.
   b. Biologic indicator *(B. atrophaeus),* external chemical indicators, sterilizer operation, and maintenance records should be reviewed to verify the adequacy of every cycle.
   c. Implants should not be used until the results of biologic testing are known.
   d. Items are completely aerated before use to eliminate harmful residues.
2. EO sterilization takes longer than steam sterilization; it is a long, slow process.
3. EO gas requires special, expensive equipment. Gas is somewhat expensive per cycle.
4. Items that absorb EO gas during sterilization, such as rubber, polyethylene, or silicone, require an **aeration** period (Table 18.4). Air admitted to the sterilizer at the end of the cycle only partially aerates the load.
5. Toxic by-products can be formed in the presence of moisture droplets during the exposure of some plastics, particularly polyvinyl chloride.
6. Repeated sterilization can increase the concentration of the total EO residues in porous items. These increased levels can be hazardous unless the gas can be dissipated.
7. EO is a vesicant when in contact with skin and mucous membranes.
   a. Liquid EO may cause serious burns if not removed immediately by thorough washing.
   b. Gloves made of neoprene, polyvinyl fluoride, nitryl or butyl rubber, or other material known to be impermeable to EO penetration should be worn for handling sterilized packages before aeration. If thick cotton gloves are worn, they should be placed in the aerator between uses.
   c. Personnel who wear contact lenses, especially soft lenses, should wear protective goggles when working around EO sterilizers to avoid eye irritation.
8. Inhaled EO gas can be irritating to mucous membranes. It is a colorless gas, but its presence is easily detectable by odor. Overexposure causes nasal and throat irritation. Prolonged

TABLE 18.4 Minimum Aeration Times after Ethylene Oxide Sterilization at Different Temperatures

	AMBIENT ROOM AIR	MECHANICAL AERATOR	
Materials	**65° F to 72° F (18° C to 22° C)**	**122° F (50° C)**	**140° F (60° C)**
Metal and glass			
Unwrapped	May be used immediately		
Wrapped	2 hours	2 hours	2 hours
Rubber for external use—not sealed in plastic	24 hours	8 hours	5 hours
Polyethylene and polypropylene for external use—not sealed in plastic	48 hours	12 hours	8 hours
Plastics except polyvinyl chloride items—not sealed in plastic	96 hours (4 days)	12 hours	8 hours
Polyvinyl chloride	168 hours (7 days)	12 hours	8 hours
Plastic and rubber items—those sealed in plastic and/or those that will come in contact with body tissues	168 hours (7 days)	12 hours	8 hours
Internal pacemaker	504 hours (21 days)	32 hours	24 hours

exposure may result in nausea, vomiting, dizziness, difficulty breathing, and peripheral paralysis.
   a. Immediately after the completion of each cycle, the sterilizer door should be opened approximately 2 inches and the area cleared of all personnel for 15 minutes before unloading.
   b. Loading carts should be pulled, not pushed, from the sterilizer to the aerator. Air currents flowing over the load may accumulate a residual gas that could be inhaled.
9. Long-term exposure to EO is known to be a potential occupational carcinogen, causing leukemia. It is also a mutagen, causing spontaneous abortion, genetic defects, chromosomal damage, and neurologic dysfunction.
   a. The standards of the Occupational Safety and Health Administration (OSHA) limit an employee's exposure to EO to 1 part per million (ppm) of air averaged over an 8-hour period to an active level of 0.5 ppm, and to a short-term limit of 5 ppm averaged over a 15-minute period. These exposure limits are referred to as permissible exposure limits (PELs).

      The short-term limit addresses exposure to bursts of gas, such as when opening a sterilizer. Breathing zone sampling is performed daily throughout an 8-hour shift on at least one employee for each job classification of exposed personnel. Passive dosimeter badges are the most popular monitoring devices for personnel. Chromatographs and other types of detectors are used for continuous gas analysis of the environment.
   b. EO gas is vented from the sterilizer to the outside atmosphere to avoid personnel exposure. Audible and visual alarm systems should be installed to indicate a failure in the ventilation system. Most sterilizers have an exhaust hood over the sterilizer door.
   c. The sterilizer door has locking and sealing mechanisms. The integrity of the seals is checked regularly. Automatic controls must function properly so the door cannot be opened until the gas is evacuated from the chamber.

Types of EO Gas Sterilizers

The capacity of EO chambers varies from approximately 2 ft (57.5 L) in a tabletop size of 12 × 12 × 24 inches (30 × 30 × 60 cm) to very large floor-loading units that are 28 × 67 × 78 inches (72 × 180 × 198 cm). These chambers automatically control gas concentration, temperature, humidity, and time. Most models have vacuum pumps to evacuate air from the chamber and steam ejectors to humidify and increase temperature. Microcomputer controls and digital printouts of cycle parameters provide evidence of proper operation.

A purge cycle follows the timed gas-exposure cycle to vent the chamber of airborne residual gas. Some chambers are a combination sterilizer/aerator, which eliminates the need for personnel to handle the load immediately after sterilization; the load is removed only after aeration.

Preparing Items for EO Gas Sterilization

All Items

All items to be sterilized with EO gas are thoroughly cleaned and dried. Detachable parts are disassembled, and syringes are separated. Impermeable items such as caps, plugs, and stylets are removed. All items must be completely dry.

Lumens

Any tubing or other item with a lumen should be blown out with air to force it dry before packaging, because water combines with EO gas to form ethylene glycol, a harmful acid that causes hemolysis of red blood cells in the patient.

Lensed Instruments

Endoscopes with cemented optical lenses require special cement for EO gas sterilization.

Lubricated Instruments

All traces of lubricant, especially petroleum-based lubricants, should be removed before sterilization. EO cannot permeate the film of the lubricant.

Cameras

As a permanent record or teaching aid, photographs are sometimes taken at the surgical site with a sterile, specially constructed camera. Digital cameras are more frequently utilized in the OR.

Some cameras and film can be sterilized with EO gas. The film is loaded before packaging for sterilization.

Packaging Materials for EO Gas Sterilization

The type and thickness of the wrapper, the size and shape of the package, and the porosity of the contents used influence the time it takes for the EO gas to penetrate. Items wrapped for EO gas sterilization should be tagged for gas to prevent them from being inadvertently steam-sterilized and damaged. Materials used for wrapping items are permeable to EO gas and water vapor and allow effective aeration. The materials discussed in the following sections are acceptable.

Woven Fabric

Reusable double-thickness woven fabrics are used as they are for steam, with the same advantages and disadvantages.

Nonwoven Fabric

Tyvek spun bonded olefin and other high-density polyethylene fabrics are highly permeable to EO and moisture. These single-use disposable wrappers offer the same advantages as the nonwoven fabrics described for use in steam, but not all of them can be used interchangeably; the cellulose/nylon/rayon combination should be used only for steam sterilization. Packages should be sequentially single- or double-wrapped or the material used according to the manufacturer's recommendations.

Peel Packs and Pouches

Double-wrapping may not allow adequate penetration of the gas and moisture. Peel pouches with either coated or uncoated paper on one side and coated Mylar on the other are generally acceptable for most gas sterilizers, and they allow visualization of contents.

Materials not to be used for EO sterilization because of inadequate permeability include nylon, polyvinyl chloride film (Saran), polyester, polyvinyl alcohol, cellophane, and aluminum foil. Combinations of materials that make a package insufficiently permeable for adequate humidification, gas penetration, and aeration are avoided.

Loading the Sterilizer

All packages are positioned in the chamber to allow free circulation and penetration of gas. Overloading creates conditions that

can slow the penetration of EO gas, moisture, and heat. Air space should be provided between the chamber ceiling and the uppermost packages in the load, and packages should not touch the chamber walls and floor. Packages should not be stacked tightly; space is allowed between them. If paper or plastic pouches are used, the packages are placed on edge, with the plastic side of one facing the paper side of another.

Timing the Load

The timing of the EO cycle varies depending on the size of the chamber, the contents of the load, gas concentration, temperature, and humidity. For example, a cool cycle at 99° F (37° C) may require more than 5 hours, whereas the same load at 131° F (55° C) may take less than 3 hours. The instructions provided by the manufacturer of the sterilizer should be followed closely.

Aerating Items after EO Gas Sterilization

EO gas exerts toxic effects on living tissue. Therefore after EO gas sterilization, adequate aeration is absolutely essential for all absorbent materials that will come into contact with skin or tissues, either directly or indirectly. Residual products after sterilization can include the following:

1. *Ethylene oxide:* Porous materials, such as plastic, silicone, rubber, wood, and leather, absorb a certain amount of gas that must be removed. The thicker the walls of items, the longer the aeration time required. Residual EO gas in plastic tubing or in parts of a heart-lung pump oxygenator causes hemolysis of blood. Rubber gloves or shoes worn immediately after exposure can cause irritation or burns on skin. The following are acceptable limits for residual EO:
   a. 25 ppm for blood dialysis units, blood oxygenators, heart-lung machines, and all implants
   b. 250 ppm for all topical medical devices
2. *Ethylene glycol:* Ethylene glycol is formed by a reaction of EO gas with water or moisture; this reaction leaves a clear or brownish oily film on exposed surfaces. This substance causes hemolysis of the red blood cells. It also can cause irritation to the mucous membranes if left on plastic or rubber endotracheal tubes or airways. The following are acceptable limits of ethylene glycol:
   a. 250 ppm for blood dialysis units, blood oxygenators, heart-lung machines, and all implants
   b. 1000 ppm for all topical medical devices
3. *Ethylene chlorohydrin:* This by-product is formed when a chloride ion is present to combine with EO, such as in polyvinyl chloride plastic. Rubber, soft nylon, and polyethylene items that have been in contact with saline solution or blood can retain enough chloride ions to cause this reaction in the presence of moisture. To avoid this hazard, disposable products should be discarded after use. The following are acceptable limits of ethylene chlorohydrin:
   a. 25 ppm for blood dialysis units, blood oxygenators, heart-lung machines, and all implants
   b. 250 ppm for all topical medical devices

Residuals are expressed as the weight of EO gas remaining in the item divided by the weight of the item. For example, 25 ppm in a device weighing 2500 g (approximately 5.5 lb) equals 0.01 mg of EO. Residues cannot be removed by rinsing items in water or liquids.

To purge residual gas, air is admitted into the chamber at the end of the sterilization cycle. In sterilizers with a pulse-purge cycle, the air is admitted and immediately removed as many as six times in 30 minutes. Additional aeration is required for all wrapped and porous items. Aeration to diffuse any residual products may be accomplished with ambient (room) air or preferably with an aerator chamber designed for this purpose.

Manufacturers of products suitable for EO sterilization should provide written instructions for the sterilizing cycle and for aerating. The available recommendations are followed. Polyvinyl chloride is one of the most difficult materials to aerate. If the composition of an item is not known, the minimum time for polyvinyl chloride should be followed (see Table 18.4). Aeration time depends on the following:

- Composition, density, porosity, weight, and configuration of the item
- Packaging material
- Sterilizing conditions, such as the size of the load, the nature of the items in it, and variable required factors
- Aeration conditions, such as ambient versus mechanical airflow and temperature
- Acceptable limits of residual products for the intended use of the item, such as external application or internal implantation

Aeration at an elevated temperature enhances the dissipation rate of absorbed gas, which results in faster removal. The entire load on the sterilizer carriage can be transferred into an aerator. A blower system draws air in from the outside to the heater in the upper part of the chamber to maintain a minimum rate of four air exchanges per minute. The aerator is vented to the outside atmosphere. Items cannot be safely used until they have been completely aerated.

All materials remain in the aerator for 8 hours at 140° F (60° C) to 12 hours at 120° F (49° C) or longer, depending on temperature and the instructions of the manufacturer of the aerator or item. In a combination sterilizer/aerator, aeration time varies according to temperature and airflow (e.g., 12 hours at 130° F [54° C] or 32 hours at 100° F [38° C]).

If an aerator is not available, packages may be moved on a cart or in a basket from the sterilizer into a well-ventilated clean storage area that has at least 10 air exchanges per hour. The cart should be pulled, not pushed, to this area to avoid being downwind of the EO gas adhering to the wrappers. Aeration time is prominently noted on the cart or basket. At a room temperature controlled between 65° F and 72° F (18° C and 22° C), a minimum aeration time of 168 hours (7 days) is required for polyvinyl chloride and plastic and rubber items sealed in plastic packages and for porous items that:

1. Come into direct contact with blood
2. Are implanted, inserted, or applied to body tissues
3. Are used for assisted respiration

Unwrapped, nonporous metal and glass may be handled immediately. Wrapped metal should be aerated for at least 2 hours. Intravenous (IV) or irrigation fluids in plastic containers must not be stored in a room where gas-sterilized items are aerating, because the residual diffusing gas could be absorbed through the plastic.

Biologic Testing of the EO Gas Sterilizer

Biologic indicators carrying endospores of *B. atrophaeus* are used to monitor EO gas sterilizers. Each sterilizer is tested in each load. Every load containing implantable devices should be tested. An implant should not be used until the test results are negative. The manufacturer's recommendations should be followed for the use of biologic test packs for EO gas sterilizers.

Hydrogen Peroxide Plasma Sterilization

Hydrogen peroxide (H_2O_2) can be activated to create a reactive plasma. Plasma has been described as the fourth state of matter, being not a liquid, gas, or solid. It can be produced through the action of either a strong electrical or magnetic field, somewhat like a neon light. The cloud of plasma created consists of ions, electrons, and neutral atomic particles that produce a visible pink glow. Free radicals of the hydrogen peroxide in the cloud interact with cell membranes, enzymes, or nucleic acids to disrupt the life functions of microorganisms. The processing time ranges between 35 and 75 minutes. The user must know the parameters necessary for the sterilization of items processed by this method.

The plasma and vapor phases of hydrogen peroxide are highly sporicidal, even at a low concentration and temperature. The sterilizer chambers are simple in design, but the process of the sterilization cycle differs with the method used to convert hydrogen peroxide into plasma or vapor. Plasma technology uses an oxidation process that can be corrosive to some polymers and adhesives. This can cause problems with some lensed instruments.

This method is used for sterilization of metal and nonmetal surgical devices at low temperatures in a dry environment. This method works well for instruments that have diffusion-restricted spaces, such as box locks on clamps. Instruments with lumens have specific requirements:

- Metallic or nonmetallic instruments with lumens of 6 mm or larger and lengths of 310 mm or shorter can be processed.
- Stainless lumens larger than 3 mm and shorter than 400 mm are safely processed.

Advantages of Hydrogen Peroxide Sterilization

- The process is dry and nontoxic.
- The by-products of oxygen and water vapor are safely evacuated into the room atmosphere.
- Aeration is not necessary.
- A low temperature allows the safe sterilization of some heat-sensitive items.
- Plasma has significantly less effect on metal than does steam sterilization; corrosion does not occur on moisture-sensitive microsurgical and powered instruments.
- The sterilizer is simple in design and connects to standard electrical outlets.

Disadvantages of Hydrogen Peroxide Sterilization

- Metal trays block radiofrequency waves and cannot be used.
- Hydrogen peroxide is not compatible with cellulose (i.e., woven textiles with cotton fibers and paper products). This causes a decrease in the sterilant concentration by absorbing the vapors. This method cannot be used with liquids.
- Nylon becomes brittle after repeated exposure to hydrogen peroxide sterilization.
- This method is not approved in the United States for use with flexible endoscopes with lumens.

Low-Temperature Gas Plasma Sterilizers

STERRAD by Advanced Sterilization Products

The STERRAD sterilizer connects to a standard electrical outlet. The supplies are placed in the chamber, and a strong vacuum is created. A solution of water and 58% hydrogen peroxide is vaporized by radiofrequency energy to create a pink, glowing reactive plasma. The reactive particles in the plasma are maintained at 104° F (40° C) and sterilize the heat- and moisture-sensitive load in approximately 1 hour.

No aeration is necessary because the by-product is primarily oxygen and water. The cycle will automatically abort if the sterilant concentration is not adequate. Users must wear PPE if handling items such as items from an aborted load or when changing the sterilant cartridge.

Vapor Phase Sterilizer

A vacuum is created in the chamber for delivery of a cold vapor of hydrogen peroxide at 39° F to 46° F (4° C to 8° C). A vacuum exhausts vapor at the end of the cycle.

Considerations for Hydrogen Peroxide Sterilization

- All items are thoroughly clean, free of organic debris, and dry.
- Items are wrapped in nonwoven polypropylene. Tyvek peel pouches may be used.
- Trays are placed flat on the shelf for penetration. Peel pouches are stood on the side. Nothing should rest on the walls of the chamber.
- The timing of the cycle varies with the process, capacity of the chamber, and contents of the load. The manufacturer's instructions are followed. May take more than 75 minutes to run a load.
- Biologic indicators with endospores of *G. stearothermophilus* with adjusted pH are used to monitor the hydrogen peroxide process daily. Monitoring with each load is preferred.

Ozone Gas Sterilization

Ozone sterilizes by oxidation, a process that destroys organic and inorganic matter. It penetrates the membrane of cells, causing them to explode. Ozone has been used to purify water since the early twentieth century. Ozone is a metastable gas that can be generated easily from oxygen and water at the point of use. No special outlet or water supply is required. No special cartridges or canisters of a chemical are needed. This is a low-temperature method of sterilization that has been in use in industry for more than 100 years.

Safety of ozone gas exposure is measured in PELs. OSHA has set limits as 0.1 ppm per 8-hour period. The PEL is not to exceed 0.3 ppm/15 minutes. Severe pulmonary edema will result at levels of 0.3 ppm exposure for 30 minutes. Personnel using ozone sterilization do not encounter the gas in its intact state. The gas is converted back to water and oxygen at the end of the cycle before the unit can be opened. There is only one setting for all cycles, so the risk for error in operating the machine is minimized. The process takes approximately 1 hour.

The U.S. Food and Drug Administration (FDA) has cleared ozone sterilizers for use on plastic, metal, and some rigid lumens. Cellulose packaging cannot be used. Nonwoven pouches or vented closed container systems are used for instrumentation in ozone sterilizers.

The ozone sterilizer works in four phases over a period of 4.5 hours:

- Cold water vapor is humidified. About 75 mL per load. Oxygen is electrically charged to create ozone ($O_{3)}$). Ozone has a bluish color.
- The water vapor and ozone combine in the chamber. One oxygen atom is released from the O_3 molecule to combine with and deactivate microorganisms.
- The water vapor, ozone, and free oxygen molecule are vented into a catalytic converter that separates out the water and oxygen (H_2O and O_2) for discharge into the drain and room air.

Advantages of Ozone Gas Sterilization

- The sterilizer generates its own agent using hospital-grade oxygen, water, and the electrical supply. It is simple and inexpensive to operate.
- Ozone gas sterilization provides an alternative to EO gas sterilization of many heat- and moisture-sensitive items.
- Ozone gas sterilization does not affect anodized aluminum, titanium, chromium, silicone, neoprene, and Teflon.
- Aeration is not necessary; ozone leaves no residue and converts to oxygen in a short time.
- Low temperature is safer for heat-sensitive instrumentation.

Disadvantages of Ozone Gas Sterilization

- Ozone can be corrosive. It will oxidize steel, iron, brass, bronze, zinc, nickel, and copper.
- It destroys natural rubber, such as latex, natural fibers, and some plastics.
- Not used to sterilize implants or flexible endoscopes at this time.
- Not used to sterilize sealed glass ampules.
- Each cycle takes 4.5 hours.
- Pure ozone damages proteins and fatty acids and is harmful if inhaled in its intact state.

Considerations for Ozone Sterilization

Preparing items, packaging, loading the sterilizer, and timing the cycle are done according to the instructions provided by the manufacturer of the sterilizer. *G. stearothermophilus* biologic indicator process challenge packs are used to monitor the process and are recommended for each cycle.

Chemical Sterilants in Solution

Liquid chemical agents registered as sterilants by the EPA provide an alternative method for sterilizing minimally invasive heat-sensitive items if a gas or plasma sterilizer is not available or the aeration period makes EO gas sterilization impractical. Items processed for patient care are categorized as critical, semicritical, and noncritical according to the Spaulding classification system. Items that enter tissue or the vascular system are considered critical and must be sterile.

Items are sterilized with a liquid sterilant by immersing them in solution for the required time specified by the manufacturer to be sporicidal (i.e., to kill endospores). All chemical solutions have advantages and disadvantages, and each sterilant has specific assets and limitations. (Additional information is available at www.fda.gov.) Policies and procedures should be in place to regulate and guide the use of chemical sterilants in solution. PPE should be worn, and eyewash stations should be conveniently located near the point of use.

Advantages of Chemical Sterilants

- The solution has a low surface tension; it penetrates into crevices and is readily rinsed from items.
- It is noncorrosive, nonstaining, and safe for instruments that can be immersed in a chemical solution.
- It does not damage lenses or cement on lensed endoscopes.
- It is not absorbed by rubber or plastic.
- It has low volatility and is stable for the time specified by the manufacturer.

Disadvantages of Chemical Sterilants

- Prolonged exposure to a chemical sterilant may be necessary for sterilization.
- Some chemical sterilants have hazardous effects associated with exposure.
- Even if a chemical has low toxicity and irritation, items must be thoroughly rinsed in sterile distilled water before use.
- Failure to adequately rinse an endoscope can cause a chemically induced colitis.
- Sterile transfer is difficult, because items are wet.
- Chemically sterilized items cannot be held in long-term sterile storage. They must be processed for immediate use.
- The solution can become diluted during use if an item is wet when placed in it.

Types of Chemical Sterilants

In addition to EPA registration, chemical sterilants are approved by the FDA as a method of sterilization for critical items that are heat sensitive and can be immersed. The manufacturer is responsible for providing processing instructions on the container label, and the user is obligated to follow the instructions. All solutions should be tested before use with an appropriate test strip to validate the concentration of the sterilant. This is the only way to know if the chemical will be effective.

Acetic Acid

Acetic acid mixed with peracetic acid and hydrogen peroxide kills microorganisms by a process of oxidation to denature proteins in a process that takes 5 to 6 hours at a room temperature of 77° F (25° C). The solution is commonly used as a sterilant for dialysis machines. It is biodegradable and leaves no residue.

Glutaraldehyde

According to the FDA, a 2.4%, 2.5%, or 3.4% aqueous solution of activated buffered alkaline glutaraldehyde kills microorganisms by the denaturation of protein in cells. The solution is activated by adding a powdered buffer to the liquid. Alkaline glutaraldehyde solution changes pH and gradually loses its effectiveness after the date of activation. The expiration date specified by the manufacturer is marked on the container when activated (e.g., 14 days for aqueous Cidex–activated dialdehyde solution). The solution is reusable until this date, after which it is discarded according to EPA requirements. In most locales it may be discarded into the sanitary sewer, where it is bioxidized by sewer microorganisms into glutaric acid and then into carbon dioxide and water.

Most manufacturers claim that glutaraldehyde is a sterilant at 10 hours and a high-level disinfectant at 20 to 30 minutes, although the long-life varieties require 90 minutes to attain the same level of disinfection. These solutions are effective at room temperature.

Glutaraldehyde vaporizes rapidly and must remain covered to retain its concentration parameters. The fumes may have a mild odor and can be irritating to the eyes, nose, and throat. OSHA has established an exposure limit of 0.2 ppm in room air averaged over 8 hours. A glutaraldehyde exposure monitor should be worn by personnel who are at risk. Nitrile or butyl rubber or polyethylene gloves are worn to prevent skin sensitivity and contact dermatitis. Double-gloving with latex provides protection. Neoprene and polyvinyl chloride gloves are not protective.

The concentration of glutaraldehyde in solution should be monitored. A test strip or kit of reagents is used for testing the

concentration before and after each use. If the solution has become diluted below 1.5%, it is ineffective and should be discarded.

Peracetic Acid

A proprietary chemical formulation of 35% peracetic acid, hydrogen peroxide, and water inactivates critical microbial cell systems. Peracetic acid is an acetic acid plus an extra oxygen atom that reacts with most cellular components to cause cell death. The mechanism may vary with each type of cell (e.g., vegetative bacterial endospores, mycobacterium). The sterilant is supplied in unit doses for each cycle and is diluted during the sterilization process to 0.2% peracetic acid solution. During the 23-minute sterilization process, the solution is heated to 122° F to 131° F (50° C to 55° C) as it passes through the self-contained processing chamber. All items and internal components of the STERIS unit are submerged in the heated sterilant.

On completion of the sterilizing cycle, the sterilant is discharged into the sanitary drain. The used chemical is not considered a hazardous material by the EPA. The instruments are automatically rinsed in tap water that is passed through ultraviolet light, filtered through two external prefilters and two 0.1-mm internal microfiltration systems. The smallest known bacterium, *Pseudomonas diminuta,* is unable to pass through the pores in this filter system. (This is the same method used by pharmaceutical manufacturers to make sterile injectable medications.)

The STERIS unit uses a standard tap water supply, a sanitary drain, and a 110-V electrical connection. This tabletop unit has a printout to document each cycle. Periodic maintenance includes filter changes based on the chemical components of the external water supply. Biologic monitoring according to the manufacturer's recommendation is performed daily with a commercially prepared endospore strip containing *G. stearothermophilus.*

Hypochlorous Acid

Hypochlorous acid is derived from electrochemical activation of a brine solution. Although technically a high-level disinfectant, it kills many endospores.

Hypochlorous acid is nontoxic and environmentally safe. This chemical is a nonaldehyde oxidation material that kills endospores. No special handling or precautions are required.

Containers for Chemical Sterilant in Solution

A large bin with a perforated inner tray (nested) and lid is used with chemical sterilant solutions at room temperature. With chemical sterilization, items are completely immersed and the lumens filled with sterilant solution. The outside of the bin is labeled with the product name, date of activation, date of expiration, and initials of the person who mixed the solution. The inside of the bin, inner tray, and its lid should be kept sterile throughout the duration of use of that batch of solution. The lid should remain on the bin to prevent evaporation of the solution and to minimize vaporization of the solution. Evaporation changes the concentration of the mix and will alter the sterilant properties.

Preparing Items for Sterilization by Chemical Immersion

Items should be clean and free of organic debris and blood. Items should be washed thoroughly in a nonfilming soapy solution, rinsed, and thoroughly dried before placing them in the chemical sterilant. Lumens should be dried with jets of forced air. The solution will become diluted and lose effectiveness if other solutions such as water are added. No biologic material should be permitted to contaminate the solution.

Timing the Immersion Cycle

The time required for sterilization varies with the sporicidal activity of the chemical agent. The FDA has published a chart with brand names and timetables on the Internet. Below is an example of chemical sterilants and time ranges:

- *Acetic acid:* 20 minutes at 77° F (25° C) in a processing unit
- *Glutaraldehyde:* 10 to 12 hours at 77° F [25° C]; concentrations of 1.12% to 3.4%; specialized processors using glutaraldehyde 2.5% take 7 hours and 40 minutes at 95° F [35° C]
- *Hydrogen peroxide:* 1% to 7.5% (3 to 8 hours at 68° F [20° C])
- *Peracetic acid:* 12 minutes at 122° to 132° F [50° C to 56° C]

A load control record of the items sterilized in solution is kept as for other methods of sterilization (see the sample record in Box 18.1).

Rinsing after Immersion

At the completion of the exposure period, all items are thoroughly rinsed in sterile distilled water before use. This step is automatic with the STERIS unit and other automatic endoscope processors. Sterile gloves are worn to transfer items from the chemical sterilant solution bin to a second sterile bin for rinsing. Items should then be dried with a sterile towel before being transferred to or placed on a sterile field. Items being terminally sterilized should be completely dry before placing in storage. Flexible endoscopes should be hung from a rack so the lumens are in a straight configuration, not coiled.

Radiation Sterilization

Microwave Sterilization

The nonionizing radiation of microwaves produces hyperthermic conditions that disrupt life processes. This heating action affects water molecules and interferes with cell membranes. Microwave sterilization uses low-pressure steam with the nonionizing radiation to produce the localized heat that kills microorganisms. The temperature is lower than conventional steam, and the cycle is faster—as short as 30 seconds. Metal instruments can be sterilized if placed under a partial vacuum in a glass container. Small tabletop units may be useful for rapid sterilization of a single instrument or a small number of instruments. Current models have a small chamber size—1 to 3 ft^3.

Gamma Ray and Beta Particle Sterilization

Some commercially available products are sterilized by irradiation. Ionizing radiation produces ions by knocking electrons out of atoms. These electrons are knocked out so violently that they strike an adjacent atom and either attach themselves to it or dislodge an electron from the second atom. The ionic energy that results becomes converted to thermal and chemical energy. This energy kills microorganisms by disrupting the DNA molecule, thus preventing cellular division and the propagation of biologic life.

The principal sources of ionizing radiation are beta particles and gamma rays. Beta particles are free electrons and are transmitted through a high-voltage electron beam from a linear accelerator. These high-energy free electrons penetrate matter before being stopped by collisions with other atoms. Thus their usefulness

in sterilizing an object is limited by the density and thickness of the object and the energy of the electrons. They produce their effect by ionizing the atoms they hit, producing secondary electrons that in turn produce lethal effects on microorganisms.

Cobalt-60 is a radioactive isotope capable of disintegrating to produce gamma rays and is the most commonly used source for irradiation sterilization. Gamma rays are electromagnetic waves and have the capability of penetrating to a much greater distance than do beta particles before losing their energy from collisions. Because they travel at the speed of light, they must pass through a thickness of several feet before making sufficient collisions to lose all of their energy.

Irradiation sterilization with beta particles or gamma rays is limited to industrial use. Depending on the strength of the source, the product is exposed to radiation for 10 to 20 hours. Ionizing radiation penetrates most materials to sterilize reliably. However, the physical properties of some materials are altered by exposure to ionizing radiation, thus limiting its use. Irradiation can be used to sterilize heat- and moisture-sensitive items because the rays have a very low temperature effect on materials and because the process is dry. Because gamma rays can penetrate large bulky objects, cartons ready for shipment can be sterilized in the cobalt-60 irradiator; this is cost effective for the manufacturer.

Ionizing radiation is the most effective sterilization method. No residual radiation is generated. The process may be monitored with biologic indicators using *Bacillus pumilus.* However, products can be released for use on the basis of dosimetry (measurements of radiation dose) without the quarantine periods required for biologic testing. It is commonly used for commercially prepared single-use, prepackaged disposable items such as drug products, catheters, syringes, IV sets, and gloves.

Control Measures

With the exception of items sterilized in a high-speed pressure flash steam sterilizer for immediate use or by immersion in a chemical solution, all items are wrapped before sterilization. The integrity of the packaging material is maintained before use and during storage. Packages are labeled so the contents are known (unless they are visible through the packaging material). The label also includes the conditions of sterilization. A chemical indicator on the exterior of each package verifies exposure to a sterilization process.

Load Control Number

Whether sterilized onsite or off-site, a load control number should be imprinted on or be part of the label on every package of sterile items. This number designates the sterilization equipment used, the cycle, and the sterilization date. For sterilizers with microcomputer processor printouts, a label gun correlates the same control number for every package put in the load. Load control numbers are used to facilitate the identification and retrieval of supplies, if necessary, in the event of a sterilization failure. A load control number also should be assigned to items immersed in a chemical sterilant.

The sterilization date can be recorded as a Julian date (day 1 through 365) or as a Georgian date (month, day, year). The package may be stamped with the date of sterilization as it is removed from the sterilizer. The date also may be written or affixed on the package when it is wrapped. Monthly, color-coded machine-labeling systems may be used. Peel-off bar code labels also help control inventory and patient charges for items.

Wet Packs

All sterilizing methods in which humidity, usually steam, is a parameter of the process potentially present the hazard of producing **wet packages**. Microorganisms migrate easily through moisture when a pathway is provided from outside to inside a package. Water droplets may be visible on the outside or inside, or absorbed moisture may be seen or felt. Unless the wrapper is completely impermeable to water, a pack should be considered unsterile and unacceptable for use if it is wet. A stain on a wrapper may indicate that moisture was present and has dried. The cause of the wet pack is investigated and promptly corrected. Reprocessing is necessary for a wet package or a load with one or more wet or suspect packages.

Closed container systems with nonvented bottoms may have some retained condensate after processing. This retained moisture within the closed tray is not considered contamination because the container is sealed and impermeable to capillary action. The condensate is considered sterile.

Causes/Conditions of Wet Packs

Excessive moisture may be related to the steam itself, to the load, or to the sterilizer.

Wet Steam

If the steam is abnormally wet, water droplets may form on the outside or inside of packages, and absorbent materials will become soaked with moisture. At the boiling point, water becomes steam. Saturated steam contains as much water in the vapor state as physically possible (98%) and minimal liquid water (2% water droplets). In a steam sterilizer, pressure increases the temperature to raise the boiling point to 250° F (121° C) or above at a pressure of 15 pounds or more above atmospheric pressure at sea level. The temperature of steam does not increase above the boiling point at normal atmospheric pressure in other types of sterilizers. If steam loses water vapor, it can achieve a higher temperature at the same pressure, thus becoming superheated. In steam sterilization, superheating decreases the effectiveness of steam to kill microorganisms.

The dryness (purity) of steam depends on the amount of water in the vapor state in proportion to the amount of solid, liquid, or vapor contamination. This contamination can come from particles in the boiler, steam lines, or sterilizer; chemical additives in the water; or moisture in the load. When steam contacts cold surfaces, a lowering of its temperature reverts steam to water, producing condensation on surfaces and raising the temperature of the remaining vapor, which causes superheating of the steam. Dry, dehydrated textiles and other porous materials will absorb water from steam, which changes the proportion of the water content of steam and causes superheating. The water content of steam should not fall below 97% during the sterilization cycle. Below this level items in the load can become supersaturated with water and subsequent drying will be inadequate.

Characteristics of the Load

Many factors affect the penetration of the sterilant through the load. The following characteristics are reiterated for emphasis:

1. Items are cleaned before they are packaged. Nonporous items must be dry. Porous materials, such as woven fabrics, are hydrated (i.e., humidified) but not wet.
2. Basins are separated by absorbent material and positioned on the side rim so the water condensate will drain out.
3. Heat penetrates different materials at different rates. For even heating of the load, it is preferable not to mix materials. For

example, a load may contain only instrument sets and metals or only packs of fabrics.
4. The density of a pack must allow the circulation of air, moisture, and sterilant within the pack. Porous items should not be wrapped tightly.
5. The permeability of packaging materials varies. A water droplet on an impermeable wrapper may not be a problem, but it can be absorbed by an adjacent package with a permeable wrapper.
6. Because condensation diffuses at different rates, the drying and cooling cycle depends on the materials in the load. Packages should not be handled until this cycle is complete.

Sterilizer Malfunctions

Clogged drains, steam traps, and air filters; inoperable control valves; worn gaskets; and a dirty chamber can cause the sterilizer to malfunction. Routine cleaning and PM techniques are imperative. Malfunctioning equipment requires the recall of the entire load.

Reprocessing Wet Packs

Wet packs are disassembled and the items properly dried and repackaged before resterilization. Reusable woven fabrics should be sent to the laundry and relaundered before use. Damp or wet fabrics will cause superheating during steam sterilization.

Shelf Life

Sterility is event related; it is not time related unless the package contains unstable components such as drugs or chemicals. Storage conditions are established to maintain the integrity of the package. An item is considered sterile on the basis of the following events:

- Handling of the package during transport and storage (i.e., the prevention of contamination and physical damage)
- Integrity, type, and configuration of packaging material
- Conditions of storage

Specific written policies should address the handling and storage of all stored sterile supplies. Expiration dates should be placed on a tray that contains medications or other unstable supplies. Most commercially sterilized products are considered sterile indefinitely or as long as the integrity of the package is maintained. An expiration date put on the label by the manufacturer indicates the maximum time the manufacturer can guarantee product stability and sterility on the basis of test data approved by the FDA.

Integrity of Packaging Material and Handling

The method of sterilization establishes the type of packaging material that may be used. Shelf life is affected by the permeability and density of the material, the type of closure used, and the method by which the package is handled. The following are considerations regarding the integrity of packaging materials:

1. An item is no longer considered sterile after an accidental puncture, tear, or rupture of the package. Paper may become brittle and crack.
2. Squeezing or crushing a package may force air out and draw unsterile air in, thus contaminating the contents. Packages wrapped in woven fabrics should be handled carefully and not packed tightly together for storage.
3. The accidental wetting of a package contaminates the contents. It is necessary to avoid the following:
   a. Handling the package with moist or wet hands
   b. Handling the package with soiled gloves
   c. Placing the package on a wet surface
4. The density of nonwoven fabrics and plastic materials protects the integrity of the package.
5. Heat- or self-sealed pouches protect the contents from dust.
6. Commercially packaged sterilized items are usually considered sterile until the package is opened or damaged or the stability of the product becomes outdated.

Dust Cover

A sealed, airtight plastic bag protects a sterile package from dust, dirt, lint, moisture, and vermin during storage. After sterilization and immediately after aerating or cooling to room temperature, infrequently used items may be sealed in plastic 2 to 3 mil thick. A dust cover will protect the integrity of the package.

Storage Conditions

The maintenance of sterility is related to the event and is not based on time. How sterile packages are handled and stored is as important as how long they can remain sterile. The following guidelines are helpful in maintaining the sterility of a package during storage:

1. Storage areas are clean and free of dust, lint, dirt, and vermin. Routine cleaning procedures are followed for all areas in the perioperative environment. Shipping containers and cardboard boxes should not be brought into the storage room. They can be sources of vermin and dust.
2. All sterile items should be stored under conditions that protect them from the extremes of temperature and humidity. Prolonged storage in a warm environment at high humidity can cause moisture to condense inside packages and thus destroy the microbial barrier of some packaging materials. Ventilating and air-conditioning systems with filtered air should maintain a temperature below 75° F (24° C) and a relative humidity between 20% and 60%. Four air exchanges per hour are recommended by AAMI.
3. Packages should be allowed to cool to room temperature before being put into storage to avoid condensation inside the package.
4. Peel pouches should be stored on their sides to minimize the pressure from items stacked on top of them.
5. For open shelving, the highest shelf should be at least 18 inches (46 cm) below the ceiling or sprinkler heads and 8 to 10 inches (20 to 25 cm) above the floor. Shelving should be at least 2 inches away from the wall. Closed cupboards are preferred.
6. Sterile storage areas should have controlled traffic patterns that do not pass by open shelving storage.

Rotation of Supplies

When the standard number of packages kept sterile is adjusted according to daily needs, packages seldom need to be held for prolonged storage periods. In the interest of economy and good management, a stock supply of day-to-day items should be regulated to have enough for the busiest day, with used items replenished daily.

Many items are seldom used, yet several are kept sterile at all times. These supplies should be sterilized, or commercially sterilized items ordered, only in quantities sufficient to ensure prompt use and rapid **turnover**.

Sterile supplies should be checked daily for the integrity of the packages. Some items deteriorate with repeated sterilization or prolonged storage (e.g., latex items). Any sterile packages that become contaminated are reprocessed and resterilized. Older

supplies always should be used first to minimize storage. The acronym FIFO (first in/first out) is helpful to remember for the rotation of supplies—particularly sterile supplies.

Loaner Instrumentation

Instrumentation brought to the facility by sales representatives should be covered by a specific set of policies and procedures for safe use. When the instruments are brought to the department, they should be inventoried and processed according to the same protocol as any instrument set used in patient care. All loaner sets should be considered contaminated until processed according to the guidelines set forth by facility policy and the manufacturer's recommendations.

The request for a loaner set should be made in enough time to deliver, process, and sterilize the instruments before the scheduled procedure. IUSS should not be used to process these items. Loaner sets should be processed with a class 5 chemical indicator and a biologic indicator, particularly those with implantables (i.e., screws, plates, and joints) appropriate for the method of processing used.

After using the set it should be decontaminated, inventoried, and processed according to policy. Documentation of each step is required. The department could utilize a loaner log that indicates receipt, inventorying, processing, use in the field, decontamination, return to owner, and documentation procedures. The names of personnel receiving, using, and returning the loaner set should be recorded.

Custom Packs

A custom pack is a preassembled collection of disposable supplies sterilized as a single unit. The components are specified by the user (i.e., the OR's specifications) for a particular procedure or specialty or a surgeon's preferences. These components are assembled and sterilized by a custom pack supplier or the manufacturer. A pack assembled by a manufacturer will have an assortment of products in a specific category, such as a kit of sutures, ligating clips, and skin staplers or a custom pack of disposable drapes. Many **custom packs** have approximately 100 diversified items needed for a specific type of surgical procedure, such as a pack for an open-heart procedure. Care should be taken in handling packs because damage to or contamination of a custom pack may waste many sterile items.

The assembler sterilizes packs with either EO gas or gamma radiation. All components of the pack must be compatible with the sterilization method. The assembler must adhere to government manufacturing regulations for testing to guarantee product stability and sterility and package integrity. Using custom packs may be cost effective for the health care facility, and the following indirect savings are shared by the materials management department and the OR:

1. Personnel time (labor costs) for handling supplies is reduced.
   a. It reduces turnover time between procedures by saving time spent gathering and opening supplies. The circulating nurse has more time for direct patient care activities.
   b. It reduces setup time for the scrub person. Items can be prearranged in order of use and with components in proximity, such as suction tubing with a tip.
   c. It facilitates transport of supplies into storage or into a case cart system.
2. Storage space requirements are consolidated by storing supplies in bulk rather than individually.
3. Inventory control is facilitated.
   a. It simplifies listing of items in inventory. The supplier may maintain a computerized information system of usage and inventory levels.
   b. It reduces inventory. A minimal backup of supplies can be maintained.
   c. It reduces lost patient charges. The circulating nurse can process one charge for the custom pack rather than itemizing items.
4. Standardization is encouraged by incorporating the basic items routinely used by surgeon(s) into custom packs. This helps standardize preparations.
5. The infection rate may be decreased. The physical activity of opening supplies can disperse lint and dust into the air. Opening fewer packages decreases this potential environmental hazard.
6. Less environmental waste is generated by packaging material. Fewer disposable wrappers are used.

Many custom pack processors have addressed the problem of changes in surgeons' preferences by offering to supply the packs in small quantities. Changes are incorporated into new stock, thus decreasing the number of pack contents that may not be used. Some manufacturers will replace older or damaged packs for new stock. Evaluation of pack usefulness is ongoing and may change as the types and complexity of surgical procedures change.

Case Cart System

Most facilities use a surgery case cart system to gather and deliver supplies for each surgical procedure. These sterile and nonsterile supplies are selected according to standard routines and the individual surgeon's preferences. For the system to be efficient, good communication must exist among the staff in the OR and the central processing department (CPD). The surgeon's preference data should be current in the computer. Personnel in CPD prepare the case carts with the required supplies and instrument sets according to computerized schedules, preference cards, and case cart pull sheets (Fig. 18.5). Designated clean elevators connect these respective areas in the two departments if they are not located on the same floor.

• **Fig. 18.5** Surgery case cart being loaded for transport to the OR.

The majority of the drapes and disposables will be contained within the custom pack that is on the cart as designated by the facility. This saves time in opening supplies for the case. The items on the cart are patient charge items. Inventory lists that are supplied with the carts may be used for patient charges and inventory control. A bar code or other computer label system may be used to facilitate these functions. Any items not used or opened during the procedure are returned to stock and credited to the patient's account. Some carts are designed to serve as the instrument table during the surgical procedure.

After use, the cart is loaded with the contaminated instrument sets and taken back to the decontamination area. Unopened sterile supplies are not placed on the contaminated cart. They are returned separately. The cart and its contaminated supplies are enclosed during transport to the decontamination area. Usually the decontamination and reprocessing of OR instruments and equipment are done in areas separated from supplies used in other hospital departments. This prevents mixing expensive surgical instruments with those of hospital grade supplied to other units.

The personnel assigned to the surgery case cart areas should be familiar with the supplies needed for each surgical procedure, how surgical instruments are used, and the proper method of cleaning and sterilizing each. Surgical technologists frequently are assigned to sterile processing because of their technical background.

19 Surgical Instrumentation

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify the use and function of each type of surgical instrument.
- Demonstrate the appropriate methods for passing each type of instrument.
- Understand the rationale and methods of decontamination of instrumentation.
- Demonstrate the assembly and passing of sharps.

KEY TERMS AND DEFINITIONS

Alloy A mixture of metals or of substances with metallic properties.
Anodized Dull blackened surface. The instrument is exposed to conditions that cause an oxide coating that is relatively impenetrable to atmospheric oxygen. Instruments can be anodized to reduce reflections. Tints and dyes can be added during the process.
Approximating Bringing edges together.
Atraumatic Without injury.
Crushing Destructive effects of specific instruments. Some procedures require the use of crushing clamps.
Cutting Separating with a sharp instrument or device.
Debulking Decrease in mass or volume using an instrument or device.
Dilation Enlarging an opening in a progressive manner.
Dissection Process of separating tissues through anatomic planes by using sharp or blunt instrumentation.
Evacuating Emptying a cavity or space.
Grasping Holding in a traumatic or atraumatic manner.
Instillation Fluid is slowly introduced into a cavity or space.
Metallurgy The study of metals.
Occlusion Closing a lumen for the purpose of the procedure. The closure can be permanent or temporary.
Percutaneous Enter directly through the skin; without incision.
Retraction Stabilizing a tissue layer in a safe position for exposure of a part. A retractor can be manual or self-retaining.
Sharp Instrument with a cutting edge or pointed tip(s) that is used to cut or dissect tissue. These items include blades, scissors, needles, and other dissection devices.
Traumatic Causing injury by penetration or crushing.
Trocar A device used for penetration of tissue layers. It is commonly used for percutaneous endoscopy. It is used as a temporary pathway for gases, fluids, other instrumentation, or the removal of an organ or substance.

Fabrication of Metal Instruments

Metallurgy is the study of metals and their properties. This science enhanced the development of surgical instruments over the centuries. Although some surgical instruments are made of titanium, cobalt-based **alloy** (Vitallium), or other metals, the vast majority are made of stainless steel. The alloys used must have specific properties to make them resistant to corrosion when exposed to blood and body fluids, cleaning solutions, sterilization, and the atmosphere. The manufacturer chooses the alloy for its durability, functional capacity, and ease of fabrication for the intended purpose.

Stainless Steel

Stainless steel is an alloy of iron, chromium, and carbon. It may also contain nickel, manganese, silicon, molybdenum, sulfur, and other elements to prevent corrosion or add tensile strength. The formulation of the steel plus the heat treatment and finishing processes determine the qualities of the instrument. Chromium in the steel makes it resistant to corrosion. Carbon is necessary to give steel its hardness, but it also reduces the corrosion-resistant effects of chromium. Iron alloys in the 400 series (low in chromium and high in carbon) are most commonly used for the fabrication of surgical instruments.

Steel is milled into blanks that are forged, spun, drawn, die cast, molded, or machined into component shapes and sizes. These components are assembled by hand, then heat-hardened (tempered) and buffed. X-ray and/or fluoroscopy techniques are used to detect any defects that may occur as a result of the forging or machining operations. The stress and tension must be in balance; that is, the instrument must have the flexibility to withstand the stresses of normal use. The temper of the steel determines this balance.

The instrument is then subjected to processes that protect its surfaces and minimize corrosion. Oxidation of the surface chromium by a process called *passivation* forms a hard chromium oxide layer. Nitric acid removes carbon particles and promotes the formation of this surface coating. Polishing creates a smooth surface for the continuous layer of chromium oxide. Passivation continues to form this layer when the instrument is exposed to the atmosphere and oxidizing agents in cleaning solutions. The term *stainless* is a misnomer. Steel does not tarnish, rust, or corrode easily, but some staining and spotting will occur with normal use and prolonged exposure to corrosive agents.

Stainless steel instruments are fabricated with one of three types of finishes before passivation:

1. A mirror finish is shiny and reflects light. This highly polished finish tends to resist surface corrosion, but the glare can be a distraction for the surgeon or an obstruction to visibility.
2. An **anodized** finish, sometimes referred to as a *satin finish,* is dull and nonreflective. Protective coatings of chromium and nickel are deposited electrolytically and reduce glare. This type of finish is somewhat more susceptible to surface corrosion than is a highly polished surface, but the corrosion is usually easily removed.
3. An ebonized finish is dull black, which eliminates glare. The surface is darkened by a process of chemical oxidation. Instruments with an ebony finish are used in laser surgery to prevent beam reflection. In other surgical procedures, instruments with an ebony finish may offer the surgeon better color contrast because they do not reflect the color of tissues.

Titanium

In comparison to stainless steel, the metallurgic properties of titanium alloy developed in 1950 are excellent for the manufacture of microsurgical instruments. Titanium is nonmagnetic and inert. Titanium alloy is harder, stronger, lighter in weight, and more resistant to corrosion than is stainless steel. A blue anodized finish of titanium oxide reduces glare. Titanium can be used in magnetic resonance imaging (MRI) procedures.

Vitallium

Vitallium is the trade name for an alloy of cobalt, chromium, and molybdenum developed in 1937. This inert alloy has the strength and corrosion-resistant properties suitable for some orthopedic devices and dental and maxillofacial implants. Vitallium contains no nickel or beryllium and causes less metal allergy than alloys with these components. Instruments made of Vitallium must be used when these devices are implanted. In an electrolytic environment such as body tissues, metals of different potentials can cause corrosion if they come into contact with each other. Therefore an implant of a cobalt-based alloy is not compatible with instruments that are iron-based alloys (stainless steel) and vice versa. Vitallium implants demonstrate three times the artifact scatter in radiography as titanium.

Other Metals

Although most instruments are made of steel alloys, other metals are used. Some instruments are fabricated from brass, silver, or aluminum. Tungsten carbide is an exceptionally hard metal used for laminating some **cutting** blades or as inserts on the functional tips or jaws of some instruments. Silver and copper are known to have antimicrobial properties. Ancient Egyptians stored water in copper jugs to decontaminate enteric microbes found in river water. Studies have validated microbial destruction in water when stored in copper containers. It has been suggested that the use of copper in the surface of touch pads in health care settings could decrease microbial transfer on high-touch surfaces.

Plated Instruments

A shiny finish can be put on a basic forging or tooling of an iron alloy. Chromium, nickel, cadmium, silver, and copper are used for coating or flash-plating. When deposited directly on the steel, any of these metals is prone to rupturing, chipping, and spontaneous peeling. It is difficult to keep plated instruments from corroding, and rust can form beneath the plating. Plated instruments are used infrequently today.

Classification of Instruments

Various basic maneuvers are common to all surgical procedures. The surgeon dissects, resects, or alters tissues and/or organs to restore or repair bodily functions or body parts. Bleeding must be controlled during the process. Surgical instruments are designed to provide the tools the surgeon needs for each maneuver. Whether they are small or large, short or long, straight or curved, **sharp** or blunt, all instruments can be classified by their function. Because the nomenclature is not standardized, the names of specific instruments must be learned in the clinical practice setting. All instruments should be used only for their intended purpose, and they should not be abused.

Dissecting and Cutting Instruments

Dissection instruments have sharp edges. They are used to cut, incise, separate, or excise tissues. There are two types of dissecting instruments: sharp and blunt.

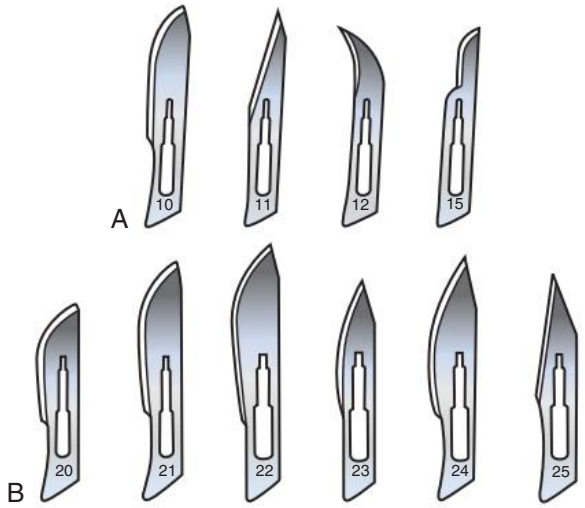
Sharp dissecting instruments should be kept separate from other instruments, and the sharp edges should be protected during cleaning, sterilizing, and storing. Specialized tip protectors may be placed on sharp instruments before the sterilization process and removed before use. To prevent injury to the handler and damage to the sharp edges, proper precautions are necessary to take during the handling or disposing of all sharps, blades, or scalpels.

Blunt dissection instruments are used to push or peel soft tissue away from another surface. Examples are Penfield or Freer elevators used to strip muscle and periosteum from bony surfaces.

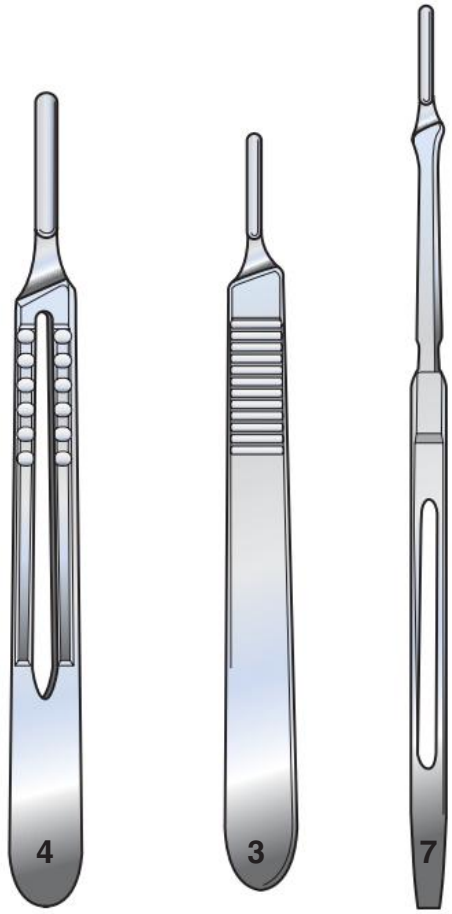
Scalpels

The type of scalpel most commonly used has a reusable handle with a disposable blade. Most handles are made of brass; the blades may be made of carbon steel. Blades vary by size and shape (Fig. 19.1); handles vary by width and length (Fig. 19.2). Blades with a numeric prefix of "1" as in a "10" series (e.g., 10, 11, 12, and 15) fit handle size number 3 or 7. Blades with a numeric prefix of "2" as in "20" series (e.g., 20, 22, or 25) fit handle size number 4. Disposable scalpels also are available, but are not weighted the same as metal handles. Most surgeons prefer reusable metal scalpel handles.

The blade is attached to a reusable handle by slipping the blade into the grooves on the narrow edge of the handle. An instrument, never the fingers, is used to attach and detach the blade;



• **FIG. 19.1** **A,** Disposable blades: Ten series for the no. 3 scalpel. Blade sizes 10, 11, 12, and 15. **B,** Twenty series for the no. 4 scalpel. Blade sizes 20, 21, 22, 23, 24, and 25.



• **FIG. 19.2** Most common scalpels: 4, 3, and 7.

this instrument, usually a heavy hemostat or Kelly clamp, should not touch the cutting edge. Needle holders are not designed to load scalpel blades, and the jaws can become misaligned by excess torque. The following are descriptions of blade and scalpel combinations:

- Number 10 blades are rounded toward the tip and are often used to open the skin.
- Number 11 blades have a linear edge with a sharp tip. Can be used to make the initial skin puncture for tiny deep incisions.
- Number 12 blades have a curved cutting surface like a hook. Commonly used for tonsillectomy.
- Number 15 blades have a short rounded edge for shallow short controlled incisions.
- Number 20 blades are shaped similar to number 10 blades but larger.
- An assortment of blades with angulations and configurations for specific uses, such as a Beaver blade, also are used (Fig. 19.3). These blades insert into a special universal handle that secures by turning a screw-in collar (Fig. 19.4).

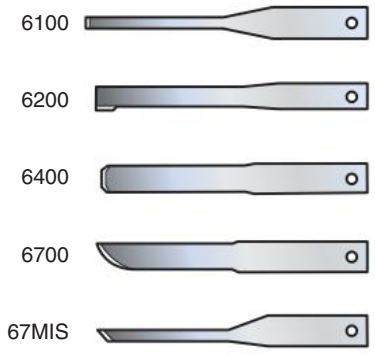
Knives

Knives come in various sizes and configurations. Like a kitchen paring knife, they usually have a blade at one end that may have one or two cutting edges. The knives are designed for very specific purposes (e.g., cataract knife). Other types of knives have detachable and replaceable blades (e.g., dermatome). A knife blade may be incorporated into a multifunctional instrument, such as a gastrointestinal anastomosis (GIA) or end-to-end anastomosis (EEA) stapler that cuts and staples tissue simultaneously.

Scissors

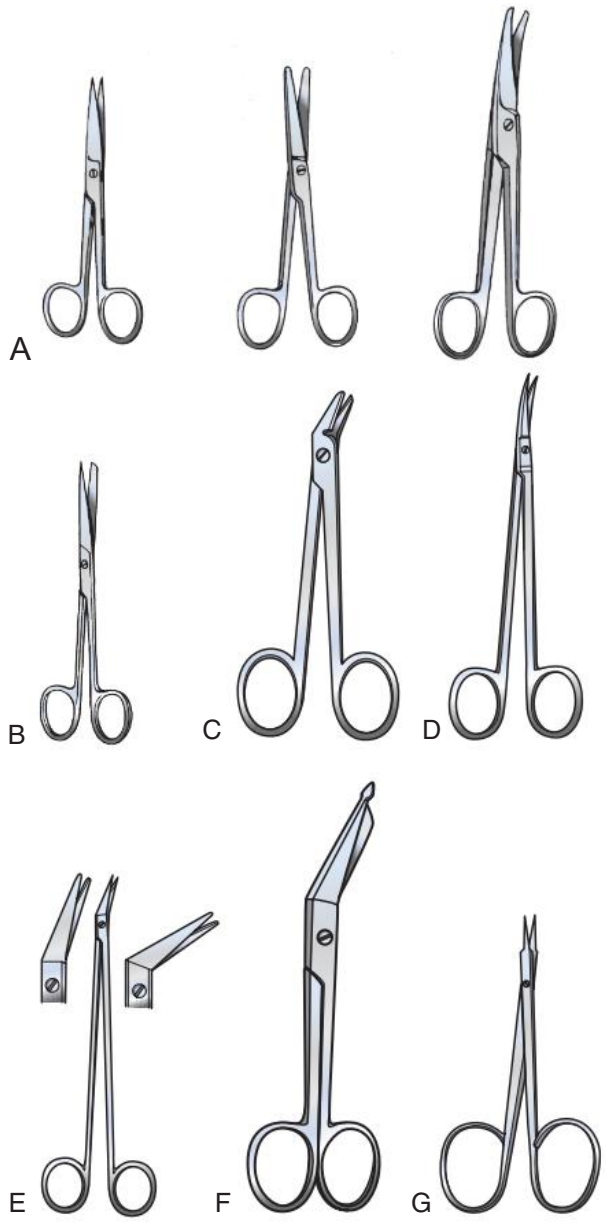
The blades of scissors may be straight, angled, or curved, as well as serrated, wedge-shaped, sharp, blunt, or combined sharp-blunt tips (Fig. 19.5). The handles may be long or short. Some scissors are used only to cut or dissect tissues; others are used to cut other materials. To maintain sharpness of the cutting edges and proper alignment of the blades, scissors should be used only for their intended purpose:

- Tissue/dissecting scissors have sharp or blunt tips. The type and location of tissue to be cut determine which scissors the



• **FIG. 19.3** Beaver scalpel blades.

• **FIG. 19.4** Beaver scalpel handle.



• **FIG. 19.5** Surgical scissors. **A,** Tissue scissors. Blades may be straight or curved, and either tip can be sharp or blunt. **B,** Suture scissors. **C,** Wire suture scissors. **D,** Joseph nasal scissors. **E,** Potts angled scissors. **F,** Lister bandage scissors. **G,** Tenotomy scissors.

surgeon will use. Blades needed to cut tough tissues are heavier than those needed to cut fine, delicate structures. Curved or angled blades are needed to reach under or around structures.

- Tissue scissors with blunt tips can be used to bluntly dissect between individual planes before sharply dissecting. Handles to reach deep into body cavities are longer than those needed for superficial tissues (Fig. 19.5, *A*).
- Suture scissors have sharp-blunt points to prevent structures close to the suture from being cut. The scrub person may use scissors to cut sutures during preparation if needed (Fig. 19.5, *B*).
- Wire scissors have short, heavy serrated blades. Wire scissors are used instead of suture scissors to cut stainless steel sutures (Fig. 19.5, *C*). Heavy wire cutters are used to cut bone fixation wires.
- Short-jaw, sharp-tipped scissors are used for deep, confined areas such as the nasal cavity (Fig. 19.5, *D*).
- Sharp-tipped angled scissors with short jaws are used for vascular surgery[1] (Fig. 19.5, *E*).
- Dressing/bandage scissors are used to cut drains and dressings and to open items such as plastic packets (Fig. 19.5, *F*). The protective tip prevents cutting into concealed structures.
- Small scissors with specially wedge-shaped tips such as tenotomy scissors used for blunt and sharp dissection (Fig. 19.5, *G*)

Bone Cutters and Saws

Many types of instruments have cutting edges suitable for cutting into or through bone and cartilage. Some have moving parts, such as rib cutters. Others, such as drills, saws, and reamers, are powered by air or electricity and have disposable tips and blades.

Blunt Dissectors

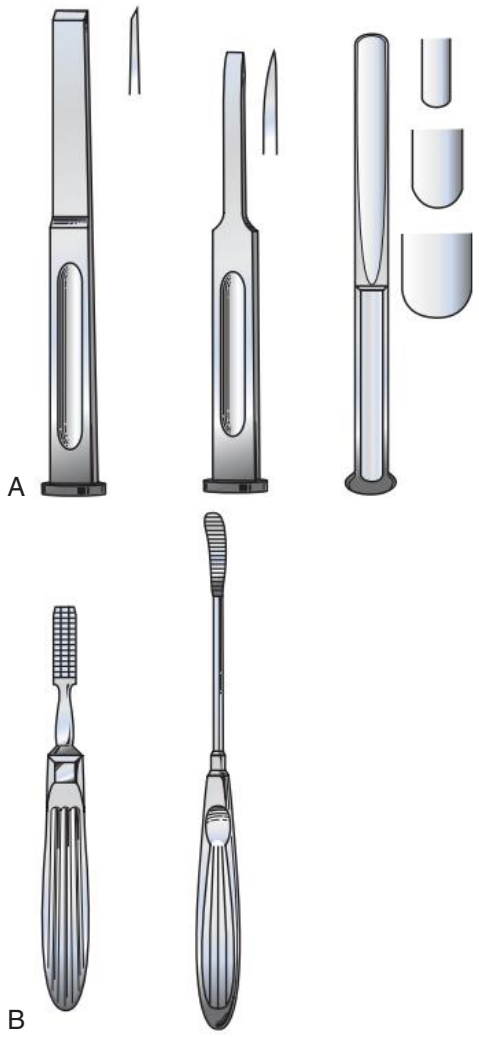
Friable tissues or tissue planes can be separated by blunt dissection. The scalpel handle, the blunt sides of tissue scissors blades, and dissecting sponges may be used for this purpose (Fig. 19.6). Elevators, strippers, and dissectors can be used to remove adherent tissue such as periosteum from bone or dura from the inner aspect of the skull.

Debulking Instruments

Debulking instruments include curettes, chisels, osteotomes, gouges, rasps, and files (Fig. 19.7). The purpose of these instruments is to decrease the bulk of firm tissue and not necessarily cut along defined tissue planes.

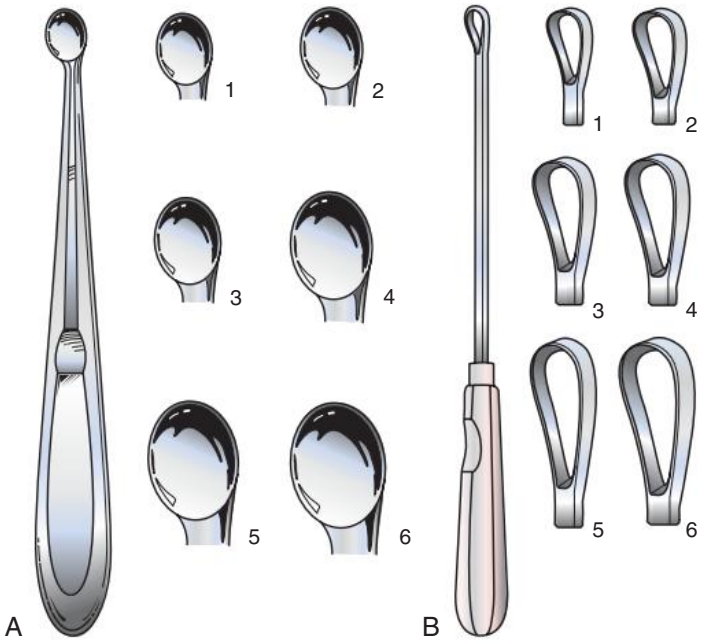
- *Biopsy forceps and punches.* A small piece of tissue for pathologic examination may be removed with a biopsy forceps or punch. These instruments may be used through an endoscope (Fig. 19.8).
- *Curettes.* Soft tissue or bone is removed by scraping with the sharp edge of the loop, ring, or scoop on the end of a curette

• **FIG. 19.6** Blunt dissectors. **A,** Penfield blunt dissectors and tamps. **B,** Periosteal elevators.



• **FIG. 19.7** **A,** Osteotomes. **B,** Rasps.

• **FIG. 19.8** Punch biopsy instrument.



• **FIG. 19.9** Tissue curettes. **A,** Soft and compact tissue curettes. **B,** Uterine curettes.

• **FIG. 19.10** Tonsil snare.

(Fig. 19.9). Blunt curettes are designed to strip away layers without damage to underlying structures. Thomas uterine curettes are blunt and are used for debulking friable postpartum endometrium.

- *Snares.* A loop of wire may be put around a pedicle to dissect tissue such as a tonsil or a polyp. The wire cuts the pedicle as it retracts into the instrument. The wire is discarded and replaced with a new one after use (Fig. 19.10).

Grasping and Holding Instruments

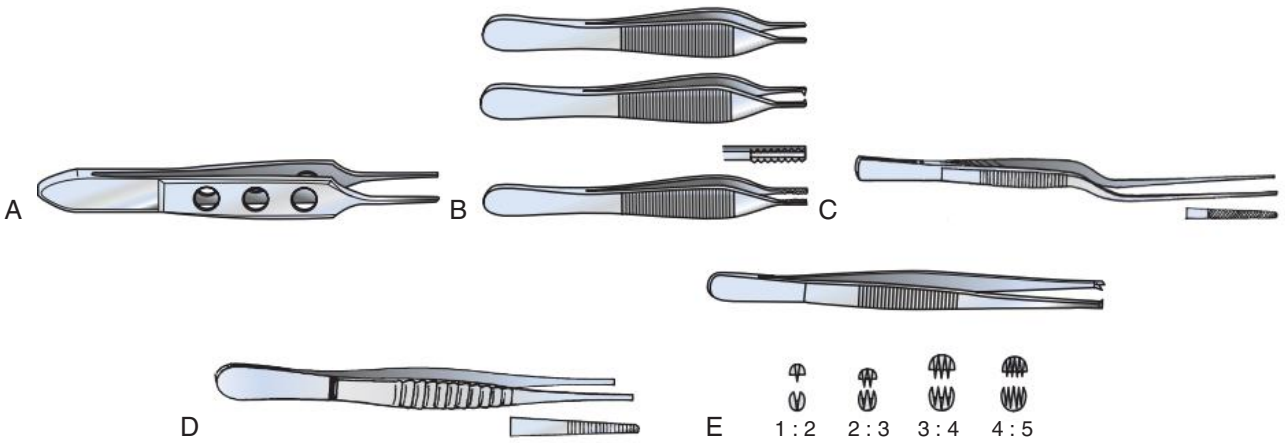
Tissues should be grasped atraumatically and held in position so the surgeon can perform the desired maneuver, such as dissecting or suturing (**approximating**), without injuring the surrounding subcutaneous tissues or perforating the skin (Fig. 19.11). Forceps without ring handles are commonly referred to as *pick-ups.*

Delicate Forceps

Fine tissues such as eye tissue are held with delicate forceps (Fig. 19.11, *A*). They can be toothed or smooth, straight, or angled.

Adson Forceps

Forceps are used to pick up or hold soft tissues in approximation during closure (Fig. 19.11, *B*). They can be toothed or smooth.



• **FIG. 19.11** Tissue forceps. **A,** Bishop eye or forceps. **B,** Adson forceps. **C,** Bayonet forceps. **D,** Smooth forceps. **E,** Forceps with teeth.

Bayonet Forceps

Forceps are angled like a bayonet to prevent the user's hand from occluding vision in a small space (Fig. 19.11, *C*). They can be toothed or smooth.

Smooth Tissue Forceps

Also referred to as *thumb forceps* or *pick-ups,* smooth forceps resemble tweezers. They are tapered and have serrations (grooves) at the tip. They may be straight or bayonet (angled), short or long, and delicate or heavy. Smooth forceps are **atraumatic** and will not injure delicate structures (Fig. 19.11, *D*).

Toothed Tissue Forceps

Toothed forceps differ from smooth forceps at the tip. Rather than being serrated, they have a single tooth on one side that fits between two teeth on the opposing side or they have a row of multiple teeth at the tip. Heavy types are sometimes referred to as *rat-toothed forceps.* Toothed forceps provide a firm hold on tough tissues, including skin. Finer versions have delicate teeth for holding more delicate tissue (Fig. 19.11, *E*). Care is taken not to perforate the epidermis or dermis when holding tissue.

Allis Forceps

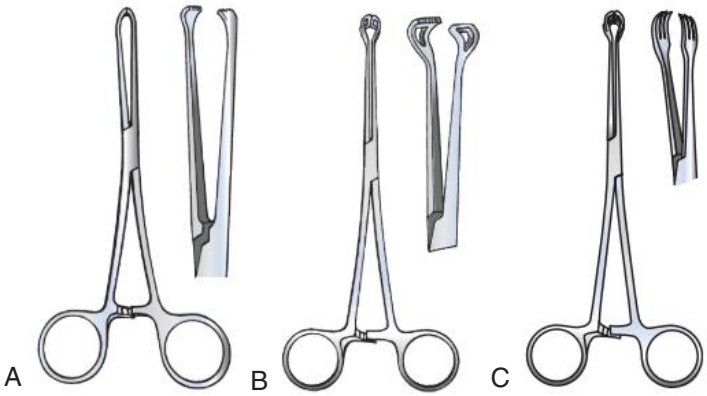
Allis forceps have ringed handles and lock with ratchets. Each jaw curves slightly inward, and there is a row of teeth at the end. The teeth grasp tissue edges securely (Fig. 19.12, *A*). Allis forceps can be short or long. Some of the long forceps have a slight curve, such as those used with a hemorrhoid band ligator.

Babcock Forceps

Babcock forceps have ringed handles and lock with ratchets. The end of each jaw of a Babcock forceps is rounded to fit around a tubular structure (i.e., fallopian tube) or to grasp tissue without injury. This rounded section is circumferentially fenestrated (Fig. 19.12, *B*). Babcock forceps are straight and can be short or long; they are not occlusive or crushing.

Lahey Forceps

Lahey forceps have ringed handles and lock with ratchets. The jaws of the Lahey forceps have sharp apposing points for **grasping** tough organs or tumors during excision (Fig. 19.12, *C*). They are not occlusive or crushing.



• **FIG. 19.12** Ring-handled forceps used for grasping. **A,** Allis forceps. **B,** Babcock forceps. **C,** Lahey forceps.

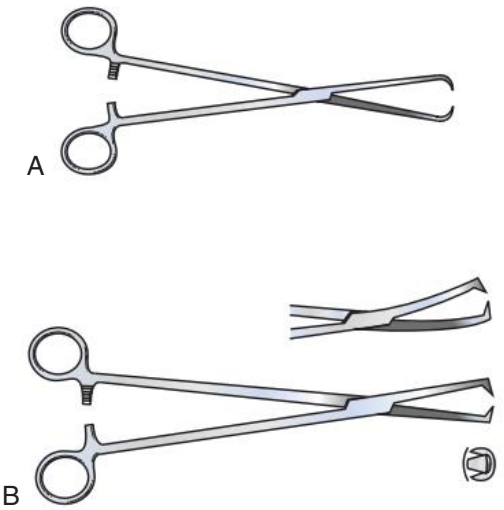
Stone Forceps

Either curved or straight forceps are used to grasp polyps or calculi such as kidney stones or gallstones. Stone forceps have blunt loops or cups at the end of the jaws and do not have ratchets.

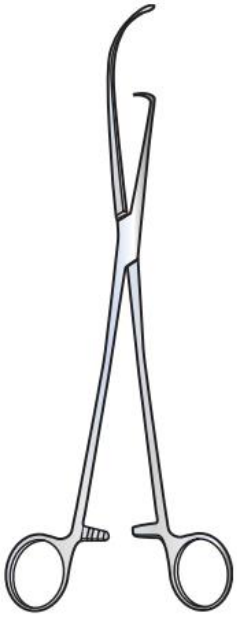
Tenaculums

Tenaculums have ringed handles and lock with ratchets and may have a single tooth or multiple teeth, such as a Jacob tenaculum (Fig. 19.13). The curved or angled points on the ends of the jaws of tenaculums penetrate tissue to grasp firmly, such as when a uterine tenaculum is attached to the cervix and used to manipulate the uterus during laparoscopy.

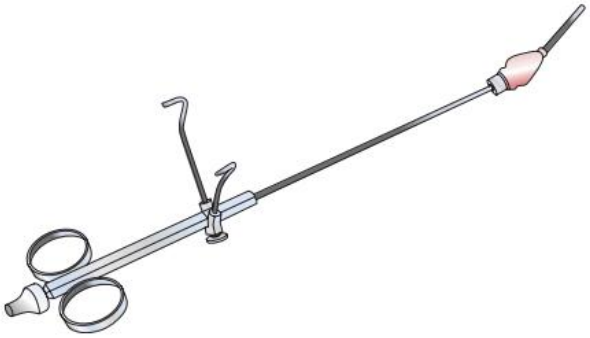
Some uterine tenaculums have a built-in uterine cannula or probe elevator tip, such as a Hulka tenaculum (Fig. 19.14). A uterine cannula, or probe, can be used during laparoscopy to raise the uterus into the visual field (Fig. 19.15). The cannula tip is inserted into the cervical os as the tenaculum is clamped on the anterior aspect of the cervix. Dye or contrast media can be instilled through the cannula into the uterine cavity to visualize tubal patency or the inner configuration of the uterine cavity. Some styles have a tenaculum stabilizer tip attached.



• **FIG. 19.13** Uterine cervix graspers. **A,** Single-tooth uterine tenaculum. **B,** Jacob multitooth uterine tenaculum.



• **FIG. 19.14** Hulka uterine elevator and tenaculum.



• **FIG. 19.15** Kahn uterine cannula and manipulator.

Bone Holders

Grasping forceps, Vice-Grip pliers, and other types of heavy holding forceps stabilize bone (Fig. 19.16). Some styles have ring handles and locking ratchets. Others have compression grips and do not lock.

Clamping and Occluding Instruments

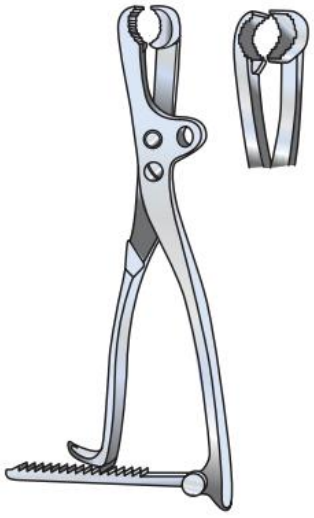
Instruments that clamp and occlude are used to apply pressure. Some clamps are designed to crush the structure as the instrument is applied and are considered **traumatic**. The clamped crushed structure is usually sewn, clipped, or electrocoagulated and then removed. Other clamps are noncrushing (atraumatic) and are used to occlude or secure tissue, which is restored to patency at some point during the surgical procedure.

Hemostatic Clamps

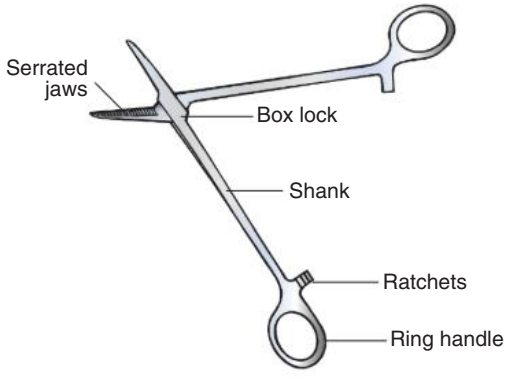
Most clamps used for occluding blood vessels have two opposing jaws (with or without serrations or fine teeth), ringed handles, and lock with ratchets. Most ring-handled clamps have a common design (Fig. 19.17). The length and shape of the shanks or jaws may vary according to the intended function of the instrument.

Hemostats

Hemostats are the most commonly used surgical instruments and are used primarily to clamp blood vessels. They have a **crushing**



• **FIG. 19.16** Lambotte bone holding forceps.



• **FIG. 19.17** Anatomy of a ring-handled clamp.

action. Hemostats have either straight or curved slender jaws that taper to a fine point. The serrations are longitudinal or horizontal inside the jaws (Fig. 19.18).

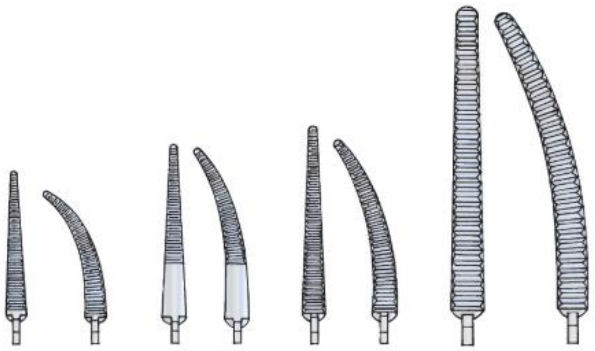
Crushing Clamps

Many variations of hemostatic forceps are used to crush tissues or clamp blood vessels. The jaws may be straight, curved, or angled, and the serrations may be horizontal, diagonal, or longitudinal. The tip may be pointed or rounded or have a tooth along the jaw such as on a Heaney clamp or hysterectomy clamps (Fig. 19.19). The length of the jaws and handles varies. Many forceps are named for the surgeon who designed the style, such as the Kocher and the Ochsner clamps (Fig. 19.20).

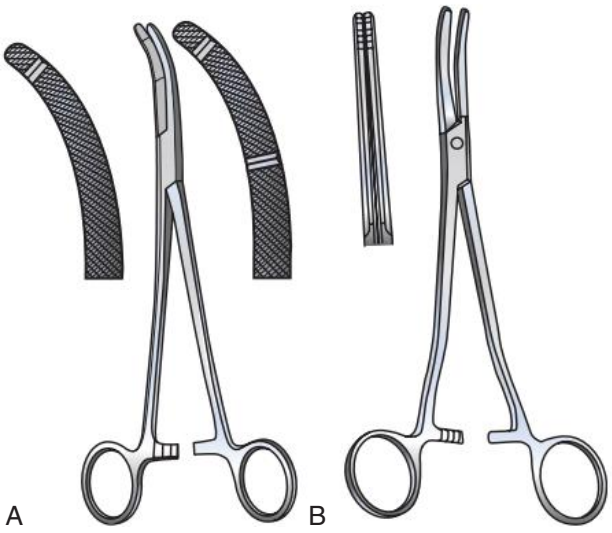
Some instruments are designed to be used on specific organs. The features of the instrument will determine its use. Fine tips are needed for small vessels and structures. Longer and sturdier jaws are needed for larger vessels, dense structures, and thick tissue. Longer shanks are needed to reach structures deep in body cavities. Tissue that has been crushed is usually sutured or stapled.

Noncrushing Clamps

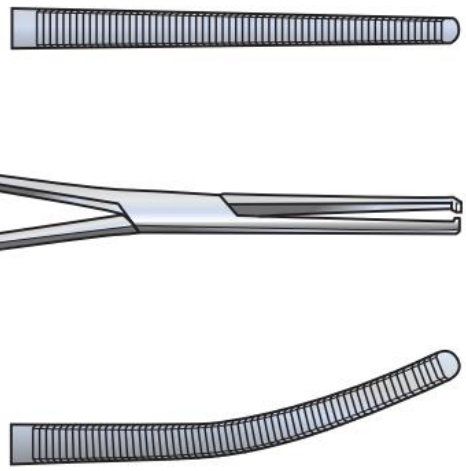
Noncrushing clamps are used to occlude bowel or major blood vessels temporarily, which minimizes tissue trauma. The jaws of these types of clamps have opposing rows of fine serrations, but have a softer hold on tissues. The jaws may be straight, curved, angled, or S-shaped (Fig. 19.21).



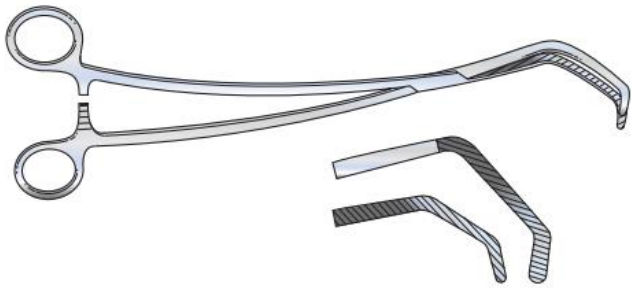
• **FIG. 19.18** Crushing clamps. Jaws may be straight or curved. Tips may be pointed or rounded. Serrations may be horizontal or longitudinal. Jaws and handles may be long or short.



• **FIG. 19.19** Hemostatic uterine clamps. **A,** Heaney clamp with teeth along crosshatched jaw. **B,** Hysterectomy clamp with longitudinal jaw and crosshatched tips.



• **FIG. 19.20** Kocher or Ochsner clamp tips.



• **FIG. 19.21** Noncrushing vascular clamp.

Retracting and Exposing Instruments

Soft tissues, muscles, and other structures should be pulled aside for exposure of the intended surgical site.

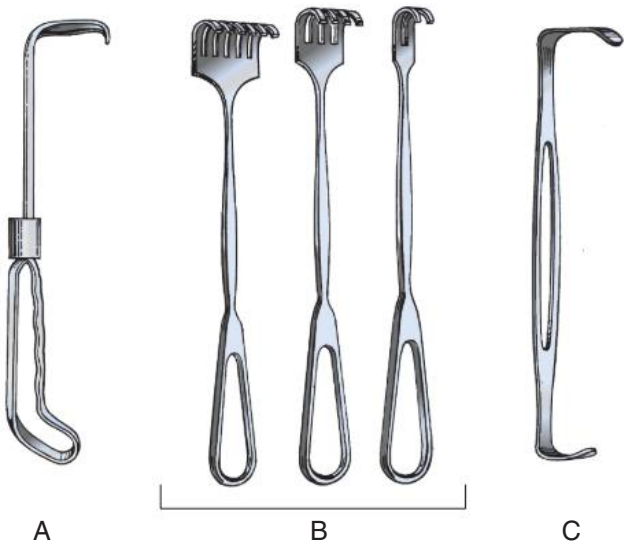
Manual Retractors

Most handheld retractors have an ergonomic handle and blade (Fig. 19.22). The term *blade* should not be confused with *scalpel*. The blades vary in width and length to correspond to the size and depth of the incision. The curved or angled blade may be solid for body wall **retraction** (i.e., Mayo, Richardson, or Kelly retractors), fenestrated like a wire whisk for delicate tissue retraction (i.e., lung retractor), or pronged like a rake for raising tissue edges (i.e., Freeman facelift retractor). The prongs on the blades of a rake can be dull or sharp.

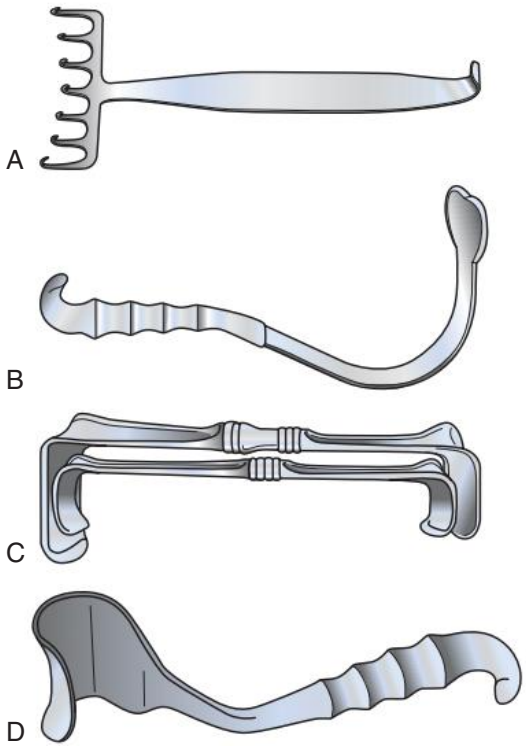
Some retractors have different sized blades at both ends with a handle in the middle (Fig. 19.23). Other retractors have traction grooves or serrations for slippery surfaces such as the tongue (Fig. 19.24). Manual retractors are often used in pairs, and they are held by the first or second assistant.

Malleable Retractors

A malleable retractor is a flat length of low-carbon stainless steel, silver, or silver-plated copper that may be bent to the desired angle and depth for retraction (Fig. 19.25). Referred to as ribbon retractors, they can be found in assorted widths from 1/2 inch to



• **FIG. 19.22** Manual retractors. **A,** Solid blade appendiceal retractor. **B,** Volkmann rake retractors (tips can be sharp or blunt). **C,** Double-ended Army-Navy retractor.

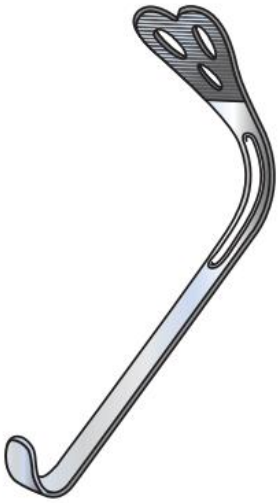


• **FIG. 19.23** Manual specialty retractors. **A,** Freeman facelift retractor. **B,** Harrington Sweetheart liver retractor. **C,** Double-ended Eastman retractor. **D,** Mayo retractor.

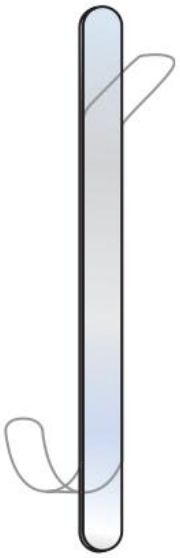
4 inches. Some malleable blades attach into self-retaining or bed-mounted retractors.

Hooks

Single, double, or multiple very fine hooks with sharp points are used to retract delicate structures. Hooks are commonly used to retract skin edges during a wide-flap dissection such as a facelift or mastectomy (Fig. 19.23, *A*). Some styles of hooks have ball tips, which cause less trauma to tissues (Fig. 19.26). Some hook styles have elastic attachments that are mounted into a preformed frame over the incision. Care is taken not to perforate the epidermis or dermis when using a hook retractor. Only the subcutaneous tissue is held back.



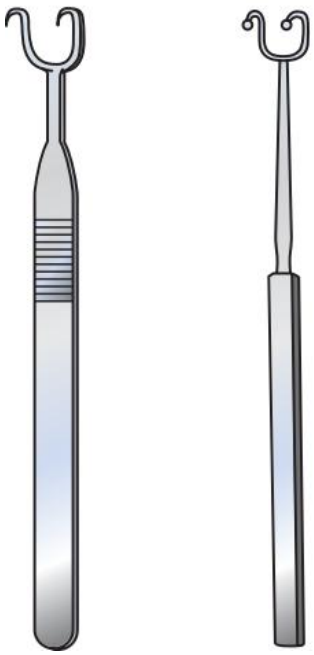
• **FIG. 19.24** Tongue retractor.



• **FIG. 19.25** Malleable "ribbon" retractor bends to the shape of the body part to be retracted. Widths vary.

Self-Retaining Retractors

Holding devices with two or more flat or hooked blades can be inserted to spread the edges of an incision and hold them apart (Fig. 19.27). For example, a rib spreader holds the chest open during a thoracic or cardiac procedure with flat blades. A self-retaining retractor may have shallow or deep blades. Some retractors have ratchets or spring locks to keep the device open; others have wing nuts to secure the blades. Some self-retaining retractors have interchangeable blades of different sizes. Each part of the self-retaining retractor is accounted for at the end of the surgical procedure. Detachable blades or wing nuts can be lost during closure.



• **FIG. 19.26** Double skin hooks depicted as sharp and ball-tipped.

Bed-Mounted Retractors

Some self-retaining retractors can be attached to the operating room (OR) bed for stability when a long surgical incision is planned (Fig. 19.28). A bed-mounted retractor is packaged and sterilized separately in one or two trays because of the numerous blades and attachments. All of the parts are counted items.

The component parts include an assortment of blades, connecting ratchets, a mounting frame for the blades (which can be an assortment of shape and sizes from round to oval), and an upright post that attaches to the side rail of the OR bed at the level of the mattress. The scrub person passes the attaching end of the upright post to the circulating nurse, who securely connects the post to the OR bed frame with a screw-bolt. The attached end touched by the circulating nurse is no longer sterile.

The upright part of the post remains sterile, and the mounting frame is attached by the surgeon at the working height desired. The individual blades and ratchets are placed by the surgeon and the first assistant to attain the exposure needed to perform the surgical procedure. Bed-mounted retractors are useful in preventing fatigue of the team for long procedures. Care is taken to prevent the upright post from resting against the patient's body. Permanent nerve injury can result from prolonged pressure of an immobile post against a nerve during the surgical procedure.

Closure and Approximation Instruments

Suture materials, surgical needles, and surgical staples are discussed in detail in Chapter 28. Only the instruments required for suture or staple placement are mentioned here.

Needle Holders

Most needle holders have ring handles and locking ratchets. They are used to grasp and hold curved surgical needles. Most needle holders resemble hemostatic forceps; the basic difference is the shortness of the jaws (Fig. 19.29). A needle holder has short, sturdy jaws for grasping a needle without damaging it or the suture material. The jaws are usually straight, but they may be curved or angled. The inner surfaces of the jaws also may differ such as crosshatched, serrated, or have a central notch for stability. The size of the needle holder should match the size of the needle (i.e., heavy jaws for large needles and slim jaws for small needles) (Fig. 19.30).

Needle holders can be constructed of various lengths and weights. Heavy snub-nosed needle holders are useful for stainless steel sutures. Long-handled needle holders facilitate needle placement in surgical sites such as the pelvis or chest. Short needle holders are used superficially on the skin or subcuticular tissue.

Specialty needle holders may have spring handles with or without locks. The jaws of the micro needle holders used for ophthalmic surgery and microsurgery may be either diamond-cut or crosshatched. They can be curved, angled, or straight. A needle holder should not be placed on a magnetic pad because it may become magnetized and cause needle release problems when suturing.

Tungsten Carbide Jaws

Tungsten carbide is a hard metal. Jaws with an insert of solid tungsten carbide with diamond-cut precision teeth are designed specifically to eliminate the twisting and turning of the needle in the needle holder (Fig. 19.31). These diamond-jaw needle holders can be identified by the gold plating on the handles.

Crosshatched Jaws

The serrations on the inside surface of the jaws are crisscrossed rather than grooved. Crosshatching provides a smoother surface and prevents damage to the needle.

Smooth Jaws

Some surgeons prefer needle holders that have jaws without serrations. These needle holders are used with small needles, such as those used for plastic surgery.

Staplers

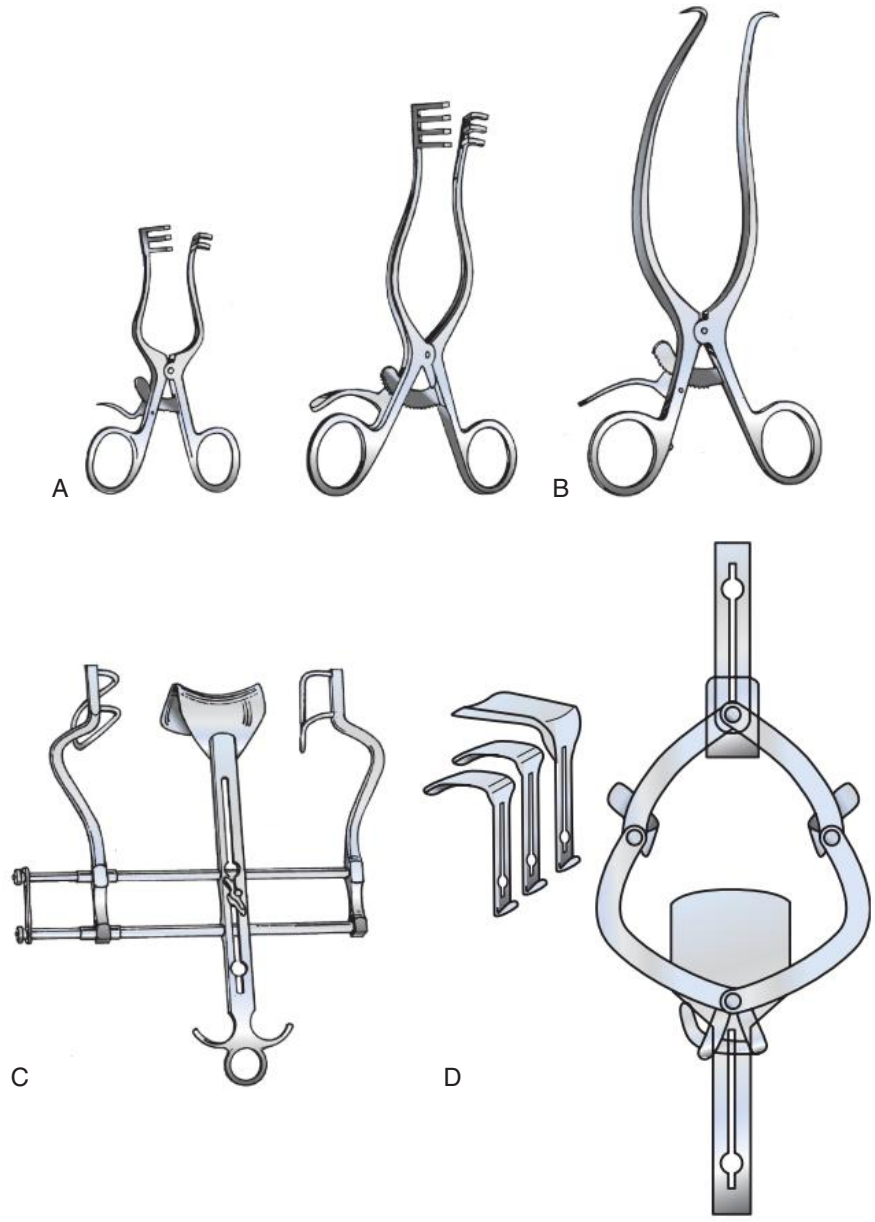
Whether reusable or disposable, all surgical staplers are bulky, heavy instruments. Reusable staplers have many moving parts and are assembled at the sterile field before use. Sterile, single-use disposable staplers that are completely assembled eliminate the many problems associated with reusable instruments. The staples are usually made from titanium, stainless steel, or absorbable material. Staplers are mechanical instruments that should never be flipped to the sterile field. The impact of the stapler when it hits the field can cause misalignment of the preloaded staples, causing a misfire.

Clip Appliers

Individual staples can be placed with a preloaded or single clip applier. These clips are used to mark tissue and occlude vessels or small lumens of tubes (Fig. 19.32). Powered or manual styles are available. Endoscopic clip appliers have been used for many years with laparoscopic tubal **occlusion** for reproductive sterilization. Some varieties can ligate and divide tissue simultaneously, which can expedite removal of large organs from multiple vascular attachments quickly, such as bowel.

Terminal End Staplers

Terminal end staplers are designed for closing the end of a hollow or large organ (e.g., bowel, stomach) with a double staggered line of staples.[2] The stapler is L-shaped and is positioned across the



• **FIG. 19.27** Self-retaining retractors. **A,** Weitlaners. **B,** Gelpi. **C,** Balfour. **D,** O'Sullivan-O'Connor.

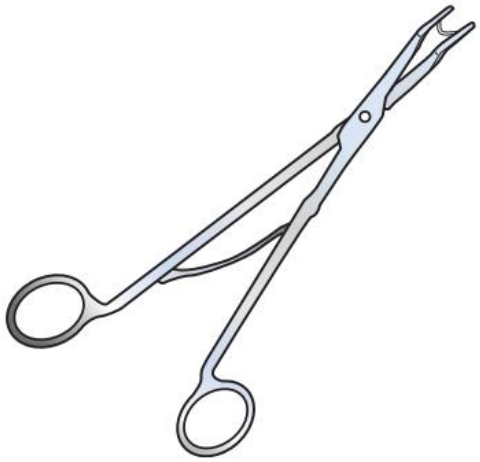
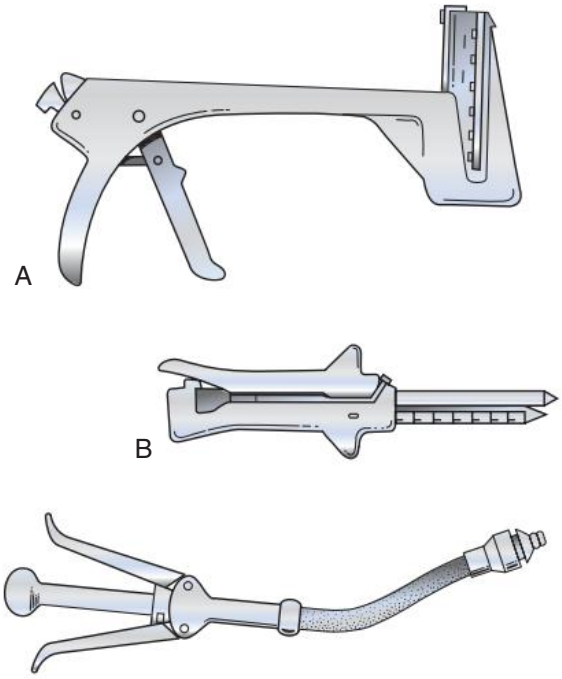
• **FIG. 19.31** Tungsten carbide insert in jaws of needle holder, with diamond-cut teeth, is designed to eliminate needle twisting and turning.

end of the hollow organ to be closed or the tissue to be amputated. A pin is positioned in the stapler head to contain the tissue neatly, and the instrument is closed and fired with a pistol grip handle. A scalpel is used to trim the tissue extruding from the end of the closed instrument. The stapler is opened, and the staple line is inspected for integrity. Some types of terminal end staplers have articulating ends for placement across hard-to-reach areas, such as the vaginal cuff during a hysterectomy (Fig. 19.33, *A*).



• **FIG. 19.32** Clip applier.



• **FIG. 19.33** Internal staplers. **A,** Terminal end stapler. **B,** Internal anastomosis stapler. **C,** End-to-end stapler.

Internal Anastomosis Staplers

Internal anastomosis staplers are designed to connect hollow organ segments to fashion a larger pouch or reservoir.[2] Two tube-shaped organs are aligned side by side, and one fork of the two-forked stapler is positioned in each opening. The instrument is fired, and the tubes are stapled along the adjoining lengths. An internal knife blade cuts between the two sets of double staple lines, creating a longitudinal opening on the inside of the anastomosed organ segments. Intestinal pouches can be fashioned in this manner. Some styles of side-to-side staplers do not have a self-contained knife. Endoscopic styles are available (Fig. 19.33, *B*).

End-to-End Circular Staplers

End-to-end circular staplers are designed to staple two hollow, tubular organs end to end to create a continuous circuit. These staplers are commonly used for bowel anastomosis after resection. The instrument can be inserted via the rectum or inserted through a small incision in the wall of one limb of the tubes to be anastomosed.

The ends of the tubes are positioned over the distal and proximal tips of the stapler and are secured with circumferential purse string sutures. The end of the stapler is closed, with the tissue of the tied ends completely enclosed in the stapler head. When the instrument is fired, a double row of staples is placed in a circle, and a circular knife automatically trims the excess rim from the joined tubes.

When the instrument is opened, the trimmed rims (donuts) are removed from the stapler head and examined for circular integrity. These trimmed rims should be carefully separated and identified as proximal and distal tissue for the pathologist; the margins may be examined for the presence or absence of cancer cells. End-to-end staplers may be curved or straight (Fig. 19.33, *C*).

Viewing Instruments

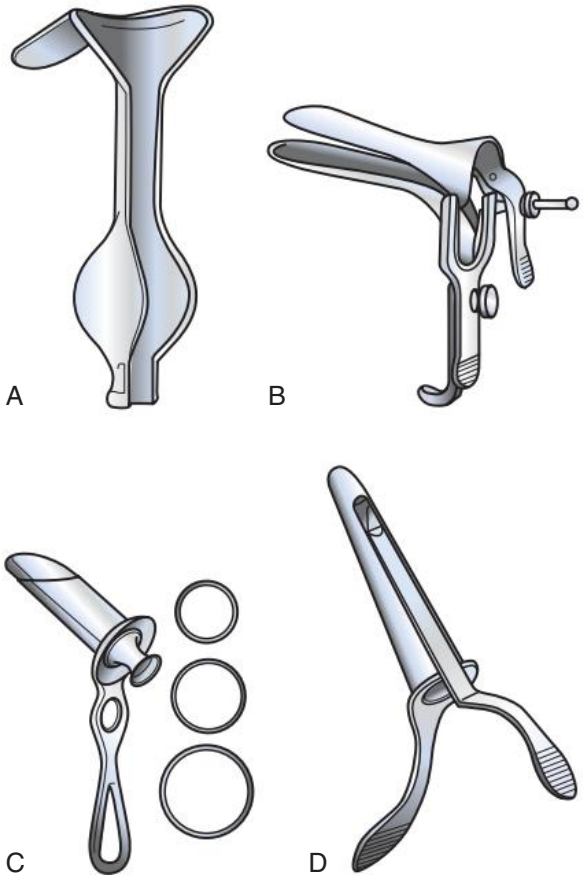
Surgeons can examine the interior of body cavities, hollow organs, or structures with viewing instruments and can perform many procedures through them. Endoscopic telescopes have a fixed lens and attach to an external light source to illuminate the interior aspect. Hollow tubes, such as sigmoidoscopes do not have a fixed lens. A small light pipe with a fiberoptic cable provides lighting through the lumen of the bowel.

Speculums

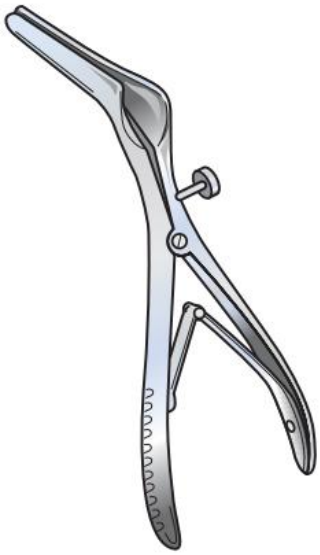
The hinged, blunt blades of a speculum enlarge and hold open a canal (e.g., vagina, rectum [Fig. 19.34]) or a cavity (e.g., nose [Fig. 19.35]). An ear speculum is like a funnel (Fig. 19.36).

Endoscopes

The round or oval sheath of an endoscope is inserted into a body orifice (rigid or flexible) or through a small **percutaneous** skin incision guided by a trocar assembly (rigid). Each type of endoscope is designed for viewing in a specific anatomic location. Many accessory instruments and robotics are used through endoscopes. Endoscopes are illuminated through a separate light source using an electric power source. Care is taken not to allow an illuminated light cable or instrument to rest on the drapes to prevent a potential fire.[3] A discussion of endoscopic and robotic principles is found in Chapter 32 of this text.



• **FIG. 19.34** Speculums and anoscopes. **A,** Auvard vaginal speculum. **B,** Graves vaginal speculum. **C,** Hirschman anoscope. **D,** Brinckerhoff anoscope.



• **FIG. 19.35** Nasal speculum.

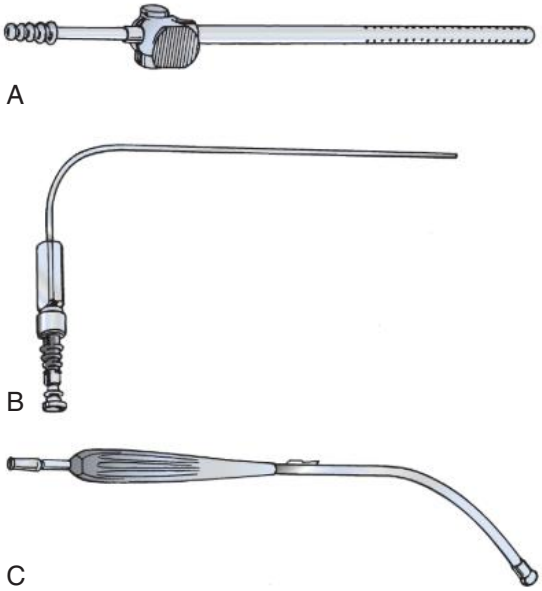
• **FIG. 19.37** Rigid and lensed endoscopes.



• **FIG. 19.38** Tips of suction tubes. **A,** Poole abdominal tip. **B,** Frazier tip. **C,** Yankauer tip.

Hollow Endoscopes

In a hollow endoscope, the rigid hollow sheath permits viewing in a forward direction through the endoscope in a natural body orifice (i.e., bronchoscope, esophagoscope, or sigmoidoscope). The sheath is made of layered polymers, stainless steel, or plastic. A light carrier supplied by a fiberoptic cable provides illumination. A working space is created by manual insufflation of air.

Lensed Endoscopes

Lensed endoscopes have either rigid or flexible sheaths, and they have an eyepiece with a telescopic lens system for viewing in several directions. Some endoscopes have motor driven lenses with optical zoom technology for high-magnification images. Lighting is provided through a fiberoptic cable and an electric light source with extremely bright lamps. Used in combination with video-assisted technology, computerization permits recording action videos and still digital photography. Many flexible endoscopes have working channels for performing specialized procedures such as biopsies. Lensed instruments are complex and require careful handling to avoid damage (Fig. 19.37).

Aspiration, Instillation, and Irrigation Instruments

Blood, body fluids, tissue, and irrigating solution may be removed by mechanical suction or manual aspiration. Reusable suction tips and aspiration devices have lumens that are difficult to terminally clean and sterilize. Most of these items are available in disposable models.

Aspiration

Aspiration, or suction, involves the application of negative pressure (less than atmospheric pressure) for **evacuating** blood or fluids, usually for visibility at the surgical site. An appropriate style tip is attached to sterile tubing; many tips are disposable. The style of the suction tip depends on where it is to be used and the surgeon's preference (Fig. 19.38). Disposable styles are preferred because the inner lumen is difficult to clean.

Blood, body fluid, or tissue may be aspirated manually to obtain a specimen for laboratory examination or to obtain bone marrow for transplantation. Suction is often performed with a needle and syringe.

Poole Abdominal Tip

The Poole abdominal suction tip is a straight hollow tube with a perforated outer filter shield. It is used during abdominal laparotomy or within any cavity in which copious amounts of fluid or pus are encountered. The outer filter shield prevents the adjacent tissues from being pulled into the suction apparatus. This outer shield is completely removable.

Frazier Tip

The Frazier tip is a right-angle tube with a small diameter. It is used when encountering little or no fluid except capillary bleeding and irrigating fluid, such as in brain, spinal, plastic, or orthopedic procedures. The Frazier tip keeps the field dry without the need for sponging. One model has a connection for

an electrosurgical unit, and the tip can be used for fulguration. A fiberoptic cable can be attached to another model. The vacuum exerted by the suction is controlled by a small hole that is covered by the thumb in the handgrip of the Frazier. Disposable right-angled suction tips are supplied with a stylet that can be inserted into the lumen to dislodge tissue or clots that could interfere with the suction quality.

Yankauer Tip

The Yankauer tip is a hollow tube that has an angled shaft and a perforated round-ball tip. This suction tip is also referred to as tonsil suction. Large quantities of blood and fluid can be suctioned quickly with a Yankauer tip, which is useful for visualization during ruptured aneurysms. Reusable Yankauer suction tips may be metal and have a removable end cap that screws in place. This must be accounted for at the end of the procedure. It is easily lost in a patient. Disposable plastic models are constructed in one piece with no removable tip.

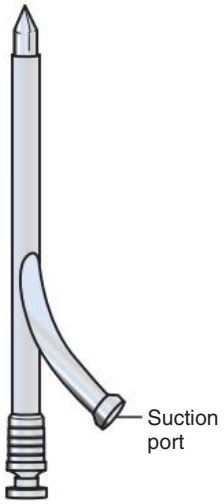
Autotransfusion

A double-lumen suction tip is used to remove blood for autotransfusion. Only blood intended for reuse is suctioned into the autotransfusion machine. Great care is taken not to suction other material into this suction line. Hemostatic material and solutions can cause serious damage to the patient if reinfused into the patient.

Trocar

A trocar assembly may be needed to cut through tissues for access to fluid or a body cavity. A **trocar** has two parts—a sharp obturator and a sheath or a blunt obturator and sheath. The sharp obturator with the sheath is used to perforate the tissues. When the trocar assembly is in place the obturator is removed, leaving the sheath in position and creating a stented tunnel for drainage of fluids, introduction of instrumentation, or **instillation** of medication. Some trocars have suction ports, such as is used for draining the gallbladder (Fig. 19.39).

Endoscopic instruments may be manipulated through special trocars that have valves for insufflation, irrigation, and aspiration. Endoscopy and the eight essentials associated with endoscopic procedures are described in detail in Chapter 32.



• **FIG. 19.39** Ochsner gallbladder trocar.

Cannula

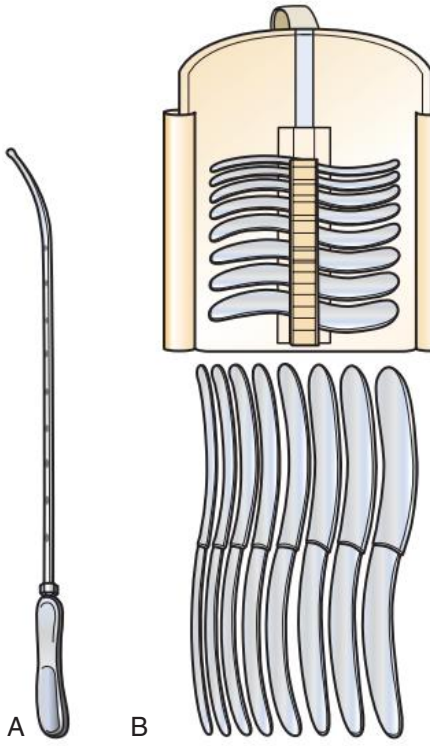
A cannula with a blunt end and perforations around the tip may be used to aspirate fluid without cutting into tissue. Cannulae also are used to open blocked vessels or ducts for drainage or to shunt blood flow from the surgical site.

Dilating and Probing Instruments

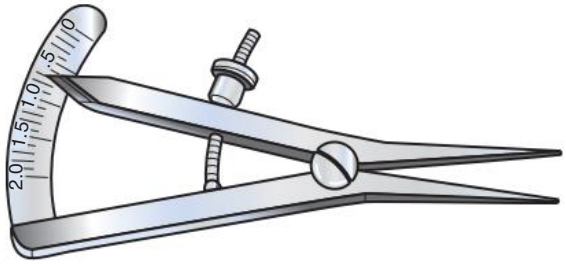
Malleable copper and brass dilators and probes can be plated with chromium or silver. A set of Hank, Hawkins, Pratt, or Hegar dilators are used to dilate the uterine cervix (Fig. 19.40). A probe is used to explore a path in the structure or to locate an obstruction. Probes are used to explore the depth of a wound or trace the path of a fistula. Probes and **dilation** instruments used as tunneling devices can make a passage under the skin for a vascular graft or shunt.

Measuring Instruments

Rulers, depth gauges, templates, and trial sizers are used to measure parts of the patient's body (Fig. 19.41). Some of these devices are used to determine the precise size needed for an implant, such as a joint or breast prosthesis.



• **FIG. 19.40** **A,** Uterine sound. **B,** Hegar uterine dilators.



• **FIG. 19.41** Calipers.

Accessory Instruments

Many accessories are used in addition to the basic instruments previously discussed. For example, a mallet may be needed to drive a cutting instrument into bone (Fig. 19.42).

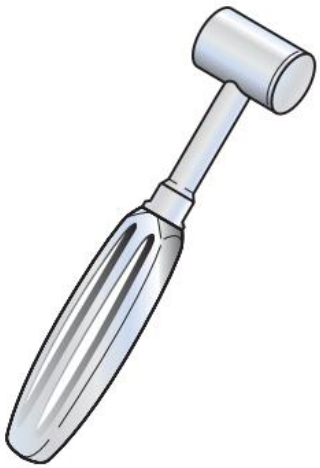
Screwdrivers are used to affix screws into bone. Each surgical specialty has its own accessories, many of which are described in the specialty chapters. One example is the Hudson brace that is used to manually drill through the cranium (Fig. 19.43).

Of the thousands of instruments available, surgeons choose those that are most suitable to meet their particular needs. Differences in the size, curvature, or angulation of jaws or blades; in the length of handles; and in the weight and shape of the instruments can simplify, improve, and even shorten surgical time, which ultimately benefits the patient. Instruments should be maintained to provide the specific function each has been designed to do.

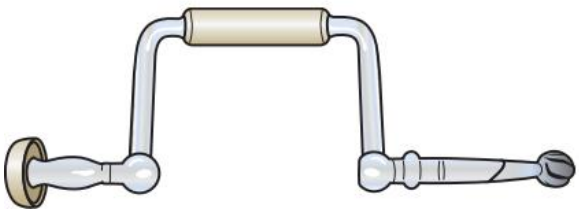
Microinstrumentation

Improved outcomes of surgical intervention using microsurgical techniques are to a great extent the result of the miniaturized precision instrumentation developed in association with the performance of these delicate procedures. The instruments are extremely fine, delicate, and miniature enough to handle in the very small working areas, such as the eye, spine, brain, or other body parts requiring microsurgery. Manipulation becomes more difficult with increased size or bulk and weight.

As with techniques, instruments are constantly being improved. Surgeons work with manufacturers to develop appropriate instruments, suture materials, and needles. Many surgeons purchase the instruments of their choice. Whether owned by the surgeon or the facility, microinstruments require exacting care to maintain desired function.



• **FIG. 19.42** Mallet.



• **FIG. 19.43** Hudson brace for manual drilling into skull.

Instruments are designed to conform to hand movements under the microscope. They must permit secure grasp, ease of holding and manipulation, and fulfillment of their intended purpose. They are shaped to not obscure the limited field of view. Although these factors are important criteria for any instrument, they are especially vital for microinstruments. Everyone assisting in or setting up for microsurgical procedures must know the identification and functions of these unique instruments. Design is coincident to function.

Material and Surface

Microinstruments are made of stainless steel or titanium. Titanium alloy is considerably stronger yet lighter weight than stainless steel. Some microinstruments are malleable for desired angling. Some are disposable. All are extremely vulnerable to abuse.

Finishes of at least the portions of instruments exposed to light in the surgical field are deliberately dulled during manufacture to reduce glare under the microscope, which is both annoying and tiring to the surgeon. Titanium microinstruments have a dull blue finish.

Shape and Tips

Microinstruments are shorter than standard instruments and often are angulated for convenience of approach and avoidance of obstruction of the surgical field.

Instrument tips have minimal separation, which is compatible with their function. Finger pressure and movement necessary to close wide tips are undesirable, because they may induce tremor.

Handles

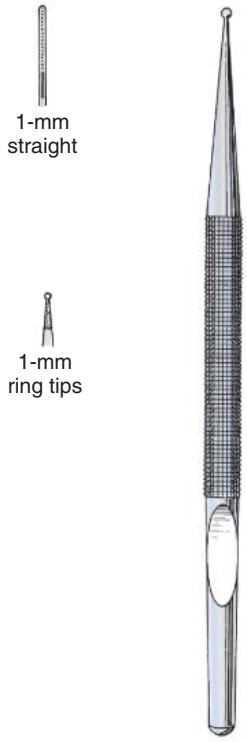
Handles are designed for a secure and comfortable grasp, with a diameter comparable to that of a pen or pencil. Minimal diameter between fingers facilitates feel and accuracy of manipulation. Double-handled instruments (scissors, needle holders) have a slightly larger diameter than single-handled ones (razor knife). The shape of the handle is also important for manipulation. For example, instruments that are rotated between fingers when in use, such as forceps, must be turned easily. Their handles therefore are rounded or have six sides like a pencil (Fig. 19.44). Those that are not rotated have finger grips or are flattened. Ring-handled instruments are not practical in microsurgery.

Many instruments, particularly scissors and some needle holders, have spring handles that return tips to the open position between cutting or grasping functions (Fig. 19.45). The distance from hinge to tip will vary according to function. Proper spring tension can be easily ruined by mishandling.

Handles should be long enough for comfort in the working position but must not extend beyond the working distance to contact the unsterile objective of the microscope. The maximum length of most microinstruments is about 4 inches (100 mm). Gripping surfaces should be functionally located to prevent fingers from slipping during manipulation. These surfaces serve as a guide to accurate finger positioning. The gripping area may have a six-sided, round, knurled, or flat and serrated surface. Tactile sense is important to the procedure so the surgeon does not have to look at the instrument to use it.

Primary Uses

Appropriate instrumentation is used for specific types of procedures. Although all surgical instruments are structured for a definitive use, the function of microinstruments is even more restricted. Tissue can be severely injured by use of an improper or imperfect instrument. Instruments, too, can be damaged by use on inappropriate tissue. Primary use includes cutting (knives, scissors, saws), exposure



• **FIG. 19.44** Microsurgical forceps.

• **FIG. 19.45** Microsurgical instruments with spring handles. **A,** Scissors. **B,** Needle holder.

(spatulas, retractors), gross and fine fixation (forceps, clamps), and suture and needle manipulation (needle holders). Instruments must not be used for manipulations other than the intended purpose.

Knives

Edges of razor, diamond, and dissecting knives have different degrees of sharpness and thickness of blades that are appropriate to the cutting function of each (i.e., to make penetrating or slicing incisions). A clean cut is desired to minimize trauma and tissue destruction. Disposable micro knives are preferred to get a clean sharp cut each procedure.

Scissors

Like knives, scissors are designed to make a specific type of incision related both to the plane and to thickness. Incisions are vertical, horizontal, or of a special configuration, such as curved or two-planed. Use is governed by hinging and blade relationship. Scissors are hinged to cut vertically or obliquely. Cutting is usually done by the distal part of blades for better control. Some scissors come in pairs with right and left curves. Often a part number inscribed by the manufacturer on the handle will be an even number for a right-handed instrument and an odd number for a left-handed one. Blades may be sharp or blunt, long or short, and straight or angulated. Available with straight or curved blades, microsurgical scissors have a spring-type handle (Fig. 19.45, *A*).

Powered Instruments

Microsurgical air-powered drills and saws vary in sizes and shapes. They have a fingertip control; some have an optional foot control. Only the operator of the powered instrument should control a foot pedal to prevent premature activation of the device.

Spatulas and Retractors

Spatulas and retractors are used to draw tissue back for better exposure or protection. Nerve hooks and elevators also are used for these purposes.

Forceps

Straight and curved forceps may be toothed or smooth. They have light spring action and minimal tip separation. Teeth of some tissue forceps may be as small as 1/250 inch (0.03 mm) in diameter. Therefore many tips are barely visible to the unaided eye. Toothed forceps are used for grasping tissue but never for grasping needles or sutures. Smooth forceps are used for tying delicate ligatures and sutures. For stability of grasp and avoidance of injury to the suture strand, the tips of the forceps should be absolutely parallel and have perfect apposition of grasping surfaces. Sutures should be grasped firmly but without trauma, often from a slippery surface. Other smooth forceps are used on friable tissues. Bipolar forceps are used for electrocoagulation.

Clamps

Mosquito hemostats and various clamps are used for vascular occlusion and for approximation of edges of tissues such as nerves and vessels. Crushing of vessels should be avoided.

Needle Holders

Microsurgical needle holders should be used to hold only minute microsurgical needles so as not to alter alignment. Handles are round to permit easy rotation between fingers. Some have spring handles. Although a lock on a needle holder may cause tips to jerk when engaged or released, some have a holding catch for use in deep wounds to prevent loss of small needles (Fig. 19.45, *B*). Needle holders held closed by finger pressure, rather than by a catch, firmly hold a needle shaft yet permit easy adjustment of the needle position. The tips can be curved or straight.

Powered Surgical Instruments

Most surgical instruments have movable parts that are manipulated by the surgeon. Some instruments are pneumatically powered by compressed air or nitrogen or are electrically powered by a battery or alternating current. Powered surgical instruments are complex assemblies of gears, rotating shafts, and seals. They require

special handling during preparation and use and special considerations for cleaning and sterilizing.

Powered instruments are used primarily for precision drilling, cutting, shaping, and beveling bone. They also may be used for skin grafts and to abrade skin. Powered instruments increase speed and decrease the fatigue caused by manually driven drills, saws, and reamers. The instrument may have rotary, reciprocating, or oscillating action. Rotary movement is used to drill holes or insert screws, wires, or pins. Reciprocating movement (a cutting action from front to back) and oscillating movement (a cutting action from side to side) are used to cut or remove bone or skin. Some instruments have a combination of movements and can be changed from one to another by adjusting controls.

Depending on the function desired, the surgeon chooses a drill, burr, blade, reamer, or abrader of appropriate size. These accessories attach securely into the handpiece. Small drill bits, burrs, cutting blades, and abraders may be disposable.

The heat generated by powered instruments can damage bone cells. The site is irrigated during the use of powered equipment. Blood loss from bone is reduced by the tiny particles that these high-speed instruments pack into the cut surfaces. The speed of these instruments may disperse a fine mist of blood and bone cells. For this reason, the Occupational Safety and Health Administration (OSHA), Centers for Disease Control and Prevention (CDC), and American Academy of Orthopaedic Surgeons recommend wearing protective eyewear; a face shield or spacesuit-type headgear should be considered if splatter is anticipated.

Unless the instrument is carefully controlled, tissue can be unintentionally caught in a rapidly spinning drill or oscillating saw or the instrument may cut more than desired. When a powered instrument is being used, particularly one with a rotating movement, all team members must be very careful to keep their hands away from the blade. Most powered instruments have a safety mechanism on the handpiece. Some are operated by foot pedals.

Power Sources

The type of power used by an instrument determines the accessories needed to operate the instrument.

Air-Powered Instruments

Air-powered instruments are small, lightweight, free of vibration, and easy to handle for pinpoint accuracy at high speeds. Compared with electrical instruments, they cause minimal heating of bone because they operate at a faster and higher speed.

In operating air-powered instruments, medical-grade compressed air or pure (99.97%) dry nitrogen is either piped into the OR or supplied from a black cylinder tank on a stable carrier. The pressure must be set and monitored by the operating pressure gauges of the regulator. The correct pounds per square inch (psi), as determined by the manufacturer, is set after the instrument is assembled and turned on. The operating pressure is usually within a range of 70 to 160 psi, and storage pressure in the cylinder is at least 500 psi. Excessive pressure can damage the instrument and the hose that connects it to the regulator. A broken air hose under pressure can whip out of control and injure personnel or the patient.

Electrically Powered Instruments

Electrically powered instruments such as saws, drills, dermatomes, and nerve stimulators are potential explosion hazards in the OR. Most of the motors are designed to be explosion-proof. All must have spark-proof connections.

Because of the heat generated when using electrical instruments, the surgeon usually has the assistant use a bulb syringe to drip saline solution on the area to cool the bone and wash away particles. Care must be taken so the syringe does not touch the blade.

Battery Power

Some battery-operated instruments are cordless and have rechargeable batteries in the handpiece. Rechargeable batteries are placed in a battery charger, which is plugged into an electrical outlet. The batteries are charged, and some can be sterilized for use on the sterile field. Batteries that cannot be sterilized are charged and dropped into a cordless instrument by the circulating nurse using a sterile transfer device provided by the scrub person. The scrub person should not send these batteries for sterilization because they can be damaged.

Alternating Current

Power switches should be off before cords are plugged into electrical outlets. The power supply cord should be connected to the outlet before anesthetic gases are administered and should not be disconnected during anesthesia administration. The anesthesia provider should be alerted that electrical equipment will be used. The scrub person may be able to disconnect the instrument from its power source when it is not in use so a team member cannot inadvertently activate it. Many of these instruments are activated by foot pedals. The circulating nurse can move the foot pedal away from the surgeon until it is needed.

Sonic Energy

Some instruments are activated by sonic energy to move cutting edges in a linear direction. This is a power assist without the rotary motion and high speed of other electrically powered instruments.

Handling Powered Instruments

Before any new or repaired powered instrument is put into use, the biomedical technician should verify that the instrument is functioning according to the manufacturer's specifications. Powered instruments are not without some inherent dangers. Key points in handling powered instruments include the following:

1. Set the instrument and attachments alone on a small sterile table or Mayo stand with the safety switch on when they are not in use. This provides added protection from inadvertent activation.
2. Handle and store the air hose or electrical power cord with care. A broken air hose can whip out of control. A broken electrical cord can short-circuit the instrument. Always inspect the hose and cord for cracks and breaks.
3. To prevent inadvertent activation, assemble the appropriate handpiece, attachments (e.g., blades, drills, reamers), and power source with the safety mechanism in position. Always be certain that attachments are completely seated and locked in the handpiece.
4. Test whether the instrument is in working condition before the surgeon is ready to use it and before it is applied to the patient. To prevent inadvertent activation, the safety mechanism must be set in position until ready to use and when changing attachments.
5. When changing sharp attachments, a sterile towel or sponge may help remove slippery attachments and prevent puncturing gloves.

Cleaning and Sterilizing Powered Instruments

Powered instruments should always be operated, cleaned, and sterilized according to the manufacturer's directions for use and care. Each instrument has different cleaning, lubricating, packaging, and sterilizing requirements because of its various component parts. The bioburden is determined by the size, design, complexity, and condition of the instrument; the degree of contamination during use; and subsequent decontaminating and cleaning procedures. Microorganisms can become entrapped around the seals on rotating shafts. For instruments with a specific biologic challenge, manufacturers test in the area most difficult to sterilize and recommend sterilization cycles accordingly. The following general guidelines apply to the care of all powered instruments:

1. Clean and decontaminate the instrument immediately after use to maintain optimal function.
   a. During the surgical procedure, the scrub person should wipe off any organic debris between uses.
   b. The accessories are disassembled for cleaning. Do not process the powered instrument with a bit, burr, or blade in place. The metal against metal prevents sterilization of the unit. If the blade, burr, or bit needs to be changed during the procedure the exposed unsterile surfaces will contaminate the field.
   c. The air hose should remain attached to the handpiece during cleaning. The air hose and electrical cord should be wiped with detergent, damp cloth, and dry towel.
   d. The motor is not immersed in liquid. The power mechanism cannot be cleaned in a basin of solution or put in a washer-sterilizer, a washer-decontaminator, or an ultrasonic cleaner. The surface of the instrument is wiped with a mild detergent, and caution is used to prevent solution from entering the internal mechanism. The detergent is wiped off with a damp cloth, and the mechanism is dried with a lint-free towel.
2. Lubricate the instrument as recommended by the manufacturer.

Handling Instruments

Surgical instruments are expensive and represent a major investment. Surgical procedures have become more complicated and intricate, and as a result, instruments have become more complex, more precise in design, and more delicate in structure. Abuse, misuse, inadequate cleaning or processing, or rough handling can damage and reduce the life expectancy of even the most durable instrument, and the cost of repair or replacement becomes unnecessarily high. Instruments do deteriorate from normal use, but with proper care an instrument should have a life of 10 years or more.

Setting Up the Instrument Table

Standardized basic sets of sterile instruments are selected for each specific surgical procedure. A set is a group of instruments that may include all appropriate classifications of instruments or the instruments needed for a specific part of the procedure (e.g., a gallbladder set). The surgeon may prefer some specific instruments that are wrapped separately or added to the instrument set.

Instruments are usually prepared, wrapped, and sterilized several hours or days before the surgical procedure so they are dry and cool for safe handling. Instruments are sometimes steam-sterilized immediately before use if there is no other alternative, but this method is not recommended as a routine practice. Key elements of decontamination and processing might be skipped, leaving the instruments unready for sterilization.

The scrub person counts all instruments, sponges, and sharps with the circulating nurse. Some sets will have printed count sheets enclosed. Observe for incidental transfer of toner from the count sheet to the instruments during steam sterilization. Instruments with fused-on toner should not be used in patient care. Essential points in handling instruments before the surgical procedure include the following:

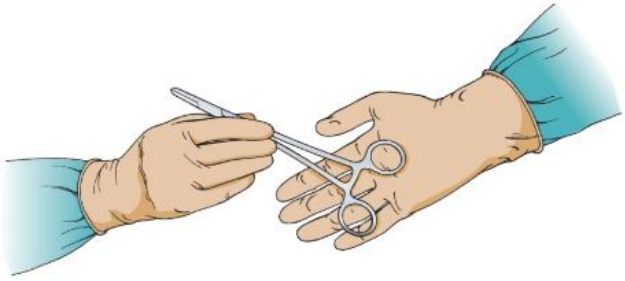
1. Handle loose instruments separately to prevent interlocking or crushing.
   a. Instruments are never piled one on top of another on an instrument table; they are laid side by side on a rolled sterile towel. Close the box locks on the instrument to avoid entanglement when placed on the Mayo stand.
   b. Microsurgical, ophthalmic, and other delicate instruments are vulnerable to damage through rough handling. Tip protectors are removed and discarded during setup.
   c. Metal-to-metal contact should be avoided or minimized. Scalpel blades should not be set in a metal basin. The edges can become dull, and small chips of metal can become dislodged and inadvertently transferred to the patient during irrigation.
2. Inspect instruments such as scissors and forceps for alignment, imperfections, cleanliness, and working condition. Unclean instruments render the entire set contaminated. Remove any malfunctioning instrument from the set. It should be labeled and sent for repair. Replace it in the set with a correctly functioning instrument before processing. If the procedure is in process, the circulating nurse can obtain a sterile replacement and tag the instrument for repair. Be sure to reconcile the count sheet.
   a. Scalpel blades should be properly set in handles using a heavy instrument, not fingers.
   b. Teeth and serrations should align exactly.
   c. Tips should be straight and in alignment.
   d. Scissors should be snug and sharp in action.
   e. Cannulae should be clear and without obstruction. Stylets should be removed.
3. Sort instruments neatly by classifications.
4. Keep ring-handled instruments together with the curvatures and angles pointed in the same direction positioned smallest to largest. Do not permit the instruments to become tangled on the towel roll.
   a. Hang ring handles over a rolled towel or over the edge of the instrument tray or container within the sterile field. Instruments hanging over the back of an instrument tray could be contaminated by someone walking past the table.
   b. Remove instrument stringers or holders if used to keep box locks open during processing.
   c. Close box locks on the first ratchet as the setup progresses.
5. Leave retractors and other heavy instruments in a tray or container, or lay them out on a flat surface of the table. Do not permit any instrument to hang over the edge of the sterile field. Everything on the field should be within 1 inch of the edge and not extend beyond the sterile field.
6. Protect sharp blades, edges, and tips. They should not touch anything. Take care not to perforate the sterile table cover. Place items so they do not get caught on gown sleeves and fall off the table.

a. Sets of instruments, such as osteotomes or microsurgical instruments, may be in sterilization racks so that the blades and tips are suspended. These instruments can remain in racks during the initial table setup and until they are needed during the surgical procedure.
b. Tip-protecting covers or instrument-protecting plastic sleeves should be removed and discarded before the instruments are used on the patient. Most covers and sleeves are not radiopaque and could become a retained foreign body.
c. If they are not in a rack, handles should be supported on a rolled towel or gauze sponge. This keeps the blades and tips of microinstruments suspended in midair for easy visualization.

Handling Instruments during the Surgical Procedure

Efficient instrument handling throughout the surgical procedure is the hallmark of an efficient scrub person. Key points in handling instruments during the surgical procedure include the following:

1. Know the name and appropriate use of each instrument. Using fine instruments for heavy tissue damages the instrument.
2. Handle instruments individually. Tangled instruments are hard to separate in an emergency. Instruments on the Mayo stand should be closed to minimize fumbling for the correct item.
   a. If several instruments of the same type will be needed in rapid succession (e.g., hemostats to clamp subcutaneous vessels), three or four may be picked up at one time, but they are closed and passed individually to the surgeon and/or first assistant.
   b. Instruments with sharp edges and fine tips are more susceptible to damage than are standard instruments. The edges are easily dulled, and the tips are easily bent or broken. Extreme caution is necessary to prevent catching the tips of microinstruments on any object that could bend them.
3. Hand the surgeon or assistant the correct instrument for each particular task. Remember the following principle: Use for the intended purpose only.
   a. Avoid placing fingers in the instrument rings as the instrument is passed. The instrument may inadvertently drop or snag on drapes, causing an untoward injury to the patient or a team member. The instrument may fall to the floor, thus becoming damaged and contaminated.
   b. Many surgeons use hand signals to indicate the type of instrument needed. An understanding of what is taking place at the surgical site makes these signals meaningful.
   c. Select instruments appropriate to the location of the surgical site; short instruments are used for superficial work, and long ones are used for work deep in a body cavity. Experience will facilitate instrument selection according to the surgeon's preference and need.
   d. Many instruments are used in pairs or in sequence. When the surgeon clamps and/or cuts tissue, he or she will usually request suture. To use suture, the surgeon will need to grasp the tissue with a pick-up for stabilization. After using suture, the surgeon or assistant will need scissors to cut or a hemostat to hold the end of the strand as a tag.
   e. Hand instruments around the incisional area, not directly over it, to prevent possible injury.
   f. Knowledge of anatomy is useful for determining which instrument is needed.
4. Pass instruments decisively and firmly. When the surgeon extends his or her hand, the instrument should be placed firmly into his or her palm in the proper position for use. In general, when passing a curved instrument, the curve of the instrument aligns with the direction of the curve of the surgeon's hand. The following points should be remembered when passing an instrument to the surgeon:
   a. If the surgeon is on the opposite side of the OR bed, pass across right hand to right hand (or with the left hand to a left-handed surgeon). The curve of the instrument should match the curve of the surgeon's hand.
   b. If the surgeon or assistant is on the same side of the OR bed and to the right, pass with your left hand; if the surgeon or assistant is to your left, pass with your right hand.
   c. Ring-handled instruments are held near the box lock by the scrub person and passed by rotating the wrist clockwise to place the handle directly into the surgeon's waiting hand (Fig. 19.46).
   d. Clip appliers are held between the fingers by the hinged joint during loading and passing. Placing fingers in the rings may cause the clip to be discharged unintentionally. The loaded applier is passed so the rings automatically pass over the surgeon's finger in a position of function for rapid use.
   e. Sharp and delicate instruments may be placed on a flat surface for the surgeon to pick up (e.g., "no touch zone"). This technique avoids potential contact with items such as cutting blades, sharp points, and needles in hand-to-hand transfer. Always protect the hands when manipulating sharp instruments. Some surgeons prefer to have all instruments passed directly, so great care is taken to place the instrument in the waiting hand without causing the surgeon to look up away from the field. This is common in microsurgery.
5. Watch the sterile field for loose instruments. After use, wipe the blood from the surface and place them promptly on the Mayo stand or instrument table in a position of function. The weight of instruments can injure the patient or cause postoperative discomfort. Keeping instruments off the field also decreases the possibility of their falling to the floor.
6. With a moist sponge, wipe blood and organic debris from instruments promptly after each use. This is referred to as point-of-use cleaning.
   a. Demineralized, sterile distilled water should be used to wipe instruments. Saline, blood, and other solutions can damage surfaces, causing corrosion and, ultimately, pitting.



• **FIG. 19.46** Passing an instrument. Tip is visible; hand is free. Handle is placed directly into waiting hand. Avoid placing fingers in the rings as the instrument is passed.

   b. Blood and debris that are allowed to dry on surfaces, in box locks, and in crevices increase the bioburden that could be carried into the surgical site. Dried material is harder to remove during processing.
   c. A nonfibrous sponge should be used to wipe off microsurgical, ophthalmic, and other delicate tips. This type of sponge prevents the snagging and breaking of delicate tips, and the potential for lint is decreased. Commercial microsurgical instrument wipes are available.
7. Flush the suction tip and tubing with sterile distilled water periodically to keep the lumens patent. Use only a few milliliters of solution if using irrigating fluids from the surgical field. Keep a tally of the amount used to clear the suction line, and deduct this amount from the total used to irrigate the surgical site. Accurate accounting of the solutions used for patient irrigation is necessary when determining the amount of blood lost during the surgical procedure.
8. Remove debris from electrosurgical unit (ESU) tips to ensure electrical contact. Disposable abrasive tip cleaners are helpful for maintaining the conductivity and effectiveness of the surface of the tip. Do not use an abrasive tip cleaner on Teflon-coated ESU tips. Avoid using a scalpel blade to clean electrosurgical tips, because the debris may become airborne and contaminate the surgical field.
9. Place used instruments that will not be needed again (except sharp, cutting, delicate, or powered instruments) into a tray or basin during or at the end of the surgical procedure.
   a. Blood and gross debris are removed at the point of use before actual cleaning and decontamination in the processing area.
   b. Carelessly dropping, tossing, or throwing instruments into a basin causes damage.
   c. Instruments that have been wiped can be immersed in a basin of sterile demineralized distilled water, not saline solution. The sodium chloride in saline solution and in blood is corrosive and can damage instrument surfaces. Bloody instruments should not soak in a basin of solution for a prolonged period.
   d. Heavy instruments such as retractors should not be placed on top of tissue and hemostatic forceps and other clamps. Place them in a separate tray.
   e. Reusable sharps should be kept separate from other instruments of the same or similar size to prevent injury to instrument processing personnel.
   f. Keep instruments accessible for final counts.

Dismantling the Instrument Table

The scrub person breaks down the instrument table at the end of the surgical procedure while wearing the gown and full personal protective equipment (PPE). This process may be delayed and the scrub person and instrument table maintained as sterile for a short time if the patient is in critical condition. The breakdown should not be started until a critical patient is out of the OR and admitted to the postanesthesia care unit (PACU). Some examples of when to wait before breakdown include cardiac, vascular, some neuro, multiple trauma, or other procedure or patient condition that could precipitate expedient return to the OR for immediate surgical reopening.

When the scrub person is assured that the patient will not return to the OR, the table breakdown can begin. Whether used or unused, all instruments on the instrument table are considered contaminated and must be promptly and properly decontaminated/cleaned, inspected, terminally sterilized, and prepared for subsequent use. Wearing gloves, a gown, a mask, and protective eyewear, the scrub person prepares instruments for the cleaning process. Instruments are cleaned in a designated instrument processing area, not in the OR. Key points in handling instruments when dismantling the instrument table include the following[4]:

1. Check drapes, towels, and table covers to be sure that instruments do not go to the laundry or into the trash. A final quick count is a safeguard.
2. Collect instruments from the Mayo stand and any other small tables, and collect those that may have been dropped or passed off the sterile field.
3. Separate delicate, small instruments and those with sharp or semisharp edges for special handling.
4. Disassemble all instruments with removable parts to expose all surfaces for cleaning.
5. Open all hinged instruments to expose box locks and serrations.
6. Separate instruments of dissimilar metals. Instruments of each type of metal should be cleaned separately to prevent electrolytic deposition of other metals.
7. Flush cold, distilled water through hollow instruments or channels, such as suction tips or endoscopes, to prevent organic debris from drying.
8. Rinse off blood and debris with demineralized distilled water or an enzymatic detergent solution.
9. Follow the procedures for preparing each instrument for decontamination or terminal sterilization. Procedures vary depending on the type of instrument and its components and on the equipment available and its location.
   a. Some air-powered instruments can be lubricated with a sterile lubricant after sterilization and just before use.
   b. Some manufacturers supply lubricant (usually a silicone-based oil).
   c. Some instruments must be run after lubrication to disperse the lubricant through the mechanism.
10. Wrap the instrument for sterilization.
   a. Most manufacturers supply sterilizing cases for powered equipment. These cases can be wrapped in woven or nonwoven material.
   b. The instrument must be disassembled.
   c. The sharp edges of accessories must be protected.
   d. Hoses or cords should be loosely coiled.
11. Sterilize the instrument in steam unless contraindicated by the manufacturer.
   a. A prevacuum sterilizer removes entrapped air and allows steam to access the internal mechanism; this type of sterilizer is therefore preferred to a gravity displacement sterilizer.
   b. Exposure time depends on the type of sterilizer, the design and complexity of the instrument, and packaging. In a gravity displacement sterilizer at 250° F (121° C), exposure time may be as long as 1 hour.
   c. Sterilization of an unwrapped instrument in a gravity displacement sterilizer at 270° F (132° C) must provide exposure that is long enough to sterilize the internal mechanism (usually at least 15 minutes).
   d. Ethylene oxide gas sterilization should be used only if the instrument cannot withstand the heat or moisture of steam sterilization. The instrument must be free of all traces of lubricant. The manufacturer should specify the aeration time.

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Distinguish between monopolar and bipolar electrosurgical units and applications.
- List the basic elements of electrosurgical safety.
- Identify three basic types of lasers.
- Describe the tissue effects of the different types of laser light in vivo.
- Identify potential safety hazards associated with high technology in patient care.

KEY TERMS AND DEFINITIONS

Active electrode Apparatus used to deliver electric current to the surgical site.

Beam splitter Attachment to the microscope that splits light; one part is reflected laterally, and the other part is relayed upward to the binocular tube; the percentage can be 50/50 or 30/70. The greater portion may be directed to a camera or video system.

Binocular Using two eyes to see in stereoscopic vision.

Bipolar electrosurgery Current is delivered to the surgical site and returned to the generator by forceps. One side of the forceps is active; the other side is inactive. The current passes only between the tips of the forceps.

Blended current Current that divides tissue and controls some bleeding.

Coaxial illumination The light path follows the same direction as the visual image.

Coagulating current Current that passes intense heat through the active electrode used to sear vessels and control bleeding.

Contraves stand Series of weights used to balance some microscopes.

Current Flow of electrical energy.

Cutting current Current that arcs between tissue and the active electrode to divide tissue without coagulation.

Depth of field Distance of focus.

Diopter Power of the lens to assist vision by refractive correction of reflected light.

Electrosurgical unit (ESU) Generator, foot pedal, cords, active electrode, and inactive dispersive return electrode designed to safely deliver electric current through tissue.

Emissions Surgical lasers emit nonionizing radiation, heat, and debris.

Focal length Distance between the lens and the object in focus.

Generator Machine that produces electric current by generating high-frequency radiowaves.

Ground Conducting connection among the generator, the patient, and the earth.

Inactive dispersive return electrode Apparatus used to return current from the patient back to the generator; also referred to as inactive electrode, return electrode, or patient plate.

Laser Acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation. Light, concentrated and focused, stimulates atoms to emit radiant energy when activated.

Laser beam Light beams, either pulsed or continuous, go through a medium to produce a lasing effect. The beam has three distinct characteristics: coherent, collimated, and monochromatic. Coherent light beams are sustained over space and time because electromagnetic waves are in the same frequency and energy phase with each other. Collimated light beams are parallel. Monochromatic refers to a light beam being one color because waves are all the same length in the electromagnetic spectrum.

Laser plume Carbonized cell fragments, toxic hydrocarbons, viruses, and noxious fumes can be dispersed from tissues exposed to the laser beam. Vaporization converts solid tissue to smoke and gas. This plume (smoke) is evacuated to maintain visibility and also to minimize the hazard of inhalation by personnel.

Medium Gases, synthetic crystals, glass rods, liquid dyes, free electrons, and semiconductors are used to produce the lasing effect.

Microscope Equipment that uses a series of lenses to magnify very small objects.

Monocular Using one eye for vision. Depth of field is absent; the image is two-dimensional.

Monopolar electrosurgery Current flows from the generator to the active electrode, through the patient to the inactive dispersive return electrode, and returns to the generator.

Objective Power of the lens that determines the focal distance of vision.

Ocular Eyepiece lens that multiplies the basic magnification of the microscope.
Power All lasers have a combination of duration, intensity, and output of radiation when wavelengths are activated.
Pupillary distance Measurement between the pupils of the eyes; used to position the binocular eyepieces.
Source Power to energize the light beam; this may be electrical, radiofrequency, or optical.
Stereopsis Vision with two eyes that enables objects to appear three-dimensional.
Wavelength Electromagnetic waves transfer energy progressively from point to point through a medium. The wavelength is the distance traveled along the electromagnetic spectrum. Radiation penetration differs at different wavelengths. Each laser has a different wavelength and color, depending on the medium the light beam passes through.
Working distance Physical space between the objective lens of the microscope and the surgical field.
Zoom To change the range of focus in continuous magnification; the change can be closer or more distant.

Using Specialized Equipment in Surgery

Advances in technology have made possible the complex surgical techniques of the present. Technology may be defined as the branch of knowledge that deals with the creation and use of technical means for scientific purposes. In the context of surgery, *technology* refers to a system that uses devices as well as people to perform specific tasks. Continuing research will further enhance technology. New devices are usually adjuncts to or extensions of devices or techniques already in use. To enhance the use of new devices in patient care, perioperative team members constantly need to learn about new equipment and its applications.

The focus of technology used in patient care is improvement of care beyond human capability. Users of multiple technologic devices in the operating room (OR) need to be acutely aware of safety. One aspect of safety in this environment is paying attention to the patient as a physical being as well as to the devices used in care. Equipment used in concert with patient care includes, but is not limited to, the following:

- Anesthesia machine
- Defibrillators
- Monitors
- Sterilizing machinery
- Warming and cooling devices
- Surgical headlights
- Pressurized fluid delivery systems

Before handling new equipment, patient care personnel on the perioperative team should be knowledgeable about its care and use. Some surgical procedures use more than one of these technologies (e.g., laser surgery through an attachment to the operating **microscope**).

Preparing and handling these expensive pieces of equipment are major responsibilities of perioperative nurses and surgical technologists. In addition, all OR personnel should be aware of and safeguard against hazards associated with equipment. The perioperative environment should be safe for patients and personnel.

The following are safety points to consider when using equipment in the OR:

- Has the equipment been serviced on a routine schedule?
- Has the equipment had calibration testing?
- Has the equipment been cleaned or processed to the degree of safety for patient use?
- Are the cords and attachments connected properly?
- Are foot pedals in a secure position for safe use?
- Are reusable components in serviceable condition?
- Are disposable components in stock in the appropriate sizes?
- Are adjunct devices and machines in proper working order?
- Are alarms in working order?
- Are power **sources** available?
- Is the team knowledgeable about the correct sequence for powering up and using the equipment?
- Have policies and procedures for equipment use been developed and provided to the OR team?
- Has the OR team had formal training on the new equipment?

All equipment in the OR has an individual asset tag number. The asset number is a combination of alphanumeric figures used to identify the particular unit. When documenting the use of equipment in the OR the identifying number is placed in the patient's record. Some departments log all asset tags in a master log and assign a simple unit-identifying number or letter that corresponds to the equipment in use. This simplifies documentation.

If any equipment is not in good working order, it must be taken out of service immediately and tagged for repair. It should not be put back into service until the biomedical engineering department clears it for use. Some manufacturers will provide loaners when equipment is out for repair. All loaner equipment must be checked by the biomedical engineering department before use in the OR. Information on the service tag of malfunctioning equipment should include the following:

- Name of person reporting
- Date of report
- Description of the problem
- Any other information that may be pertinent

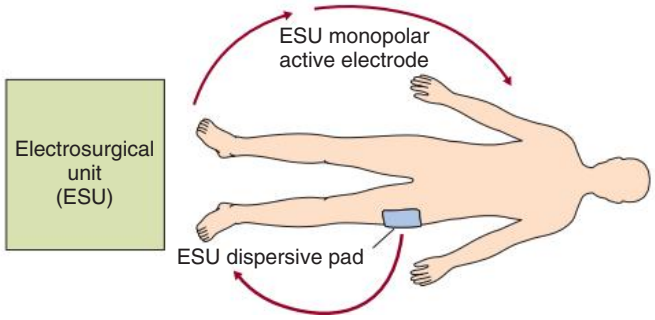
Electrosurgery

Principles of Electrosurgery

Electrosurgery is used to a greater or lesser extent in all surgical specialties. Personnel should be familiar with the manufacturer's detailed manual of operating instructions for each type used. Electric **current** can be used to cut or coagulate most tissues.[1] Attempts to coagulate large vessels can result in an extensive burn and necrosis. Excess charring and devitalized tissue creates a barrier for wound healing and may provide a **medium** for infection.

The initial incision is made by a scalpel. The **electrosurgical unit (ESU)** is not used to incise the skin. Electrosurgery can be used on fat, fascia, muscle, internal organs, and vessels. ESUs operate at frequencies between 100,000 Hz and 10,000,000 Hz. This current can be passed through tissue without causing stimulation of muscles or nerves.

Electrosurgery differs from electrocautery. Electrocautery is the use of a unidirectional current generated by a self-contained battery-operated disposable instrument with a wire at the tip. The



• **Fig. 20.1** Monopolar current path.

wire heats when activated and coagulates the tissue. The energy does not enter the patient's body. The ESU uses an alternating current that passes through the patient's tissues and returns to the **generator**.[2] Two forms of ESU generators are commonly used in surgery: monopolar and bipolar. Each type has specific uses and considerations.

Monopolar Electrosurgery

With **monopolar** ESUs the electric current flows from the generator to the **active electrode**, through the patient to a return electrode, and returns back to the generator (Fig. 20.1). The generator returns the current to **ground**. Any break in the current flow from the generator and back again causes the machine to shut down and sound an alarm as a safety feature.

The surgeon selects the type of current and **power** setting. The circulating nurse verbally confirms and documents the power settings before the generator is activated. It is seldom necessary to use full-power settings. A safe general rule is to start with the lowest setting of current that accomplishes the desired effect, and then increase the current at the surgeon's request.

ESU Generator

The generator produces the electrical current in three forms. The generator is mounted on a portable rolling stand. Nothing should be set on the machine. Each machine has an asset number that should be recorded in the patient's records. The machine can be set to one or a combination of the three currents:[2]

1. ***Coagulating current:*** Intense heat is produced to seal small to moderate vessels on contact. The current is continuous, but diminishes for short gaps of time.
2. ***Cutting current:*** The current is a constant flow of high energy output without gaps of time. The continuous flow of current causes the tissues to separate before high levels of heat build up.
3. ***Blended current:*** Both coagulating and cutting currents are produced at the same time in modified cycles. Small vessels are sealed as the tissue divides. Settings can be selected that have varied degrees of coagulation and cutting.

Active Electrode

The sterile active electrode directs flow of current to the surgical site. The style of the electrode tip (i.e., blade, loop, ball, or needle) will be determined by the type of surgical procedure and current to be used. It is attached to a conductor cord, which is connected to the generator. The active electrode tip may be in a pencil-shaped handpiece operated by a rocker switch, or it may be incorporated into a tissue forceps or suction tip operated by a foot pedal. Only the user of the active electrode should activate the current with the pedal to prevent accidental discharge of electricity into the field.

The end of the cord for the active electrode is passed off the field by the scrub person and attached to the generator by the circulating nurse. The sterile part of the cord should not be secured to the field by a metal instrument because cracks in the cord could permit conduction of electrical energy sufficient to cause a fire or severe burns. When not in use, the handpiece and active tip should be kept clean and housed in a holder designed for this purpose. Standard active electrodes are cleaned with an abrasive tip polisher. Teflon-coated tips are wiped clean with a saline dampened sponge. A crusty tip prevents the current from effectively passing into tissues. Do not scrape off the char with a scalpel. This causes debris to be discharged into the room atmosphere.

When in use, the generator emits a buzzing sound as the handpiece is activated. There are two pitches to the sound. One sound signifies the use of the coagulating current, and the other sound indicates activation of the cutting current. The alarm system has a volume control. It should never be set to "off."

The surgeon places the active electrode tip on the tissue and then activates the foot switch or hand control to transfer electric current from the generator to the tissue. Some hand switches are color-coded to identify coagulating and cutting functions. Rather than placing the tip directly on tissue, bleeding vessels may be clamped with a hemostat or smooth-tipped tissue forceps. As little extraneous tissue as possible should be clamped to minimize damage to adjacent tissue. Vessels are coagulated when any part of the metal instrument is touched with the active electrode; this is frequently referred to as *buzzing*.

To avoid arcing, the active electrode should be in contact with the instrument before electric current is applied. The person holding it should have a firm grip on as large an area of instrument as possible and avoid touching the patient. The active current should not be applied for more than 3 seconds. Inadvertent patient injury can occur if the metal instrument is in contact with retractors or other instrumentation placed in the surgical field. Low-voltage cutting current should be used. Current can burn through surgical gloves if these precautions are not taken.

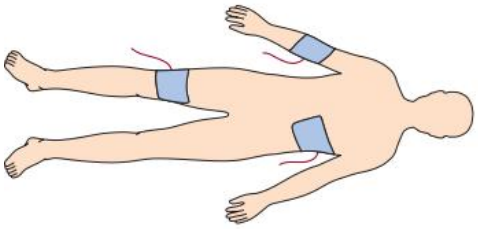
The active electrode handpiece and cord are disposable. Reusable active monopolar forceps and cords should be inspected for damage before reprocessing and before use at the sterile field.

Patient Return Electrode (Inactive Dispersive Electrode)

When using monopolar electrosurgery the current is returned to the generator through an **inactive return electrode** attached to the patient. The active tip sends the current through the patient's tissues. The current returns to the generator through the inactive return electrode attached to the patient.

The current's path from the generator to the patient and from the patient to the return electrode and back to the generator completes a circuit. If the circuit is broken, the current will find an alternative route back to ground, such as through metal in contact with a body. An isolated generator offers the advantage of a non–ground-seeking circuit. The flow of current is isolated and restricted to active and dispersive return electrodes, and the current returns directly back to the generator. With an isolated generator, if the circuit is broken, the generator shuts down.

One form of a patient return electrode adhesive pad is placed in direct contact with skin (Fig. 20.2). The contact area must exceed 100 mm^2 and have a diameter greater than 1.2 cm. The adhesive return electrodes are flexible to mold to the appropriate body surface.



• **Fig. 20.2** Placement of ESU patient return electrode.

MEGADYNE manufactures a reusable capacitative return electrode, MEGA 2000, which measures 720 in^2 and does not adhere to the patient's body. This large gel pad is placed in a plastic sheath underneath the bed sheet on the OR bed. The patient makes contact with the pad over most of the contact surface through the bed sheets. This style of return electrode is useful when there is not a suitable site for a disposable return electrode, such as on a burn patient. Positioning in lithotomy can be difficult with this type of electrode. Imaging can be distorted if used under the patient during fluoroscopy. The cord attaches to the generator in the patient return electrode socket.

Electrosurgery causes more patient injuries than any other electrical device used in the OR. Most incidents are caused by user error. Regardless of which return electrode is used, the following safeguards must be followed:

1. The return electrode should be as close as possible to the site where the active electrode will be used to minimize current through the body.
2. The patient should be in the desired position before the adhesive return electrode is applied to prevent its becoming dislodged or buckled during patient positioning. Do not remove or reposition the disposable return electrode because the integrity of the adhesive will be altered. A new electrode is used each time.
3. The return electrode should never be cut to fit.
4. The return electrode should cover as large an area of the patient's skin as possible in an area free of hair or scar tissue, both of which tend to act as insulation. An area may need to be dry shaved. The surface area affects heat buildup and dissipation.

   Avoid areas where bony prominences might result in pressure points, which in turn can cause current concentration. Place the pad on a clean, dry skin surface over or under as large a muscle mass area as possible. The gel conduction material on the pad is cold and sticky to the touch; a patient who is awake should be forewarned of its application.
5. Any area that overlies an implant is a former surgical site and is not suitable for placement of a return electrode. The surgical scar tissue will not disperse the current. The return electrode should not be placed on skin over a metal implant, such as a hip prosthesis, because current could be diverted to the implant and generate excessive heat.
6. The integrity of the package of a disposable return electrode should be inspected before use. Do not use the electrode if the package is damaged or has been previously opened.
7. Special care should be taken to ensure that the cord does not become dislodged. Do not put a safety belt over the electrode or cord. The connector should not create a pressure point on the patient's skin.
8. The connection between the return electrode and generator should be secure and made with compatible attachments. If the return circuit is faulty, the ground circuit may be completed through inadvertent contact with the metal OR bed or its attachments. This is referred to as an *alternative pathway* for the current.

If the return pad surface area is too small, current passing through an exposed area of skin in contact with metal will create intense heat. For example, one such contact point could be the thigh touching a leg stirrup while the patient is in the lithotomy position. A serious full-thickness burn can occur.

The circulating nurse should record on the patient's chart the type and/or location of the dispersive return electrode, the condition of the patient's skin before and after electrosurgery, the generator identification number, and the settings used. Some institutions also require documentation of the dispersive return electrode lot number.

Argon Beam Coagulator

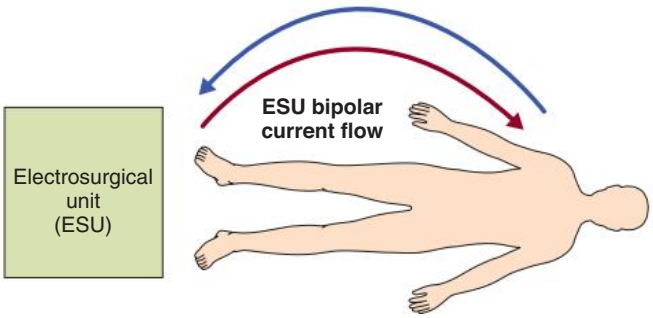
Argon gas can be incorporated into a monopolar ESU to create a path between the tissue and the active electrode handpiece. The gas is inert and noncombustible and is easily ionized by the electrical current. Argon is heavier than air and creates less plume. The argon-enhanced ESU tip is held at a 60-degree angle and does not contact the tissue during coagulation, thereby causing less tissue damage. The depth of penetration is less than with other forms of monopolar energy.

The active ESU tip and gas stream are passed over tissue to evenly coagulate larger areas. The gas displaces the bleeding over the surface of the target organ. Care is taken not to cause the gas to enter large open vessels because of the risk for gas embolism. Argon-enhanced electrosurgery is a form of monopolar ESU and requires the use of a patient return electrode.

Argon-enhanced electrosurgery is used with caution during laparoscopy. The argon gas adds to the cumulative effect of pneumoperitoneum and overpressurization. Argon is less soluble in blood than CO_2 and could persist long enough to pass to the heart in the form of a gas embolus. One port should be available for venting gases between extended uses of the argon to prevent build up of the gas.

Bipolar Electrosurgery

With **bipolar electrosurgery** the current is directed from the generator to a special forceps with one active tip and one inactive tip. The current flows from the generator to the active tip and returns to the generator through the inactive tip (Fig. 20.3). The energy does not flow through the patient's body as in monopolar electrosurgery. No return electrode is used. Output voltage is relatively low. This provides extremely precise control of the coagulated area.



• **Fig. 20.3** Bipolar current path. No patient return electrode is used.

Bipolar electrosurgery is safe to use in cases in which electrical current passing through the body could cause disruption in implantable devices such as pacemakers or internal defibrillators. Because the current does not pass beyond the tines of the forceps the function of peripheral devices remains uninterrupted.

Other bipolar energized devices include the *LigaSure* instrument designed to permanently divide and fuse vessels and tissue of up to 7 mm. The grasper tip dissects and holds securely. The generator has an activation sound when operating and an alarm if the device is not working properly. Each application should last no longer than 1 minute for the best tissue effects.

Coblation

Coblators use high-frequency bipolar energy in a conductive medium to create a highly focused plasma field. The energy is passed through a flow of saline irrigation to cause a field of highly charged electrons to break the molecular bonds of the target tissue while preserving the integrity of surrounding healthy tissue. The saline is conductive, causing a vaporized plasma field the thickness of a sheet of paper. The temperature does not need to reach extremes of thermal effect as with other coagulation devices to separate the tissues. The average temperature is only 68° F to 158° F (20° C to 70° C).

The tip of the wand instrument is 1 to 2.5 mm wide and has two tiny electrodes through which the saline is passed over the target area. Coblation was originally designed for use in arthroscopy, but later found favor with otorhinolaryngologists for nasal and tonsil procedures. In oral and nasal tissue procedures the greatest limitation is in sinus procedures, in which a bony obstruction may be encountered. Plastic surgeons have been working with coblation as a tool for skin resurfacing for deep acne scars and facial wrinkles. Coblation offers an alternative to chemical peels and laser surface modifications.

Generalized Safety Factors for the Use of Electrosurgery

Electrical burn through the patient's skin is the greatest hazard of electrosurgery. These burns are usually deeper than flame burns, causing widespread tissue necrosis and deep thrombosis to the extent that debridement and grafting may be required. Not all deep thermal injury is immediately apparent.

In addition to the precautions noted for preparing the ESU and for positioning the dispersive return electrode used with monopolar units, other precautions should be taken as follows:

1. Electrosurgery (monopolar and bipolar) should not be used in the mouth, trachea, around the head, or in the pleural cavity when high concentrations of oxygen or nitrous oxide are used. During some procedures, such as eye surgery, oxygen is administered via nasal cannula or mask. Oxygen builds up under the drapes and sets the stage for a combustible situation. Flame-retardant drapes can conceal a fire in a confined space. The anesthesia provider is advised to administer medical air instead of oxygen to minimize the risk for fire. Safety regulations for use with all inhalation anesthetic agents are followed.
2. Electrocardiogram electrodes should be placed as far away from the surgical site as possible. Burns can occur at the site of electrocardiogram electrodes and other low-impedance points from invasive monitor probes if the current diverts to an alternative path of least resistance. Metallic electromyographic or neurologic monitoring needles should not be used.
3. Rings and other jewelry should be removed. Metallic jewelry, including those used in body piercings, presents a potential risk for burn in the patient from diverted currents from the monopolar unit with either an isolated or ground-referenced output.
4. Flammable agents containing alcohol should be used with great care in skin preparation. If they are used, the skin surface should be completely dry before draping. Volatile fumes and vapors may collect in drapes and ignite when the electrosurgical or cautery unit is used.
5. If another piece of electrical equipment is used in direct contact with the patient at the same time as the ESU, connect it to a different source of current if possible. The cutting current of the ESU may not work if another piece of electrical equipment is on the same circuit. The ESU may interfere with the operation of some equipment, such as older models of cardiac monitors. The isolated power system of solid-state generators may prevent these problems.
6. New models of cardiac pacemakers are unaffected by monopolar ESU generators. Other implanted electrical devices such as defibrillators could malfunction. Check with the device manufacturer regarding compatibility.[2]

   The bipolar ESU may be used because the current does not pass through the patient's body and return to the generator. The patient is continuously monitored. A defibrillator should be on standby in the OR.
7. Connection of a bipolar active electrode to a monopolar receptacle may activate current, causing a short circuit. Plugs on cords should be differentiated to prevent misconnections of active and inactive electrodes.
8. Secure the active electrode handle in an insulated holster/container when not in use. Do not immerse an active electrode in liquid.
9. To prevent fire, only moist sponges should be permitted on the sterile field while the ESU is in use. This includes using moist sponges during the use of battery-operated electrocautery. Dry sponges can ignite.
10. Investigate a repeated request by the surgeon for more current. The dispersive return electrode or connecting cord may be at fault and should be checked first, followed by the handpiece connection. Shock to those touching the patient may result. The patient may be burned at the dispersive return electrode site.
11. For safety of the patient and personnel, follow instructions for use and care; these appear on the machine or in the manual provided by the manufacturer that accompanies each ESU. Grasp and pull only the plugs, not cords, when disconnecting attachments from the generator or the power source. Position the power cord away from the team to avoid tripping team members. Avoid rolling equipment over the power cord. Disposable cords should not be cut with scissors.
12. Any malfunctioning ESU should be labeled with the problem and taken out of service until cleared for use by biomedical engineering department personnel.
13. The patient and personnel should be protected from inhaling plume (smoke) generated during electrosurgery. A suction evacuator device should be placed as close to the source of plume as possible to maximize evacuation of smoke and enhance visibility at the surgical site.
14. Electrosurgery devices are available with combined suction systems for removal of surgical plume and fluid.
15. Inspect insulated instruments for breaks in the insulation covering. Current can leak from fractures in the insulation and create a thermal burn.

Laser Surgery

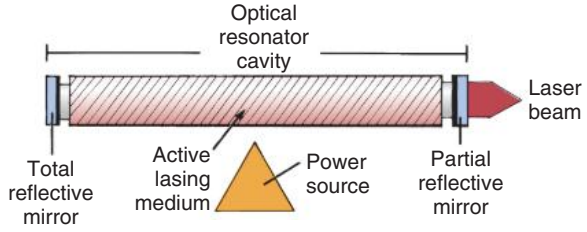
The term **laser** is an acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation.

Physical Properties of Lasers

The laser focuses light on atoms to stimulate them to a high point of excitation. The resulting radiation is then amplified and metamorphosed into the **wavelengths** of laser light. This light beam is monochromatic (one color), because all of the electromagnetic waves are the same length and collimated or parallel to each other. The light is totally concentrated and easily focused. Unlike conventional light waves, which spread and dissipate electromagnetic radiation by many different wavelengths, the coherence of the **laser beam** is sustained over space and time with wavelengths in the same frequency and energy phase.

Lasers may emit their energy in brief, repeating **emissions** that have a duration of only an extremely small fraction of a second; these are pulsed laser systems. Or they are capable of producing continuous light beams; these are continuous-wave lasers. All lasers have a combination of duration, level, and output wavelengths of radiation emitted when activated. Power density, the irradiance, is the amount of power per unit surface area during a single pulse or exposure. This is expressed as watts per centimeter squared. Regardless of beam characteristics, components of a laser system are the same (Fig. 20.4). These components include the following:

- An active medium to produce a lasing effect of the stimulated emission. Gases, solid rods or crystals, liquid dyes, and free electrons are used. Each produces a different wavelength, color, and effect.
- An excitation power source to create population inversion by pumping energy into the active medium. This may be electrical or radiofrequency power or an optical power source such as a xenon flash lamp or another laser.
- An amplification mechanism to change random directional movement of stimulated emissions to a parallel direction. This occurs within an optical resonator or laser cavity, which is a tube with mirrors at each end. As photons traveling the length of the resonator reflect back through the medium, they stimulate more atoms to release photons, thus amplifying the lasing effect. The power density of the beam determines the laser's capacity to cut, coagulate, or vaporize tissue.
- Wave guides to aim and control the direction of the laser beam. The optical resonator has a small opening in one end that permits transmission of a small beam of laser light. The smaller the beam, the higher its power density will be. Fiberoptic wave guides or a series of rhodium reflecting mirrors then direct the beam to tissue. The wave mode may be continuous, pulsed, or a Q-switched single pulse of high energy.
- Backstops to stop the laser beam from penetrating beyond the expected impact site and affecting nontargeted tissue. Quartz or titanium rods will stop the beam.



• **Fig. 20.4** Basic laser components.

· BOX 20.1 Factors Associated with Tissue Reaction to Laser Light

- Type of laser (wavelength)
- Intensity of laser focus
- Duration of application
- Depth of penetration
- Type of tissue (color and composition)

Types of Lasers

Lasers use argon, carbon dioxide, holmium, krypton, neodymium, phosphate, ruby, or xenon as their active medium.[3] When delivered to tissues, laser light can be absorbed, reflected, transmitted, or scattered, depending on the characteristics of the laser and the type of tissue. Only absorbed light produces thermal effects in tissue. Thermal penetration varies according to the ratio of absorption versus scattering. Energy absorbed at the surface will destroy superficial cells; further penetration extends cell destruction in surrounding tissues.

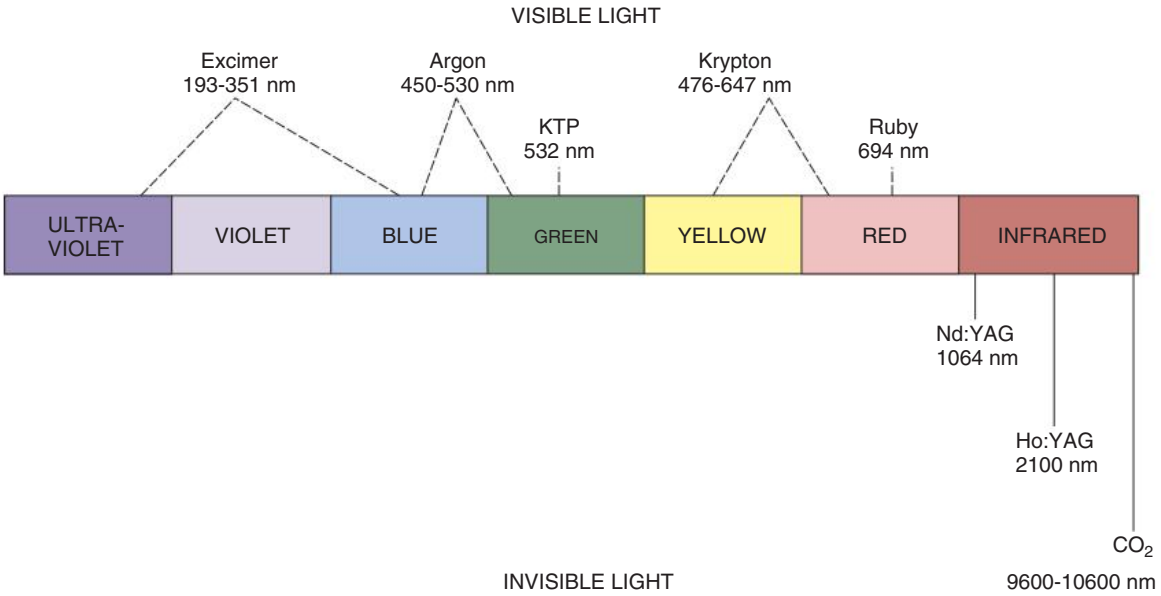
The wavelength of the laser light, power density, rate of delivery of energy, and exposure time will vary the effects on tissue. Energy density is based on the laser's wattage, beam or spot size, and time of exposure. The spot size depends on the laser fiber size and distance of the tip from tissue; it increases and becomes defocused as fiber is moved farther from tissue. Variables in tissue reaction are listed in Box 20.1.

Laser beams cut, vaporize, or coagulate tissue. Coagulative effect causes collagen bonding and welding of tissue surfaces. Each laser has selective uses. Laser light colors vary from the visible, near-ultraviolet range to the invisible, far-infrared range of the electromagnetic spectrum (Fig. 20.5). Wavelengths also vary, providing different radiation penetration depths. Lasers are commonly used in conjunction with the operating microscope and/or an endoscope. The surgeon selects the appropriate laser for the tissue to be incised, excised, or coagulated.

Argon Laser

Argon ion gas emits a blue-green light beam in the visible electromagnetic spectrum at wavelengths of 450 and 530 nm. This wavelength passes through water and clear fluid, such as cerebrospinal fluid, with minimal absorption. It is intensely absorbed by the brown-red pigment of hemoglobin in blood or melanin in pigmented tissue and converted into heat. Thermal radiation penetrates to a depth of 1 or 2 mm in most tissue.

The argon laser operates from electrical power. A water-cooling system is often required to dissipate heat generated in the argon medium. The argon laser beam usually is transmitted through a flexible quartz fiberoptic wave guide that is 200 to 600 mm in diameter. This can be directed to a handpiece or through an endoscope or operating microscope. Most argon laser machines deliver a nonfocused beam that vaporizes tissue poorly and scatters more radiation than other types of lasers. Irradiance may vary from less than 1 watt to 20 watts, depending on the model.



• **Fig. 20.5** Electromagnetic spectrum of laser light beams at wavelengths in nanometers (nm). *CO_2,* Carbon dioxide; *Ho:YAG,* holmium:yttrium aluminum garnet; *KTP,* potassium titanyl phosphate; *Nd:YAG,* neodymium:yttrium aluminum garnet.

Argon lasers coagulate bleeding points or lesions involving many small superficial vessels, such as a port-wine stain. They are used primarily to destroy specific cutaneous lesions while sparing adjacent tissue and minimizing scarring. Argon lasers may be used to treat vascular lesions and remove plaque and to coagulate superficial vessels in mucosa, such as in the gastrointestinal tract. They are also used in ophthalmology, otolaryngology, gynecology, urology, neurosurgery, and dermatology.

Carbon Dioxide Laser

Using a mixture of carbon dioxide (CO_2), nitrogen, and helium molecular gases, the CO_2 laser emits an invisible beam from the mid- to far-infrared range of the electromagnetic spectrum at wavelengths of 9600 and 10,600 nm. This wavelength is intensely absorbed by water. It raises water temperature in cells to the flash boiling point, thus vaporizing tissue. Vaporization is the conversion of solid tissue to smoke and gas. This plume should be evacuated or suctioned through a filter device from the site of lasing. The intense heat of the CO_2 laser also coagulates vessels as it cuts through them. It penetrates the surface to a depth of 0.1 to 0.2 mm per application to tissue, with minimal thermal effect to surrounding tissue.

The CO_2 laser operates from electrical power. The machine has a self-contained cooling system. The CO_2 laser beam should be delivered in a direct line of vision. It can be directed through a rigid endoscope, but it cannot be transmitted through a fiberoptic wave guide because its longer wavelength prevents conduction through crystal fibers. It is transmitted through an operating microscope or an articulating arm with a series of mirrors. The articulating arm allows precise focus and direction of the beam to a pencil-like handpiece.

CO_2 lasers have a helium-neon (HeNe) laser coaxial target beam that superimposes the invisible CO_2 beam to provide a visible red aiming light. The wave generated may be continuous or pulsed. Irradiance can vary from less than 1 watt to up to 300 watts. A portable handheld laser tube with a hollow needle to deliver the CO_2 beam is available for use in vascular surgery and microsurgery.

The vaporization and hemostatic actions of the CO_2 laser are of value to the surgeon in treating soft tissue and vascular lesions. Large or small masses of tissue can be removed rapidly and efficiently. The CO_2 laser cannot be used in a fluid environment. The peritoneal cavity is insufflated with gas to create a working space before the beam is directed through an endoscope.[4] This laser is used primarily in otolaryngology, gynecology, plastic surgery, dermatology, neurosurgery, orthopedics, and cardiovascular and general surgery.

Excimer Laser

When organic molecular bonds are broken up by a photochemical reaction, cool laser energy is emitted. Short wavelengths in the ultraviolet to visible blue-green spectrum are produced by gas used in the excimer laser combining with a halide medium. Argon fluoride produces a wavelength of 193 nm; krypton fluoride, 248 nm; xenon chloride, 308 nm; and xenon fluoride, 351 nm. These gases are extremely toxic. The beams they produce offer precision in cutting and coagulating without thermal damage to adjacent tissue. Excimer lasers have been developed for use in ophthalmology, peripheral and coronary angioplasty, orthopedics (to cut bone), and neurosurgery.

Free Electron Laser

Free electrons, which are not bound to a specific atom, pass from a particle accelerator through a series of magnets to create a light beam. The beam can be tuned anywhere within the electromagnetic spectrum from ultraviolet to infrared. The free electron laser (FEL) produces light waves as a series of rapid superpulses of high energy and short duration, with minimal thermal damage. These light waves can fragment calculi. The FEL can be used for precise cutting of tissues.

Holmium:Yttrium Aluminum Garnet (Ho:YAG) Laser

A crystal that contains holmium, thulium, and chromium elements increases the wavelength of YAG laser energy to 2100 nm. This invisible beam in the midinfrared range of the electromagnetic spectrum is absorbed by tissues containing water. Combined with high-energy pulsed delivery, it penetrates less deeply into tissue than does the neodymium (Nd:YAG) laser for more precise cutting and less generalized heating of tissue. It may be used percutaneously through a laser fiber threaded through a hollow needle or can be delivered through a fine fiberoptic fiber. It may be used in a fluid medium. It acts on water in cells without char or extensive tissue damage.

Approved for use in all joints except the spine, the Ho:YAG laser is useful in orthopedics to cut, shape, and sculpt cartilage and bone and to ablate soft tissues. Holmium lasers are also used in urology for prostate surgery and kidney stone lithotripsy.[5]

Krypton Laser

The krypton ion gas laser emits a red-yellow light beam in the visible electromagnetic spectrum at wavelengths of 476.2 to 647.1 nm. It is intensely absorbed by pigment in blood and retinal epithelium. The krypton laser resembles the argon laser in construction and use. It operates from electrical power and is water cooled. Used in ophthalmology, it is more versatile than the argon laser in selective photocoagulation of the retina.

Neodymium:Yttrium Aluminum Garnet (Nd:YAG) Laser

Neodymium, yttrium, aluminum, and garnet (Nd:YAG) constitute the solid-state crystal medium from which the light beam of this laser emanates. This invisible beam in the near-infrared range of the electromagnetic spectrum has a wavelength of 1064 nm. It is poorly absorbed by hemoglobin and water but is intensely absorbed by tissue protein. The wavelength penetrates to a depth of 3 to 7 mm to denature protein by thermal coagulation and shrinkage of tissue beneath the surface.

The Nd:YAG laser operates from electric current through the optical power source of xenon flash lamps. It must have an air, carbon dioxide, or water cooling system.

The Nd:YAG laser beam can be transmitted through a flexible quartz fiber, 200 to 600 mm in diameter, which passes through a rigid endoscope. It also can be transmitted through a fiberoptic wave guide to a handpiece or a flexible endoscope or be focused through an operating microscope. An aiming light of blue xenon or red neon-helium may be used in conjunction with the Nd:YAG beam. Sapphire or ceramic tips allow direct contact with tissue for cutting and vaporizing without diffuse coagulation, using less than 25 watts of power. These tips are available on handheld scalpels or to fit on the ends of fibers for endoscopic use. Many of these tips are reusable; some are for single use only.

The Nd:YAG laser has the most powerful coagulating action of all the surgical lasers. Its continuous or pulsed wave penetrates deeper into tissues than do other lasers (i.e., up to 2 cm) and will coagulate large vessels (up to 4 mm). It is used to coagulate and vaporize large volumes of tissue. This versatile laser has applications in rhinolaryngology, urology, gynecology, neurosurgery, orthopedics, thoracic and general surgery.

For ophthalmology, the Nd:YAG laser uses a Q-switching mode to store energy in a resonator during pumping action, followed by release of a single short pulse of high energy. This does not burn tissue but disrupts it with minute shock waves.

Potassium Titanyl Phosphate Laser

The solid-state potassium titanyl phosphate (KTP) crystal emits a visible green light at a wavelength of 532 mm. This laser produces less power than CO_2 or Nd:YAG lasers but can be focused to a smaller diameter for precision work, such as in the middle ear. KTP absorbs most effectively into red or black tissue for coagulation. The beam can be directed by a handpiece at or in contact with tissue or through a rigid or flexible fiberoptic fiber or micromanipulator. The beam cuts, vaporizes, or coagulates tissue with minimal lateral thermal damage and plume. Cooling gases are not necessary, but the system should be water cooled. Instruments are available that provide both KTP and Nd:YAG wavelengths selected by a button on the control panel or that pass the Nd:YAG beam through the KTP crystal. Many accessories are available for specific applications in all surgical specialties. The KTP laser has good cutting properties.

Ruby Laser

The ruby solid-state crystal laser emits a visible red light at a wavelength of 694 nm. A synthetically machined crystal rod is placed in a resonator cavity with a xenon flash lamp that when activated creates the optical pumping to produce the ruby laser beam. Blood vessels and transparent substances do not absorb this beam. A pulsed system, the ruby laser is capable of generating large fields of energy on impact. This shock wave effect can injure internal tissues and bone. Irradiance is 1 watt. Originally used in ophthalmology, the ruby laser currently is used primarily to eradicate port wine stain lesions of the skin.[6]

Tunable Dye Laser

Fluorescent liquid dyes or vapors can produce lasing energy. When exposed to intense laser light, usually an argon beam, dye absorbs light and fluoresces over a broad spectrum from ultraviolet to the far-infrared range. The laser may be delivered interstitially, endoscopically, externally, or retrobulbarly. A tunable prism can adjust the laser wavelength from 400 to 1000 nm, in either continuous or pulsed mode, for the specific dye in use.

The argon tunable dye laser system emits a blue-green beam at a wavelength of 430 to 530 nm from an argon laser that pumps a rhodamine B dye laser to produce a red laser beam at a wavelength of approximately 630 nm for selective destruction of malignant tumor cells. A dye laser tuned to 577 nm can be used on vascular lesions. Other wavelengths, such as through copper vapor, may be used to treat skin lesions or superficial tumors, such as of the bladder wall. The site can be repeatedly treated as long as cells remain photosensitive. This tunable dye laser is used most commonly for photodynamic therapy.

Photodynamic Therapy

For photodynamic therapy, the patient is injected 24 to 48 hours before laser therapy with a photosensitive drug that is absorbed by normal and malignant tissue. Normal tissue gradually releases the drug, but abnormal tissue retains it. The abnormal photosensitive tissue is destroyed when exposed to the laser beam. Normal adjacent tissue appears sunburned but is not permanently damaged. All dyes used with tunable dye lasers are potentially toxic and are handled with caution.

Safety Factors

All surgical lasers present hazards to patients and to the OR team. This equipment should be used in accordance with established

regulations, standards and recommended practices, manufacturer's recommendations, and institutional policies. Laser safety is based on knowledge of the specific laser to be used, its instrumentation, its mode of operation, its power densities, its action in tissues, and its risks.

Regulatory Agencies

Lasers are classified as medical devices and are subject to regulation. The Code of Federal Regulations' Performance Standards for Light Emitting Products provides specifications for manufacturers of medical laser systems.

The Center for Devices and Radiological Health

The Center for Devices and Radiological Health (CDRH) is the regulatory section of the U.S. Food and Drug Administration (FDA) in the Department of Health and Human Services (HHS). More than 250 types of lasers are regulated by the FDA. Those intended for medical and surgical use come under the jurisdiction of medical device regulations. They are categorized as class III, subdivision class 4, because lasers are potentially hazardous (Box 20.2).

Manufacturers must verify that their products meet all safety requirements of the federal standard. They must receive approval from the CDRH to market or test a laser for a particular clinical application or use, and they must comply with labeling requirements.

· BOX 20.2 Medical Device Regulations

FDA Classification of Medical Devices

Medical devices were classified in 1976 by the FDA according to their safety factors.

Class I
Subject to general controls

Class II
Devices for which general controls are not enough

Class III
Implants and life support devices

Classification of Lasers

Lasers are classified according to potential hazard of exposure.

Class 1
Enclosed system, considered safe based on current medical knowledge; no light emission escapes the enclosure.

Class 2
Limited to visible light (400-780 nm). Output power is 1 mW or less. Momentary viewing (0.25-second maximum permissible exposure) is not considered hazardous. Staring into the beam is not recommended. Protective eyewear of the correct optical density should be worn.

Class 3A
Emitted laser viewed directly through collecting optics would cause permanent eye damage. Output power is 0.5 mW or less. Protective eyewear of the correct optical density should be worn.

Class 3B
Continuous laser light with 0.5-watt or less output can cause permanent eye damage. Exposure to the beam should be avoided. Protective eyewear of the correct optical density should be worn.

Class 4
Laser light produced is hazardous to skin and eyes. Strict control measures are enforced. Protective eyewear of the correct optical density should be worn.

FDA, U.S. Food and Drug Administration.

American National Standards Institute

The American National Standards Institute (ANSI) is a voluntary organization of experts who determine industry consensus standards in technical fields. The standard developed specifically for laser safety in health care facilities is intended for all users. Existing federal legislation and state laser safety regulations are based on the ANSI standard. Simply stated, this standard implies that every health care facility that uses surgical lasers must establish and maintain an adequate program for control of laser hazards. This program shall include provisions for the following:

- *Laser safety officer:* This person should have authority to suspend, restrict, or terminate operation of a laser system if hazard controls are inadequate. A laser safety committee, often a subcommittee of the OR committee, may appoint this surveillance officer.
- *Education of users:* A safety training program must ensure that all users, including surgeons, perioperative nurses, surgical technologists, and biomedical engineers and technicians, are knowledgeable of correct operation, potential hazards, and control measures.
- *Protective measures:* Protective measures are for patients, personnel, and the environment.
- *Management of accidents:* Management includes reporting accidents and developing plans of action to prevent a future occurrence.

Occupational Safety and Health Administration

The Occupational Safety and Health Administration (OSHA) is concerned primarily with the safety of health care workers. The agency can enforce ANSI standards.

State and Local Agencies

State regulations and local ordinances vary. Knowledge of and compliance with any requirements should be established.

Policies and Procedures

Specific policies and procedures related to use of lasers should be written by the laser safety committee before a laser program is instituted. These policies and procedures will need to be revised or updated when new equipment is installed. Applicable policies include, but are not limited to, the following:

1. Credentialing and clinical practice privileges of medical staff. Physicians authorized to use a laser should be required to complete a postgraduate laser course in their specialties.[7] Hands-on experience and a preceptorship with a qualified user also should be required. The physician must have training for each type and wavelength of laser. A list of approved physicians should be available to the perioperative staff. Scheduling privileges should be denied to those surgeons who are not appropriately credentialed.
2. Initial and ongoing educational laser use and safety programs for perioperative personnel. Perioperative personnel should have thorough knowledge and understanding of laser equipment, laser physics, tissue reactions, applications, and safety precautions.
3. Continuous quality improvement. A program of continuous quality improvement includes appropriate care, use, and maintenance of equipment and prevention of laser-related accidents.
4. Documentation. The surgeon, procedure, type of laser used, length of use, and wattage should be recorded in the patient's medical record. This information, plus the patient's name, also should be recorded in the OR log.

Patient Safety

The surgeon must explain laser surgery and its potential complications to the patient before obtaining written consent. Some lasers are considered investigational devices by the FDA. The patient must sign a specific consent form permitting experimental use and data collection. With all lasers, appropriate precautions (including protection of the patient's eyes, skin, respiratory tract, and tissue surrounding the target area from thermal burns) are taken to ensure patient safety, as follows:

1. The eyes and eyelids should be adequately protected from the specific laser beam in use.
   a. Patients who are awake must wear the same types of safety glasses or goggles with side shields of the correct optical density as those worn by the laser team.
   b. The eyelids can be taped shut on patients who are under general anesthesia.
   c. Eye pads moistened with saline solution should be taped securely in place for procedures around the head and neck, except for ophthalmic procedures and those using the Nd:YAG laser. Nonflammable material, such as aluminum foil with the reflective side down, can be taped over the eyes for Nd:YAG laser procedures. Moistened eye pads will not stop a laser beam.
   d. Protective shields should be used on the eyes during ophthalmic procedures. Corneal eye shields can be applied directly onto anesthetized eyes to protect corneal tissue.
2. Antiseptics used for skin preparation should be nonflammable.
   a. Aqueous solutions are safest, but they can retain laser heat if they are allowed to pool on or around skin. The skin should be thoroughly dry before the laser is activated.
   b. Alcohol and tinctures are flammable and volatile when wet. Vapors must not accumulate under drapes because they can ignite.
3. The immediate area around the incision and/or tissue surrounding the target site should be protected from thermal injury. Hair is flammable and should be completely covered with wet sponges or coated with water-soluble jelly. Flammable materials are avoided or safeguarded to prevent fire.
   a. Flame or fire-resistant drapes should be used. Metallic foil and polypropylene laser-retardant and ignition-resistant drapes are available. Polypropylene and plastic incise drapes can melt if a laser beam strikes them. Woven and nonwoven fabrics can ignite.
   b. Woven textile or cellulose-based absorbent nonwoven towels saturated with sterile normal saline solution or water should be placed over fabric drapes around the incision before the laser is used.
   c. The laser handpiece should be laid on a moistened surface. The laser tip is extremely hot and may shatter if placed in contact with a cold surface.
   d. Moistened sponges, towels, or compressed patties should be placed around target tissue except when the Nd:YAG laser is used. Sponges and other material should be removed from tissue near the target site of the Nd:YAG laser because wetting will not stop this beam and they could be ignited.
   e. The rectum should be packed with a moistened sponge to prevent methane gas, which is potentially explosive, from escaping from the intestinal tract during use of a laser in the perineal area. Placement of the sponge in the anal orifice and removal of the rectal packing should be recorded as part of the sponge count.
4. Anesthetic agents should be noncombustible. Nonflammable anesthetics and oxygen mixed with nonflammable agents are administered in a closed system.
   a. Oxygen and nitrous oxide concentrations around the head should be as low as possible during use of a laser in the aerodigestive tract (i.e., oral, laryngeal, bronchial, or esophageal procedures).
   b. Flexible metallic or insulated silicone endotracheal tubes are preferred for aerodigestive tract procedures. Laser-approved varieties are commercially available. If used, red rubber tubes are wrapped with reflective aluminum or copper tape to prevent ignition. Polyvinyl chloride endotracheal tubes should not be used because they ignite easily. The endotracheal tube cuff should be inflated with saline solution, which may be tinted with methylene blue to facilitate detection of a leak.
5. The teeth should be covered during oropharyngeal procedures to protect against reflective radiation.
6. Patients who are awake may wear a protective high-filtration mask during CO_2 laser ablation, such as of condylomata (venereal warts), to prevent inhaling airborne material into the lungs. An intubated patient is not considered at risk for respiratory contamination.
7. Postoperative instructions should include care of a healing thermal skin wound.

Personnel Safety

Exposure to nonionizing laser radiation can be hazardous for personnel. Precautions are taken to avoid eye and skin exposure to direct or scattered radiation and inhalation of plume. Some facilities require laser personnel to have baseline retinal screening performed before working in the laser unit.

Eye Protection

The eye is the organ most susceptible to laser injury. Different laser wavelengths affect eyes differently: argon and Nd:YAG lasers will be absorbed by the retina, and the CO_2 laser will be absorbed by the cornea. Therefore safety glasses or goggles of the correct optical density are worn at all times while the laser is in use. Optical density is the ability of the lens to absorb a specific wavelength (Table 20.1). The color of the lens is not the protective feature of the eyewear. Each type of wavelength requires protective eyewear

TABLE 20.1 Optical Density Necessary for Protective Eyewear

Optical Density	Transmission of Light (% of Wavelength)
0	1
1	0.1
2	0.01
3	0.001
4	0.0001
5	0.00001
6	0.000001

Light transmission is measured with a spectrophotometer to calculate the optical density needed for protective eyewear.

of a specific optical density as recommended by the manufacturer of the laser. The following considerations apply to eye protection:

1. Protective eyewear is available outside the room near posted signs designating the specific type of laser in use. Only people with appropriate eye protection are admitted in the room while the laser is in use.
   a. All protective eyewear (i.e., safety glasses, goggles) must shield the wearer's eyes from the top, bottom, and sides of the visual field.
   b. Goggles will fit over eyeglasses, or prescription lenses of the correct optical density can be obtained. Contact lenses do not provide eye protection.
   c. Scratches on the lens or breaks in the frame can negate eye protection.
2. Lens covers with filter caps are available for optical eyepieces of endoscopes and operating microscopes. Their use does not eliminate the need for the entire team to wear eye protection.

Skin Protection

Skin sensitivities can develop from overexposure to ultraviolet radiation. Skin also can be burned from exposure to direct or reflected laser energy. These hazards are minimized if personnel are alert to precautions for environmental safety. Other personnel safety precautions reduce risks and include the following:

- Metallic jewelry should not be worn. It could absorb heat or reflect the beam.
- Fire-resistant gowns may be worn.

Laser Plume

Toxic substances, including carcinogens and viruses, may become airborne from vaporization of tissues, especially from CO_2 and Nd:YAG lasers. The smoke produced, referred to as **laser plume**, contains water, carbonized particles, mutated DNA, and intact cells. It may have a distinct odor.

Laser plume should not be inhaled. One gram of plume is equivalent to smoking six cigarettes. Smoke evacuation from the site of lasing and high-filtration masks prevent personnel from inhaling plume. Removal of plume also enhances visibility at the target site for the surgeon. Plume can bend or refract the beam, thus inadvertently causing injury to adjacent tissues. The following precautions should be taken:

1. A mechanical smoke evacuator or suction with a high-efficiency filter should be turned on before or at the same time as the laser and should be run during activation and for 20 to 30 seconds after the laser is deactivated. The tip should be placed as close as possible, at least within 2 inches (5 cm), to the lasing site of tissue vaporization.
   a. Several types of mechanical smoke evacuators are available. Many systems have charcoal filters.
   b. Charcoal filters in most evacuators are changed regularly. Gloves, eyewear, and a mask (personnel protective equipment [PPE]) are worn when handling contaminated filters.
2. Masks should be tight fitting and should filter particles as small as 0.1 mm.

Environmental Safety

Only properly trained personnel are authorized to participate in laser surgery. Others should be made aware of its hazards. The following considerations apply to environmental safety:[7]

1. Warning signs (e.g., Laser Surgery in Progress) should be posted on the outside of all OR doors when the laser is in use. The design, symbols, and wording on the warning sign should be specific for the type of laser in use.
2. Walls and ceilings should have nonreflective surfaces. Glass, as in windows, cabinet doors, and/or the x-ray viewing box, should be covered with nonreflective material to stop reflective beams. CO_2 laser beams do not penetrate glass and plastic, but can bounce off reflective surfaces.
3. Warning labels on the machine, affixed by the manufacturer, must indicate points of danger to avoid personnel exposure to laser radiation.
4. The machine should be prepared, checked, and tested before the patient is brought into the room. A preoperative checklist is helpful. Any malfunction should be reported immediately, and the equipment should not be used until it is in proper working order.
5. When not in use, the machine should be kept on the "standby" setting with the beam terminated in a beam stop of highly absorbent, nonreflecting, fire-resistant material to avoid accidental activation. It should be turned off and locked with a key when left unattended. Only authorized personnel should have access to the key.
6. The foot switch should be operated by the surgeon who delivers the laser energy to the tissue. The foot pedal can be covered when not in use so that the surgeon will not inadvertently activate the laser. Foot pedals for other equipment should be moved away while the laser is in use. The laser pedal can then be removed after use.
7. Nonreflective instruments should be used in or near the beam. These instruments may be of a dull blue titanium alloy or an ebonized or anodized stainless steel. These finishes defocus and disperse the laser beam. Reflective instruments can cause burns or start fires.
8. Fire is a potential hazard that must not be underestimated. Personnel should be aware of fire safeguards and adhere to precautions for their own and the patient's safety.
   a. A basin of sterile water or normal saline solution should be readily available at the sterile field.
   b. A halon fire extinguisher should be available.
   c. Oxygen concentration in the room should be as low as possible. Oxygen leaking from the side of a patient's facemask can be ignited by the laser beam. The anesthesia provider should be knowledgeable about flash points and fire retardation when the laser is in use.
   d. Liquids should not be placed on the machine. A spill could act as a conductor and short-circuit the mechanism.
9. Electrical codes and standards should be enforced to avoid electrical hazards. An isolation transformer is recommended for a high-power laser power source to avoid dangerous overload of the existing OR power system. Electrical circuitry must provide adequate amperage for power requirements. Preferably, the laser should have its own dedicated circuit.
10. The manufacturer's instructions for operation, care, handling, and sterilization of the laser system should be followed. Proper care of lasers and accessory equipment is essential to patient, personnel, and environmental safety.

Laser Team

A laser team should be designated to carry out the duties that are different from those of the traditional OR team. This team may include the following personnel:

1. *Clinical laser nurse:* The responsibilities of the clinical laser nurse are different from those of the circulating nurse. Duties include the following:
   a. Preparing and teaching the patient preoperatively, intraoperatively, and postoperatively.

b. Bringing laser equipment to the OR and checking it. The chassis and the floor around it should be inspected for water leak. Using sterile technique, the clinical laser nurse and scrub person calibrate the laser as appropriate.
c. Covering windows, posting signs, and distributing appropriate protective eyewear.
d. Covering the patient's eyes.
e. Positioning the laser foot pedal for the surgeon's convenience and removing it after use.
f. Operating the key switch and monitoring activation of the laser. The wattage and exposure time are set according to the surgeon's orders. These should be repeated before and after adjusting controls.
g. Cleaning and checking laser fibers after use and preparing them for sterilization.
h. Completing the laser log.
i. Collaborating with the laser safety officer and biomedical engineer and/or technician to ensure safe use of laser equipment.

2. *Biomedical technician:* The biomedical technician provides preventive maintenance and handles minor problems with the laser system. A log of laser use and maintenance is maintained.
3. *Camera operator:* Endoscopic procedures performed under video control may require an additional sterile team member to operate the camera attached to the endoscope while the surgeon controls the laser fiber.

Advantages of Laser Surgery

Surgical lasers emit nonionizing radiation. This radiation is selectively absorbed by different tissues with resultant penetration and destruction at the focal point but with differential thermal protection of surrounding tissues. Lasers offer the surgeon and the patient many advantages over other surgical techniques, including the following:

- Precise control for accurate incision, excision, or ablation of tissue. The laser beam is precisely focused for localized tissue destruction. The depth of radiation penetration is precisely regulated by the duration of focus, power density, and type of tissue.
- Access to areas inaccessible to other surgical instruments through minimally invasive techniques. The beam can be directed through endoscopes or deflected off of rhodium reflector mirrors.
- An unobstructed view of the surgical site. The laser beam comes in contact with tissue to be cut, coagulated, or vaporized. It can be directed through the operating microscope.
- Minimal handling of and trauma to tissues. Traction on target tissue is unnecessary.
- A dry, bloodless surgical field. The laser beam simultaneously cuts and coagulates blood vessels, thus providing hemostasis in vascular areas.
- Minimal thermal effect on surrounding tissue. Essentially no permanent thermal necrosis of tissue occurs beyond 100 mm from the edge of the area incised. This minimizes postoperative pain.
- Reduced risk for contamination or infection. The laser beam vaporizes microorganisms, thus essentially sterilizing the contact area.
- Prompt healing with minimal postoperative edema, sloughing of tissue, pain, and scarring.
- Reduced operating time. Because procedures can be done more quickly, both anesthesia time and operating time are shorter. Many procedures can be done without general anesthesia. Many are done in ambulatory care facilities.

Disadvantages of Laser Surgery

- The costs to start and maintain a program are high. Equipment, instrumentation, supplies, and staff education are expensive initial investments. Most aspects need frequent updates and maintenance.
- Decisions should be made about the use of disposable versus reusable supplies and the effect on patient care. Most reusable supplies are fragile and should be replaced on a regular basis.
- Liability may increase as the number of users increases. Specific credentialing and continuing education require planning and are time consuming.

Microsurgery

The simplest magnifying instrument consists of a single lens with relatively high magnification (e.g., a magnifying glass or a jeweler's lens). Surgeons requiring less magnification than that provided by the microscope use operating loupes. Loupes magnify approximately two times the **diopter** power of the native lens in the surgeon's eye. Loupes attach to a headband or to the surgeon's spectacles like binoculars. The use of loupes in surgery terminates where microsurgery begins. From loupe surgery and refinements of the **binocular** microscope, microsurgery has evolved.

Technique of Microsurgery

Performance of surgical procedures while directly viewing the surgical field under magnification affords surgeons greater visual acuity of small structures. The microscope provides a more limited, although more readily visible, surgical field. All things look considerably different under magnification. Tissues not otherwise visible can be manipulated.

Use of microsurgical instrumentation and techniques is not simply a matter of adapting formerly learned conventional methods for use under the microscope. The techniques themselves for handling instruments, sutures, and tissues are different and infinitely more complex, precise, and time consuming because of the meticulous skill involved. Coordination must be adapted to working with minute materials in a field of altered perception and position.

Proficiency and facility in using the operating microscope entail laboratory practice in movements and manipulation of instruments and suture materials under various magnifications.

Divergence from tactile-manual to vision-oriented techniques requires that the surgeon and assistants pay maximum attention to detail. The most common maneuvers for placing and manipulating instruments, making an incision with scissors, and tying sutures involve a combination of several basic movements:

- *Compression-decompression:* To close scissors and forceps
- *Rotation:* To insert a needle, to cut, to extract, to engage or disengage
- *Push-pull, direct,* or *linear:* To incise with a razor knife

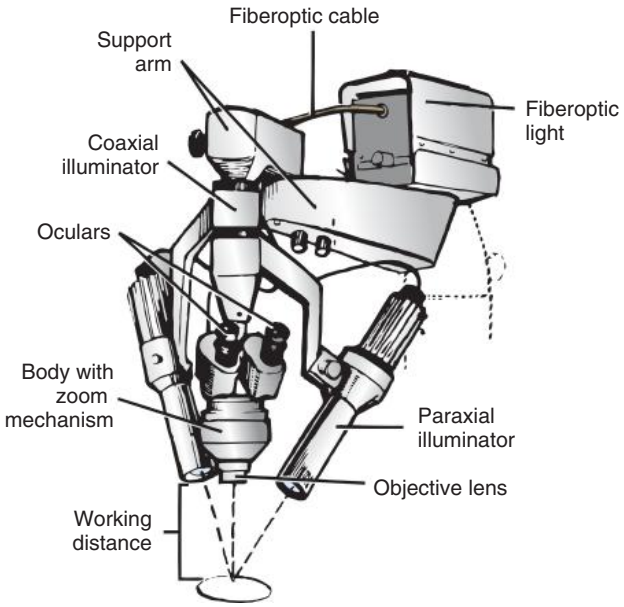
The surgeon also must be able to maintain a steady, stationary position during remote activation of equipment such as a laser beam. It is advisable that surgeons and assistants do no manual labor for at least a day before operating. Caffeinated drinks such as coffee the morning of surgery may decrease steadiness in some individuals. Very little tremor is tolerable in microsurgery.

Advantages of Microsurgery

Microsurgery provides unique advantages in the restoration of wholeness and function of the body, such as restitution of hearing, vision, tactile sensation, circulation, and/or motion. It is used in many surgical specialties to improve precision of already-established surgical procedures and permit successful performance of procedures previously not possible. For example, blood vessels less than 3 mm in exterior diameter can be sutured. Nerves can be anastomosed.

Replantation of amputated parts and some reconstructive surgery are possible only under magnification. In general, microsurgery allows the following:

- Dissection and repair of fine structures through better visualization
- Adaptation of surgical procedures to individual patient requirements (variation in anatomic landmarks is more distinct with magnification)
- Diminution of surgical trauma and complications because of safer dissection
- Superior focal lighting of the surgical field, particularly in deep areas



• **Fig. 20.6** Microscope body in detail.

Operating Microscope

Compound microscopes use two or more lens systems or several lenses grouped in one unit. The operating microscope is a compound binocular instrument. Single eye viewing with a **monocular** lens does not provide the depth of field necessary for surgical procedures. Interchangeable **objective** lenses combined with interchangeable binocular eyepieces allow a wide range of magnification and **working distances** adjustable to the surgeon's needs.

The operating microscope uses light waves for illumination. These waves are bent as they pass through the microscope, causing the image seen by the viewer's eye to be magnified.

The users must understand the parts and their functions. Basically, all operating microscopes incorporate the same essential components: an optical lens system and controls for magnification and focus, an illumination system, a mounting system for stability, an electrical system, and accessories.

Optical Lens System

The ability to enlarge an image is known as magnifying power. This is the ratio of the size of the image produced on the viewer's retina by magnification to the size of the retinal image when the object is viewed without optical aid. To create a distinct image, adjacent images must be separated. An indistinct image remains unclear no matter how many times it is magnified. The ability to discern detail is known as resolving power.

Components

The heart of the optical system is the body, which contains the objective lens (lens closest to the object). The head or binocular oculars (eyepieces) through which the surgeon looks are physically and optically attached to the body. The optical combination of the objective lens and the oculars determines the magnification of the microscope (Fig. 20.6).

Objective lenses are available in various **focal lengths** ranging from 100 to 400 mm, with intervening increases by 25-mm increments. The 400-mm lens provides the greatest magnification. The designation of the objective lens enumerates the working distance (the distance from the lens to the surgical field). Distances vary from 6 to 10 inches (15 to 25 cm). For example, a 200-mm lens will be in focus at a working distance of 200 mm, or approximately 8 inches (20 cm).

The **oculars** serve as magnifying glasses used to examine the real image formed by the objective. Most objectives are achromatic so the true color of tissues can be viewed in sharp detail. The binocular arrangement provides stereoscopic viewing. **Stereopsis** is basically achieved through binocular viewing, wherein each eye has a slightly different positional view of the object under examination.

The observer's brain then combines the two dissimilar images taken from points of view a little distance apart, thus producing a perception of a single three-dimensional image. If the user is wearing corrective lenses, the eyepieces are set to zero. If the user needs corrective lenses but is not wearing them, he or she should preset the eyepieces to a position of visual comfort, **pupillary distance**, and acuity before draping the microscope. Detachable rubber eyecups for the eyepieces are commercially available for the user's comfort.

Magnification

The ability of the microscope to magnify depends on the design and quality of the parts in addition to the resolving power. The total magnification is computed by multiplying the enlarging power of the objective lens by that of the lenses of the oculars. The **depth of the field**, which is the vertical dimension within which objects are seen in clear focus, decreases with increases in magnification of power. Likewise, the width of the field of view narrows as the power of magnification increases. For example, at 20× magnification, the field of view narrows to ½ inch (10 mm, or less than 1.25 cm).

Vertical viewing of the surgical field is extremely important, particularly in higher magnification ranges. It allows the surgeon more effective use of the increasingly limited depth of field.

In more complex microscopes, a third set of lenses is interposed between the oculars and the objective lens to provide additional magnification in variable degrees as desired by the surgeon. A continuously variable system of magnification for increasing or decreasing images is possible with a **zoom** lens. Most

surgeons prefer a faster, easier-to-handle zoom lens to a simpler turret magnifier that manually changes magnification by fixed increments.

The zoom lens is usually operated by a foot control that permits the surgeon to change magnification without removing the hands from the surgical field. The popular range of magnification in the zoom microscope is from 3.5× to 20× magnification. At 3.5× magnification, the depth of the field is about 0.01 inch (2.5 mm); at 20× magnification, the depth is about ½ inch (1 mm).[8] Some microscopes magnify to 50 times.

Focus

Focusing is accomplished manually or by a foot-controlled motor that raises and lowers the body of the microscope to the desired distance from the object to be viewed. Some microscopes divide the focus into gross and fine. The focus of the ocular lens usually is set at zero; the surgeon adjusts the focus as desired.

Illumination System

Illumination of the operating microscope uses light waves. The shorter the wavelength, the greater the resolving power. The intensity of illumination can be varied by controls mounted on the support arm of the body. The operating microscope has two basic sources of illumination: paraxial and coaxial.

Paraxial Illuminators

One or more light tubes (paraxial illuminators) contain tungsten or halogen bulbs and focusing lenses. The illuminators are attached to the mounting of the body of the microscope in a position to illuminate the field of view. Light is focused to coincide with the working distance of the microscope.

One of the paraxial illuminators may be equipped with a diaphragm containing a variable-width slit aperture. This device permits a narrow beam of light to be brought into focus on the objective field. This slit image assists the surgeon in defining depth perception (i.e., in ascertaining the relative distance of objects within the field—which are closer, which are farther).

Coaxial Illuminators

In fiberoptic **coaxial illumination**, light is transmitted through the optical system of the microscope body. This type of illumination is called coaxial because it illuminates the same area in the same focus as the viewing, or objective, field of the microscope. The fiberoptic system provides intense, though cool, light that protects the patient's tissues and the optics of the microscope from excessive heat. The light intensity ranges from 600 to 2250 footcandles without creating shadows. Reflected glare may be a problem. Frequent wound irrigation with a cool solution is necessary to avoid tissue damage from radiant energy during long procedures.

If a fiberoptic system is not used for coaxial illumination, a heat-absorbing filter must be interposed in the illumination system. Direct heat from a high-intensity source can damage and even burn tissues. Tungsten and halogen bulbs are used in some housings.

Another type of optical prism assembly provides a larger area of coaxial illumination with a brighter light than that obtained with fiberoptic light bundles. Known as *liquid light,* it uses ionic, inorganic saline solution with quartz glass inserts inside a flexible aluminum spiral tube insulated with a polyvinyl chloride coating. Light is conducted throughout the cross section of the liquid, unlike the light provided by a fiberoptic bundle.

Mounting Systems

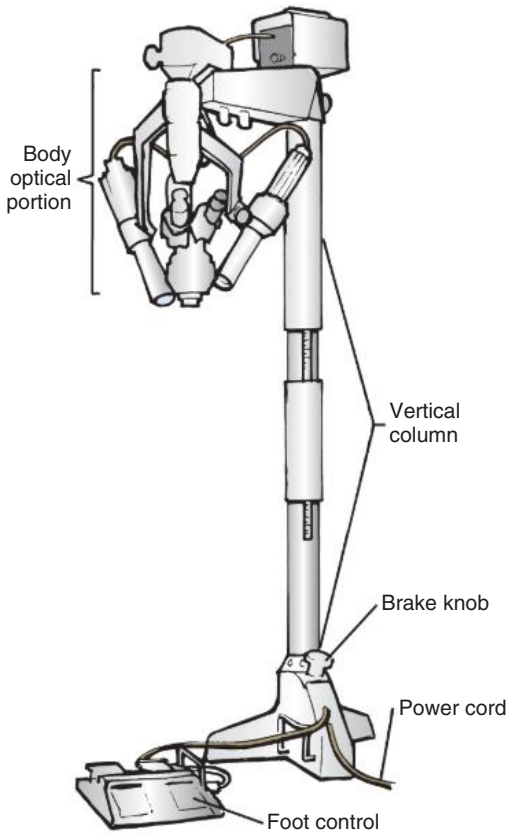
The stability of the microscope is of paramount importance. The body, the optical portion, is mounted on a vertical column that may be supported by the floor, ceiling, or wall or by attachment to the OR bed. The body of the microscope is attached to the column by a hinged arm and a central pivot. The mounting permits positioning as desired. It may be adjusted horizontally or vertically, rotated on its axis, and tilted at different angles. The microscope can be aimed in any direction. The objective is aimed at the principal surgical site.

Floor and ceiling mounting systems are the most popular and versatile. All microscopes must have a locking mechanism to immobilize the microscope body over the surgical field.

Floor Mount

The base of the vertical support, which rests on the floor, has retractable casters for ease in moving the entire instrument. When the base is lowered to working position, it is locked into position (Fig. 20.7).

The base should be properly positioned in relation to the OR bed before the anesthetic is administered or the patient is prepped. To maintain balance and control, one should gently push (not pull) the microscope when moving it. Jarring or banging the scope should be avoided, because the lenses may dislocate and obscure vision. The brake should be released or casters activated before the microscope is moved. The arms should be folded close to the column, with all of the attachments locked into place. Cords should be out of the way. Observation tubes should not be used as handles. Force should never be used in moving the microscope or in applying attachments; one should look for the



• **Fig. 20.7** Floor-mounted operating microscope.

problem instead. A floor-based microscope with column support is placed to the left of a right-handed surgeon. The base should not interfere with foot controls or power cables. It should be clear of any table attachments.

Some microscopes use a **Contraves stand**. This is a counterbalanced weight system used to position the operating microscope in a suspended position over the surgical field. The weights are set and locked according to the types of attachments on the body of the microscope. The balance is set before activating the power switch.

As a safety factor, the base must not be moved when the microscope is positioned over the patient, because it is top heavy. Gross adjustments, such as height in relation to the surgical field and focus, are made with the microscope swung away from the patient. The OR bed height, chair, and armrest heights are adjusted at the same time that gross adjustments are made. Fine focusing and adjustments are done after the microscope is in position for the surgical procedure. The assistant's microscope is adjusted to the same focus as that of the surgeon. During prepping and draping, the microscope is rotated out of position and then brought over the surgical field for the procedure.

Ceiling Mount

A ceiling mount, either a fixed or track-mounted model, provides more floor space for placement of foot pedals. The fixed unit is suspended from a telescoping column attached directly to the ceiling. Vertical support of a track-mounted unit is suspended from a ceiling rail. It can be moved out of the way when not in use (Fig. 20.8). The microscope is positioned and focused after the patient is anesthetized. A ceiling-mounted instrument is operated by a control panel on a wall (on-off switch) and by foot controls for focusing, magnifying, raising, and lowering.

A ceiling mount is generally very stable, but it is only as stable as the supporting ceiling. Mechanical devices adjacent to the OR, such as air conditioning units, may cause vibration. The microscope should be vibration free. A ceiling mount permits the same flexibility of positioning as a floor mount. Care is taken to assure that the mounting track is dust free. Flecks of dust falling into the field can cause serious problems with infection and adhesions.

The vertical support has a memory stop mechanism that can be preset for a preselected OR bed height. This setting should be checked and adjusted for each OR bed position change. The mechanism is a safety factor to prevent accidental lowering of the microscope at high speed too close to the patient. High-speed lowering should be done away from the patient until the memory stop is reached. As with the floor-mounted instrument, gross adjustments are never made over the patient. Fine adjustment and focusing are done after the microscope is over the surgical field.

Wall Mount

The microscope is bracketed by a flexible arm to a stable wall. The swing-arm extension permits proper positioning.

Operating Bed Mount

Smaller microscopes may be mounted on the framework of the OR bed. This system has many disadvantages and thus is not popular.

Electrical System

The same precautions are observed with the operating microscope as with any electrical equipment in the OR. Switches and wall interlocks should be explosion proof. Circuits are protected from overload by breaker relays and fuses. All light controls should be in the off position when the power plug is inserted or removed from the wall outlet to avoid short-circuiting or sparking. A red pilot light illuminates on the control panel when the electrical power is on.

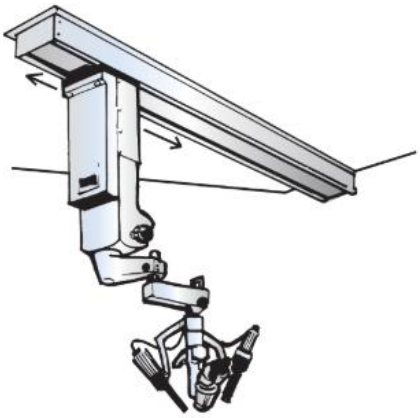
Accessories

A number of accessories are available to enhance the versatility of microsurgery. The value of a good microscope is negated without proper ancillary equipment.

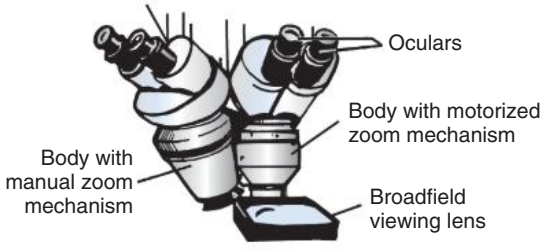
Assistant's Binoculars

A separate optical body with a nonmotorized, hand-controlled zoom lens can be attached to the main microscope body for use by the assistant (Fig. 20.9). This mechanism can be focused in the same plane as the surgeon's oculars. Its field of view may not coincide exactly with that of the surgeon. This can be rectified by using a **beam splitter**, which takes the image from one of the surgeon's oculars and transmits it through an observer tube, thereby providing the assistant with an identical image of the surgeon's view (see Fig. 20.8). This is particularly important in critical areas where a difference of 1 or 2 mm is crucial.

The assistant's binocular co-observer tubes can be placed on the body of the microscope so that the assistant can work and observe from the same side of the OR bed as, at a right angle to, or directly opposite the surgeon. Binocular tubes (tiltable, straight, or inclined) can be attached on the right or left side of the body of the microscope. A dual viewing bridge, the quadroscope, is attached when the surgeon and assistant sit opposite each other. They have exactly the same view of the field with this accessory. Binoculars should be appropriately placed on the microscope body before the surgical procedure begins.



• **Fig. 20.8** Ceiling track-mounted microscope.



• **Fig. 20.9** Surgeon's microscope on right with assistant's binoculars attached on left.

Broadfield Viewing Lens

A low-power magnifying glass is used for grasping needles or for getting an overall view of the field adjacent to the objective. This lens attaches to the front of the body of the surgeon's ocular (see Fig. 20.9).

Couplings

Couplings allow versatility in positioning the microscope for specific applications. An automated mechanism, the X-Y attachment, provides precision in controlling small movements of the microscope in the field of view. A coupling piece lets surgeons change the angle for side-to-side or front-to-back viewing. A universal tilt coupling can be integrated into the X-Y coupling.

Cameras

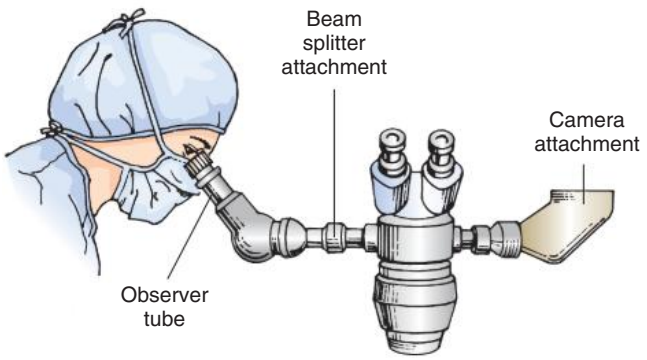
Still photographic, motion picture, videotape, and television cameras may be attached to the beam splitter, permitting filming of the surgical procedure (Fig. 20.10). The camera unit should be in the upright position when connected to the operating microscope. It may require the use of a stronger illumination source. One should check to ensure film is in the camera by trying to rewind the film cartridge holder. The patient's and surgeon's names, the date, and the time are documented on the film or video cartridge to prevent mixing recorded images among patients. The use of recording equipment may require special patient consent in some institutions. The recorded procedure is useful in assisting, teaching, and research.

Laser Microadapter

Laser beams can be directed through the operating microscope. The microscope and laser head couplings should be perfectly aligned in the grooves and protrusions on the metal adapters. A screw and locking pin secure the coupling. In the operating position, the laser head is at approximately a 60-degree angle to the microscope. It will not fire in a horizontal or upside-down position.

The microadapter must have a compatible lens with a focal length of 200, 300, or 400 mm so that the surgeon can properly adjust the focal point of the laser beam. A CO_2 laser with electronic components that delivers milliwatt energy may be used to vaporize tissues or weld tissues together. Colposcopes can be used for laser ablation of the uterine cervix. The laser is directed using a joystick.

Other types of lasers are directed through fiberoptics. To protect the surgeon's eyes, filter caps over optics should be the appropriate optical density for the wavelength of the laser being used. The entire team and patient must wear eye protection of the appropriate optical density when the laser is in use.



• **Fig. 20.10** Microscope accessories.

Remote Foot Controls

Simple microscopes are manually operated. It is more convenient for the surgeon to use motorized foot controls for functions such as focus, zoom, and tilt. Foot controls may be activated by switches of the pushbutton type, heel-to-toe, or side-to-side motion. The number of switches corresponds to the number of motor-controlled functions. There may be additional foot switches for the camera or for other non–microscope-associated equipment, such as cryosurgical, bipolar electrosurgical, or laser units.

Switches may be separated by a vertical bar to prevent inadvertent contact. The bar also serves as a footrest for the surgeon. Because the surgeon and assistant usually are seated during microsurgical procedures, the height of the OR bed must permit them adequate knee room to operate foot controls.

Microscope Drape

The entire working mechanism and support arm of the microscope are encased in a sterile drape. Draping the entire microscope permits it to be brought into the sterile field so that the surgeon can position the body and adjust the optics. Disposable drapes that are heat resistant, lint-free, nonreflective, transparent, and quiet are available to fit the configuration of all microscopes and attachments. The scrub person slides the drape over the body of the microscope, with hands protected as for draping a Mayo stand. The circulating nurse helps guide the drape toward the vertical column and secures it. The scrub person secures the drape to the oculars. Sterile lens covers or rubber bands may be supplied with the drape for this purpose.

If it is not heat resistant, a plastic drape may cause heat buildup beneath it that can damage the microscope. A heat guard may be applied over the light source, or heat may be evacuated through an opening in the top of the drape.

Care of the Microscope

Persons responsible for the microscope should consult the manufacturer's manual. Any malfunction should be reported to the OR manager or appropriate person who can arrange for repair service. A checklist to verify care and functioning of various parts before the surgical procedure is helpful. Everyone who assists with microsurgery must know how to set up, position, and otherwise care for the microscope as follows:

1. The microscope should be damp-dusted before use.
   a. External surfaces, except the lenses, are wiped with a clean cloth saturated with detergent-disinfectant solution.
   b. Casters or wheels should be clean to reduce contamination and prevent interference with mobility.
2. Lenses should be cleaned according to the manufacturer's recommendations only, to avoid scratching or damage to antireflective lens coating. Most manufacturers recommend sterile distilled water and lens paper. They must not be soaked in any solution.
3. The circulating nurse should prepare the microscope.
   a. When changing oculars, do not drop or fingerprint lenses. Avoid stripping the threads of screw mounts by seating the optics and turning in a counterclockwise direction until the threads align. Proceed by turning in a clockwise motion until secure. Take care not to overtighten. Right turns tighten; left turns loosen.
   b. Both hands should be used for attaching observation tubes, which are heavy.

c. Extra lamp bulbs and fuses should be on hand. The circulating nurse must know where they are stored and how to change them. It is advisable to check bulbs periodically to avoid the necessity of replacing them during a procedure. New bulbs should be inserted if a long procedure is anticipated. Bulbs should be changed with the power off.
d. Check electrical connections for proper fit or wire fraying. Take special care of power cables to prevent accidental breakage from heavy equipment rolling over them.
e. Check that all knobs are secured after the microscope is in the operating position.
f. Place foot controls in a convenient position so the surgeon does not have to search for them.

4. The microscope and accessories should be properly stored. Store away from traffic but close to areas where used.
   a. Openings into the microscope body for attachment of accessory devices, such as the observer tube, should be closed with covers provided by the manufacturer when not in use to prevent accumulation of dust.
   b. Lenses and viewing tubes should be protected.
   c. The microscope and attachments should be enclosed in an antistatic plastic cover when not in use to keep them free from dust.
   d. Power cords should be neatly coiled for storage.

General Considerations in Microsurgery

Patient

The patient is prepared for the surgical procedure according to the location of the surgical site. He or she should be positioned comfortably and safely with the OR bed locked in position. The surgical site is immobilized if possible.

Anesthesia

If a general anesthetic is to be administered, the anesthesia provider should be informed in advance of the surgeon's intention to use the microscope. This is especially pertinent in procedures in which patient movements under light anesthesia could result in disaster. In addition, the anesthesia provider's position in relation to the patient should be considered to allow room for the microscope. The anesthesia provider should be aware that microsurgical procedures will take somewhat longer.

With local anesthesia, the patient should be instructed to lie quietly and tell the anesthesia provider or circulating nurse of a desire to move. Many patients sleep during the procedure. A startle reflex on awakening or unexpected movement is especially hazardous in microsurgery, wherein the surgeon's mobility and field of view are limited. If the patient jerks or turns, he or she literally may move out of the surgeon's hands and often out of view of the microsurgical field. Therefore the patient should be closely monitored.

Stability of the Surgical Field

A vital factor for successful microsurgery is stability of the surgical field, microscope, and surgeon's hands. The complete microsurgical unit consists of the OR bed with the patient, the microscope, and the surgeon's position. These should be functionally positioned in relation to each other so that major adjustments need not be made during the surgical procedure. The surgeon and circulating nurse should check that all components are properly placed before the incision is made.

Armrests and Chair

It is important that the surgeon's hands be adequately supported, because a shift of even ½ inch (1 mm) can alter the precision of motion, particularly at high magnifications. Support of the surgeon's arm should be continuous from shoulder to hand to give stability and to minimize tremor, especially in fine finger movements. A detachable, sterile, padded wrist support such as the Chan wrist rest may be affixed to the OR bed for eye procedures.

If the surgeon is seated, a chair with hydraulic foot controls for raising or lowering provides the necessary forearm support by means of attached armrests. These armrests are individually draped. Mayo stand covers are convenient. Armrests can be moved independently to a variety of levels and positions. They are secured in the desired position. The surgeon should be in a comfortable position to work.

Duties of the Scrub Person

Although a stabilized situation is crucial, a second fundamental necessity is for the surgeon to keep his or her eyes on the field of view through the microscope at all times. Looking away from the field requires readjustment of vision to the field. Cooperation and coordination by the scrub person in carrying out the following duties will prevent the surgeon's distraction from the surgical site:

1. Set up the Mayo stand and instrument table without touching the tips of instruments. Holders are available to keep instrument tips in the air and to keep them separated. Microinstruments are handled individually. They are more susceptible to damage than are standard instruments. Edges are easily dulled, and fine tips are easily bent or broken. Extreme caution is necessary not to catch tips on any object that could bend them.
