2. Place instruments on the Mayo stand in anticipated order of use. Place the Mayo stand and instrument table conveniently to the surgeon's hand so that he or she does not have to look around the microscope.
3. Pass instruments by placing them in the surgeon's hand in position for use, and guide the hand toward the surgical field so that the surgeon may keep his or her eyes on the field.
4. Keep debris (e.g., blood, mucus, suture ends) from the tips of instruments by wiping them gently on a nonfibrous sponge or lint-free gauze. Replace them in their original position on the Mayo stand, not touching each other.
5. Assist efficiently but never put hands in the surgical field unless requested to do so.
6. Understand the need for slow dissection at times. Do not let attention stray or make excessive movements; observe the video monitor if one is available. Noise should be kept to a minimum during critical times to avoid distraction.

The increased time needed for use of the operating microscope can be minimized by adequate preparation and efficient assistance. Each team member should thoroughly understand the microscope and every aspect of microsurgical techniques.

Team members can be kept up to date by inservice explanation of new instruments and demonstration of the microscope. It is extremely helpful and contributory to understanding for the surgeon to show perioperative team members anatomic structures and instruments through the microscope. A comparison of microinstruments with standard instruments under the microscope is always a revelation.

A television monitor is advantageous in providing the scrub person and anesthesia provider continuous observation of the surgical procedure. All members should be completely familiar

with instrumentation. Not only are instruments then properly cared for, but even more important, surgical time is reduced.

Ultrasonosurgery

Ultrasonosurgery, also referred to as cytoreductive debulking surgery, is useful in removing or reducing tumors in highly vascular, delicate tissue such as the brain, liver, kidney, and spleen. The original prototypes of ultrasonic equipment were developed in 1967 to fragment and aspirate cataracts. An ultrasonic aspirator, such as the Cavitron, simultaneously fragments, irrigates, and aspirates tissue. During the fragmentation process, sterile fluid passes through the handpiece to emulsify target tissue. The emulsified tissue is aspirated and collected in a closed-container system.

A transducer in the handpiece converts electrical energy into mechanical motion. Ultrahigh-frequency sound waves produce vibrations at the tip. These vibrations are of the same physical nature as sound but with frequencies above the range of human hearing. Ultrasound has a frequency greater than 30,000 Hz. The vibrating tip of the ultrasonic aspirator fragments tissues at the cellular level. When the tip contacts tissue, vapor pockets within high-water-content cells cause cell walls to separate and collapse. The ultrasonic aspirator is used to disrupt tissues, or tracts, particularly in the central nervous system. It is also used to emulsify tumors with minimal mechanical trauma to surrounding nerves and blood vessels. A device that combines electrosurgery with ultrasonic dissection also allows coagulation during resection and aspiration of a tumor mass.

An ultrasonic probe can be inserted through an endoscope to fragment renal or ureteral calculi (i.e., kidney stones). A suction channel is incorporated into the probe to aspirate fragments as stone is pulverized by ultrasonic energy.

Ultrasonic Blade and Scissors

The harmonic scalpel is a handpiece that receives electrical energy from a generator activated by a foot pedal or finger control, but does not function as an ESU. The bipolar energy is converted into mechanical vibrations at the rate of 55,000 waves per minute. The instrument cuts and spot coagulates protein molecules by ultrasonic vibration with minimal thermal effects. The tissue dissolves on contact and coagulates in response to the protein denaturation.

The working end of the handpiece accommodates scissors or a blade tip. The tip should be kept clean with a moist sponge during the procedure and the team should avoid contact with any by-products of the protein molecule destruction such as steam or plume. Although heat production is minimal, the risk for burning nontarget tissue is possible until the tip cools. Do not place the hot tip on a wet towel over the patient because the heat will transfer to the patient's tissues via the moisture and cause a burn. When activated, the generator emits a humming sound.

Integrated Technologies

As mentioned, several technologies may be used for minimally invasive surgical procedures. Video-assisted laser endoscopy allows the surgeon to remove organs and tumors and ablate or repair tissues without making a major incision. An endoscope is introduced into a body cavity through a small incision. The viewing area from the telescopic lens of the scope is magnified from a video camera to a video screen. While viewing the screen, the surgeon can direct a laser beam through the endoscope to the target tissue. (Endoscopy is described in detail in Chapter 32.)

Other instrumentation may be introduced through adjacent small incisions for dissection, ligation, and suturing. These instruments can be manipulated while the surgeon looks through the endoscope or at a monitor. Manipulations may be observed with use of fluoroscopy or a video camera. Ultrasonic and thermal probes, electrosurgical electrodes, and laser beams can be directed through endoscopes.

Laser beams also can be directed through the operating microscope. Lasers and microscopes may be controlled by computerized systems. Computers can automatically scan tissues to select target tissue for the laser beam. Operating microscopes may contain voice-activated minicomputers that manipulate controls for fine adjustments, thus eliminating foot and hand switches.

21 Preoperative Preparation of the Patient

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Discuss the importance of preoperative preparation.
- Describe the content of preoperative patient teaching.
- List several preoperative assessment factors relevant to all presurgical patients.
- Identify the key elements in a successful preoperative interview.

KEY TERMS AND DEFINITIONS

Anxiety Emotional state characterized by subjective feelings of tension, apprehension, and/or worry. The autonomic nervous system is activated.

Electronic medical record (EMR) Patient charts are primarily electronic and require password access. Paper documentation is not used in all facilities.

Preadmission testing (PAT) Preadmission testing area where preoperative patients are assessed and instructed.

Presurgical holding area Area within the perioperative environment where the patient waits immediately before entering the operating room.

Hospitalized Patient

Regardless of the physical setting in which an invasive or surgical procedure will be performed, each patient should be adequately assessed and prepared so the effects and potential risks of the surgical intervention are minimized. This involves both physical and emotional preparation. Perioperative caregivers should establish a baseline for the patient's preoperative condition so changes occurring during the perioperative/perianesthesia care period can be easily recognized.

Although most patients undergoing a surgical procedure are admitted the day of surgery, some are admitted to the hospital one or more days before the scheduled procedure. The acuity of illness or the patient's general health status, as well as the surgical procedure to be performed, will influence whether the patient should be admitted to the hospital preoperatively or can arrive the day of the procedure. Radiologic, endoscopic, or other diagnostic studies may be performed to confirm the medical diagnosis. Systemic disease or chronic illness, such as diabetes or heart disease, should be under control to the extent possible preoperatively.

Most patients who will remain in the hospital postoperatively are admitted the day of the surgical procedure. Often referred to as am or morning admission, to come in (TCI), or to be admitted (TBA), these patients may be prepared for the procedure in a same-day admission unit before transferring to the operating room (OR) suite. (Some facilities have a preoperative check-in area within the OR suite.) From the OR, some patients may go to the postanesthesia care unit (PACU) to recover from anesthesia before being transferred to a patient care unit; others are transferred directly from the OR to the intensive care unit (ICU). The magnitude of the surgical procedure and the patient's postoperative needs for complex care will determine when the patient can be discharged safely to home.

Preoperative Preparation of All Patients

Specific activities such as the preoperative history and physical examination are completed and documented before the patient arrives in the OR. This process can be performed before admission to the hospital or ambulatory care facility; other activities are performed when the patient arrives in the **preadmission testing (PAT)** area. The preoperative physical preparation is designed to help all patients overcome the stresses of anesthesia, pain, fluid and blood loss, immobilization, and tissue trauma. Preparation often begins before the patient's hospital admission, with the institution of nutritional or drug therapy. An attempt is made to bring all patients to their best possible physical status before surgery. Appropriate consultations, such as a cardiac workup, or

weight loss, and physical therapy are sought when necessary. Some facilities offer programs that include preoperative and postoperative therapies for total joint and bariatric surgeries.

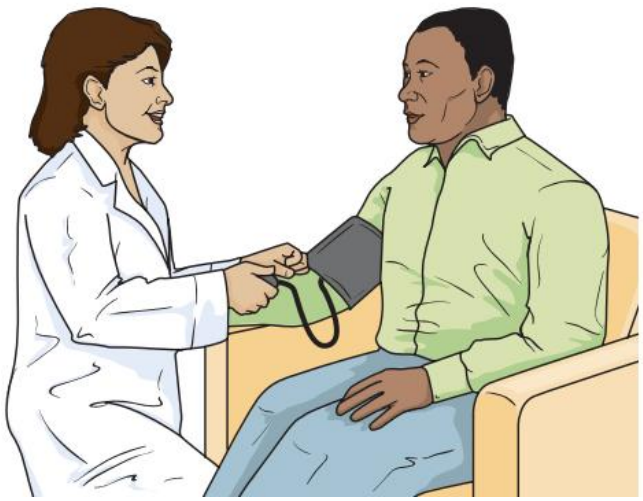
Preadmission Procedures

Some preoperative preparations can be performed in the surgeon's office. Patients are then referred to the preoperative testing center of the hospital or ambulatory care facility. Tests and records should be completed and available before the patient is admitted the day of the surgical procedure. PATs are scheduled according to the guidelines of each facility. Some tests are acceptable for up to a 30-day period or are repeated before admission. The type of testing performed depends on the patient's known or suspected condition and the complexity of the surgical procedure. The preoperative preparations include the following:

1. *Medical history and physical examination:* These are performed and documented by a physician, nurse practitioner, physician assistant (PA), or the registered nurse first assistant (RNFA). A list of medications and herbal supplements should be documented, and any allergies and sensitivities should be noted. The preoperative nurse establishes the baseline for the patient's vital signs (Fig. 21.1).
2. *Laboratory tests:* Testing should be based on specific clinical indicators or risk factors that could affect surgical management or anesthesia. Tests include age, sex, preexisting disease, magnitude of surgical procedure, and type of anesthesia. Ideally these tests should be completed 24 hours before admission so the results are available for review. Some facilities perform laboratory studies the morning of the procedure.
   a. Hemoglobin, hematocrit, blood urea nitrogen, and blood glucose may be routinely tested for patients who are age 60 or older.
   b. Hematocrit is usually ordered for women of all ages before the administration of a general anesthetic.
   c. Complete blood count and blood chemistry profile may be indicated. Differential, platelet count, activated partial thromboplastin time, and prothrombin time tests also may be ordered.
   d. Urinalysis may be indicated by the type of surgical procedure, medical history, and/or physical examination.
   e. A pregnancy test may be required for females of childbearing age who have not had a hysterectomy.
3. *Blood type and crossmatch:* If a transfusion is anticipated, the patient's blood is typed and crossmatched. Many patients prefer to have their own blood drawn and stored for autotransfusion. Patients should be advised that blood banks charge an additional fee to store and preserve autologous blood for personal use.

   Even if the patient is to have an autotransfusion, his or her blood should still be typed and crossmatched in the event that additional transfusions are needed. If the patient refuses to accept blood transfusions, the appropriate documentation of refusal should be completed according to the policies and procedures of the facility.
4. *Chest x-ray:* A preoperative chest x-ray study is not routinely required for all patients. It may be required by facility policy or medically indicated as an adjunct to the clinical evaluation of patients with cardiac or pulmonary disease and for smokers, patients age 60 years or older, and cancer patients.
5. *Electrocardiogram (ECG):* If the patient has known or suspected cardiac disease, an ECG is mandatory. Depending on the policy of the facility, an ECG may be routine for patients ages 40 years or older.
6. *Diagnostic procedures:* Special diagnostic procedures are performed when specifically indicated (e.g., Doppler studies for vascular surgery).
7. *Written instructions:* The patient should receive written preoperative instructions to follow before admission for the surgical procedure. The written literature should be written with the patient's literacy level in mind. Additional methods of instruction should be made available for patients with special needs. Do not use abbreviations or acronyms because they can be confused and misunderstood. Web-based videos can be helpful for patients who cannot read. These instructions should be reviewed with the patient in the surgeon's office or in the preoperative testing center (Fig. 21.2).
   a. To prevent regurgitation or emesis and aspiration of gastric contents, the patient should not ingest solid foods before the surgical procedure. These instructions are usually stated as *NPO* (NPO is the Latin abbreviation for nil per os, or nothing by mouth). Solid foods empty from the stomach after changing to a liquid state, which may take up to 12 hours. The patient should be given an NPO time based on the time of surgery.

      Clear fluids may be unrestricted until 2 to 3 hours before the surgical procedure, but only at the discretion of the surgeon or anesthesia provider in selected patients. NPO time usually is reduced for infants, small children, patients with diabetes, and older adults prone to dehydration.
   b. The physician may want the patient to take any essential oral medications that he or she normally takes. These can be taken as prescribed with a minimal fluid intake (a few sips of water) up to 1 hour before the surgical procedure. Diabetic patients may be asked to hold medications the day of surgery. Patients taking anticoagulants or steroids may be asked to stop the medication for a specific number of days before the procedure.
   c. The skin should be cleansed to prepare the surgical site. Many surgeons want patients to clean the surgical area with an antimicrobial soap or wipes preoperatively. The patient



• **Fig. 21.1** Performance of the preoperative assessment is important to establish a health baseline. Vital signs, height in centimeters, weight in kilograms, and review of systems should be done.

GETBETTER HOSPITAL

PREOPERATIVE INSTRUCTIONS

Your doctor has scheduled your surgery to be performed at Getbetter Hospital on _____ (day) _____ (date) at _____ AM/PM. Please arrive at _____ AM/PM.

If you develop a cold, flu, or illness before surgery or cannot keep your surgery appointment, please call your surgeon.

DIETARY RESTRICTIONS

- Avoid alcoholic beverages and cigarette smoking for at least 24 hours before surgery.
- Finish dinner the evening before surgery no later than 8 PM.
- Nothing to eat or drink after midnight the night before surgery.
  (This includes candy, gum, mints, Lifesavers, ice chips, and water.)
- Eating or drinking may result in the delay or cancellation of surgery.
- Medications to be taken the day of surgery _____ with sip (1 ounce) of water.
- Medications not to be taken the day of surgery _____ .

FOR YOUR SAFETY AND COMFORT

- No makeup—it may cause eye irritation or corneal abrasions while under anesthesia.
- Remove nail polish and artificial nails from at least one finger on each hand—oxygen is measured by placing a sensor on your fingertip.
- Do not bring valuables or jewelry—jewelry must be removed before surgery.
- Dress simply in loose-fitting clothes (sweatsuits or yoga attire are ideal).

UPON YOUR ARRIVAL

- Report to Main Lobby Admissions Desk.

AFTER YOUR SURGERY

- No driving, operating of heavy machinery, heavy physical activity, or decision making for 24 hours after receiving an anesthetic.
- If you are returning home on the same day as your surgery, make arrangements for a responsible adult to accompany you. Your operation cannot be performed if a responsible adult is not with you.
- Call your surgeon for postoperative appointments.

If you have any questions, do not hesitate to call the Preadmission Testing Unit at xxx-xxx-xxxx or The Department of Anesthesia at xxx-xxx-xxxx.

Patient signature: _____

RN signature: _____

• **Fig. 21.2** Sample of written preoperative instructions for the patient.

may be instructed to shower with an antimicrobial soap, commonly chlorhexidine, for several days before and the morning of surgery.[1] Patients should be told not to allow the soap to get in the eyes or ears. Chlorhexidine preparations can harm the corneas and tympanic membranes. Patients who will undergo a surgical procedure on the face, ear, or neck are advised to shampoo their hair before admission, because this may not be permitted again for a few days or weeks after the procedure.

d. Nail polish and acrylic nails should be removed to permit observation of and access to the nailbed during the surgical procedure. The patient should be advised to uncover at least one fingernail if the anesthesia provider will use these monitoring devices during the procedure. Either the finger or toe can be used when a digit is desired, but the finger is usually more accessible.

Some sensors are adhesive and can be placed on an earlobe or across the bridge of the nose. The nailbed is a vascular area,

and the color of the nailbed is one indicator of peripheral oxygenation and circulation. The Oxisensor (optode) of a pulse oximeter may be attached to the nailbed to monitor oxygen saturation and pulse rate. A finger cuff may be used for continuous blood pressure monitoring. Nail polish or acrylic nails inhibit contact between these devices and the vascular bed.

e. Jewelry and valuables should be left at home to ensure safekeeping. If electrosurgery will be used, patients should be informed that all metal jewelry, including wedding bands and religious artifacts, should be removed to prevent possible burns. Loss prevention is a consideration as well.

f. Patients should be given other special instructions about what is expected, such as when to arrive at the surgical facility. A responsible adult should be available to take the patient home if the procedure, medication, or anesthetic agent renders the patient incapable of driving. Family members or significant others should know where to wait and where the patient will be taken after the surgical procedure.

8. *Informed consent:* The physician should obtain informed consent from the patient or legal designee. After explaining the surgical procedure and its risks, benefits, and alternatives, the surgeon should document the process and have the patient sign the consent form. This documentation becomes part of the permanent record and accompanies the patient to the OR. Policy and state laws dictate the parameters for ascertaining an informed consent.
9. *Nurse interview:* A perioperative/perianesthesia nurse should meet with the patient to make a preoperative assessment. Through physiologic and psychosocial assessments the nurse collects data for the nursing diagnoses, expected outcomes, and plan of care.

   From the assessment data and nursing diagnoses, the nurse establishes expected outcomes with the patient. The nurse develops the plan of care, which becomes a part of the patient's record. The nurse reviews the written preoperative instructions and consent form with the patient to assess the patient's knowledge and understanding. The nurse also provides emotional support and teaches the patient in preparation for postoperative recovery. Educational information and instruction may be given with a list of additional resources.
10. *Anesthesia assessment:* An anesthesia history and physical assessment are performed before a general or regional anesthetic is administered. The history may be obtained by the surgeon, and/or the patient may be asked to complete a questionnaire for the anesthesia provider in the surgeon's office or in the preoperative testing center.

    An interview by an anesthesia provider or nurse anesthetist may be conducted before admission if the patient has a complex medical history, is high risk, or has a high degree of **anxiety**.[2] All patients should understand the risks of and alternatives to the type of anesthetic to be administered. After discussion with the anesthesia provider, the patient should sign an anesthesia consent form.

A preoperative phone call by a perioperative nurse to the patient several days in advance of the scheduled surgical procedure may prevent cancellation because of inadequate preoperative testing. Testing requirements are reviewed with the patient, and arrangements for additional tests can be made as needed. The importance of preoperative preparations is reiterated, especially NPO status, when to take medications, and the availability of a responsible adult for transportation home after the surgical procedure (if having ambulatory surgery).

Before an Elective Surgical Procedure

In addition to the preadmission procedures described, the surgeon may write specific orders for other appropriate preoperative preparations.[3] All preadmission assessment and testing procedures may be performed after the patient is admitted to a surgical unit before the surgical procedure. Some patients may have the following requirements:

1. Bowel preparation: "Enemas till clear" may be ordered when it is advantageous to have the bowel and rectum empty (e.g., gastrointestinal procedures such as bowel resection or endoscopy, and surgical procedures in the pelvic, perineal, or perianal areas). An intestinal lavage with an oral solution that induces diarrhea may be ordered to clear the intestine of feces. Solutions such as GoLYTELY or Colyte normally will clear the bowel in 4 to 6 hours. Because potassium is lost during diarrhea, serum potassium levels should be checked before the surgical procedure. Geriatric, underweight, and malnourished patients are prone to other electrolyte disturbances from intestinal lavage.
2. Bedtime sedation for sleep in select circumstances for in-house patients.
3. The patient may be sent to the radiology department for x-rays or placement of a J-wire before breast biopsy surgery.

Preoperative Visit by the Perioperative/Perianesthesia Nurse

The patient should be assessed preoperatively. Every effort should be made through supportive measures to minimize the potential hazards of adverse psychosocial distress. Ideally this assessment takes place before the day of the surgical procedure; its purpose is to alleviate anxiety and fears. Factual information and clarification of misunderstandings will be helpful in this regard, as will the opportunity for the patient to express his or her feelings.

The broadened scope of perioperative nursing encompasses the phases of preoperative and postoperative care that contribute to the continuity of patient care. Preoperative visits to patients are made by RNFAs or perioperative/perianesthesia nurses skilled in interviewing and assessment. The interview provides the nurse an opportunity to learn about the patient, establish rapport, and develop a plan of care before the patient is brought to the perioperative environment.

Pros of Preoperative Visits

Preoperative visits with patients include the following list of advantages:

1. An experienced perioperative/perianesthesia nurse is well qualified to discuss a patient's OR experience. The nurse can orient and prepare the patient and family for the procedure and for the postoperative period.
2. The perioperative/perianesthesia nurse can review critical data before the procedure and assess the patient before planning care. The surgical site is marked with initials by the surgeon or surgeon's designee. An X is never used to mark the surgical site. Some surgical sites cannot be marked. The facility should have a policy and procedure for identifying surgical sites that cannot be easily marked, such as perineal regions, teeth, pharyngeal, intracranial, and other areas of the body not readily seen and initialed.
3. Visits improve and individualize intraoperative care and efficiency and prevent needless delays in the OR.

4. Visits foster a meaningful nurse-patient relationship. Some patients are reluctant to reveal their feelings and needs to someone in a short-term relationship.
5. Visits make intraoperative observations more meaningful by establishing a baseline for the measurement of patient outcomes.
6. Visits contribute to patient cooperation and involvement by facilitating communication. Mutual goals and expected outcomes are more easily developed.
7. Visits enhance the positive self-image of the perioperative nurse and contribute to job satisfaction, which in turn reduce job turnover and are thus benefits to the hospital. Because of increased patient contact, visits make perioperative and perianesthesia nursing more attractive to those who enjoy patient proximity and teaching.

Cons of Preoperative Visits

The disadvantages associated with preoperative visits include the following:

1. Cost-containment measures may not provide adequate qualified staffing or allow time to visit patients.
2. The admission of patients on the day of the surgical procedure or late the day before the procedure makes the timing of visits difficult.
3. Visits may produce friction among different patient care divisions if the preoperative visit program is not well planned and performed.
4. Repetitious use of interviewing terminology may lead to a lack of enthusiasm and spontaneity on the part of nurse interviewers.
5. If the nurse's interviewing skills are not practiced, patients may feel their privacy is being invaded. This could foster mistrust of the health care personnel.
6. Barriers to visits may arise from the perioperative nurse's inability to do the following functions:
   a. Verbalize and communicate effectively.
   b. Handle or accept a patient's illness.
   c. Handle emotionally stressed persons.
   d. Understand cultural, ethnic, and value system differences.
   e. Function efficiently outside of his or her customary environment.
   f. Recognize how personal beliefs and biases can influence objectivity.

Interviewing Skills

Interviewing is a form of verbal interaction and is a valuable tool for obtaining information. The interview can be directive and structured with predetermined questions in a specific, predetermined order that limits responses. An example of a directive question is, "Have you had a surgical procedure before?" A nondirective interview gives the patient more of an opportunity to respond openly. An example of a nondirective question is, "Can you tell me about your previous surgical experience?" The choice of technique depends on the information desired.

Determine the level of patient understanding about the surgical procedure. One method is to ask, "Can you tell me what we will be doing for you during your surgical procedure?" Some patients will not be able to articulate the terms or adequately describe the procedure. Direct inquiry about specific procedures may be necessary, but give the patient plenty of opportunities to describe the anticipated procedure in his or her own words. Nonverbal patients may be able to point to a body region.

A structured interview is valuable in learning about an individual's health history. The unstructured interview gives a portrait of the patient's emotional reactions, concerns, and personality. An effective preoperative interview usually includes questions about both facts and feelings. The informal observation of nonverbal behavior is an essential component of the interview. The setting should be conducive to communication, and all questions should be relevant. The interviewer should be able to handle the situation with spontaneity, judgment, and tact. The interview should be meaningful to both the patient and the nurse.

Structured Preoperative Visits

1. Review the patient's chart and **electronic medical records (EMRs)**. Focus on medical and nursing diagnoses and the surgical procedure to be performed. Collect any information relevant to planning care in the OR. If the patient is admitted to the hospital, discuss the assessment data and the plan of care with the unit nurses before visiting the patient.

   Consideration is given to the patient who is a health care professional. Nurses, surgeons, technologists, and others may need surgical intervention. They may have extended knowledge of what will be done in the procedure and the potential for complications beyond what the average patient may possess. It is suggested that these patients be treated with respect for their knowledge, but still treated as patients. Do not assume they know everything about what will happen. Elicit feedback as the visit progresses to determine where to fill in or hold back on explanations. Never discuss personal information concerning the patient who is a health care professional with colleagues unless it is a need-to-know situation involving direct care. Privacy is a serious ethical concern.

   The perioperative nurse should not do the preoperative visit for a family member, neighbor, or personal friend. This visit should be deferred to another nurse, who is unknown to the patient.

   Nursing data include the following pertinent information; these baseline parameters are essential for accurate intraoperative and postoperative assessment.
   a. Biographic information (name, age, sex, family status, ethnic background, educational level, literacy, patterns of living, previous hospitalization and surgical procedures, religion).
   b. Physical findings (vital signs; height; weight; skin integrity; allergies; the presence of pain, drainage, or bleeding; state of consciousness and orientation; sensory or physical deficits; assistive aids or prosthetics).
   c. Special therapy (tracheostomy, inhalation therapy, hyperalimentation).
   d. Emotional status (understanding, expectations, specific problems concerning comfort, safety, language barrier, and other concerns).
2. Choose an optimal time and place without interruptions. Handwashing should be done before and after the visit.
   a. Patients who will be admitted on the day of the surgical procedure may be interviewed in the preoperative testing center several days before the surgical procedure. If this is not feasible, a telephone call to the patient may provide an alternative means of contact.
   b. Patients who have been admitted to the hospital may be visited in a patient care unit the day before the surgical procedure.
   c. Allow adequate time for the interview, usually 10 to 20 minutes unless the patient has complex problems or

special needs that require more time. Give the patient time to think and respond and to ask questions.
   d. If the patient is in acute physical or psychological distress, offer support and consider rescheduling the visit. The visit may need to be canceled or conducted through a family member or significant other. An emergency surgical patient may be assessed in the preoperative holding area.
   e. Do not conduct the interview on the morning of the procedure unless there is no other option. Patients are not psychologically receptive to preoperative teaching at this time. Premedicated patients may be susceptible to suggestions such as, "You will have minimal discomfort after the surgical procedure."
3. Greet the patient by introducing yourself and explaining the purpose of the visit. Tell the patient that the visit is a routine part of care so that he or she does not feel singled out because of his or her medical diagnosis. Unless specifically requested to use a first name, demonstrate respect at all times by addressing the patient by his or her last name, preceded by Mr., Mrs., or Ms. Terms such as "honey," "dear," or "sweetheart" are unacceptable. Children are usually addressed by their given first name unless the family uses a nickname.
   a. Put the patient at ease. Sit close enough so the patient can easily see and hear you. Avoid standing over the patient. Sitting will make the patient feel that there is no hurry.
   b. Secure the patient's attention and cooperation. Establish eye contact.
   c. Speak first with the patient alone (unless the patient is a small child, an individual who needs an interpreter, or an individual who is mentally impaired). This affords the patient privacy so he or she may feel free to talk. Then, if the patient is willing, the family may be invited to participate and ask questions. The family should be present during the preoperative teaching to learn how to assist the patient postoperatively.
   d. Allow the patient to maintain self-respect and dignity.
   e. Instill confidence in the patient by having a neat appearance and a positive attitude. Establish rapport by demonstrating warmth and genuine interest. Avoid displaying an authoritative manner.
   f. Use language at the patient's level of development, understanding, and education.[4]

Gathering Information

1. Obtain information by asking about the patient's understanding of the surgical procedure. Disfiguring or palliative procedures can be stressful to the patient. Psychological counseling may be indicated.
   a. Assess the patient's level of information and understanding and check its accuracy to determine whether further instruction or clarification is needed. Ask questions such as, "What has your surgeon told you about the surgical procedure?" Correct any misconceptions about the surgical procedure as appropriate within the scope of nursing.
   b. Permit the patient to talk openly. The objective is to gather data that will generate the plan of care to be implemented by the perioperative team.
   c. Direct questions should be used with caution and are not suitable for collecting all objective data. Construct open-ended questions to elicit information more detailed than one-word answers.
   d. Listen attentively. To preserve self-esteem the patient may tell you what he or she thinks you want to hear. A patient's statement that ends in a question may be either a request for more information or an expression of a feeling or attitude.
2. Orient the patient to the environment of the OR suite and interpret policies and routines.
   a. Tell the patient the scheduled time of the surgical procedure, the approximate length of the procedure, and the probable length of stay in the PACU. Explain the procedures that will be performed in the preoperative holding area before the surgery if this is the routine.
   b. Ask the patient if family members or friends will be at the facility during the surgical procedure. They should be informed how early to be there to see the patient before sedation is given. Tell the patient and family where the waiting room is located.
   c. Tell the patient that the family will be updated on the progress of the surgical procedure and informed when he or she arrives in the PACU if this is hospital policy. Communicating the progress of the procedure, especially if it is prolonged, provides emotional support and decreases the family's anxiety.
3. Review the preoperative preparations that the patient will experience.
   a. Familiarize the patient with whom and what will be seen in the perioperative environment. Many perioperative nurses wear OR attire and cover jackets with name tags when they visit patients; attire can familiarize patients with the way they will see personnel the next day. Attire should be changed if the nurse reenters the OR suite after the visit.
   b. Use discretion regarding how much the patient should know and wants to know. Use words that do not evoke an anxiety-inducing state of mind. Do not use words with unpleasant associations, such as *knife, needle,* or *nausea.*
   c. Postoperative recovery begins with preoperative teaching, but keep the explanations short and simple. Excessive detail can increase patient anxiety, which reduces the attention span.
   d. Give practical information about what the patient should expect, such as withholding fluids, drowsiness, and/or dry mouth caused by preoperative medications; transportation to the OR and the holding area; and where he or she will be taken after the surgical procedure. Instruct the patient not to hesitate to ask for assistance at any time. Explain any other relevant special precautions.
   e. Give the basic reasons for procedures and regulations; this reduces patient anxiety. With children and older adults, the nurse may have to repeat information as reinforcement.
   f. Explain only the procedures of which the patient will be aware.
   g. If patient will be going to the ICU after the procedure, tell the family what they will see there, such as monitors and machines.
4. Tell the patient that an anesthesia provider will visit to discuss specific questions relative to anesthesia if this is routine.
5. Answer the patient's questions about the surgical procedure in general terms. Refer specific questions to the surgeon.
   a. Be honest and responsible in communications about a proposed diagnostic or surgical procedure. Complement, but do not overlap, the surgeon's area of responsibility. Do not

be unrealistic, falsify the truth, or give false reassurances to the patient or family. Do not say things such as, "It will be alright," or "Everything will be fine." Better to express, "We will take very good care of you."

b. Be extremely cautious about spelling out specific details of the treatment, procedure, and postoperative care unless you have been thoroughly briefed by the surgeon in charge. Surgeons individualize and tailor their plan of care to their own techniques and the patient's needs, and certain forms of therapy may be controversial. Continual interdisciplinary communication is essential.

c. If unable or unprepared to answer a legitimate question, tell the patient that his or her concern will be answered by the appropriate personnel. For example, say, "I don't know, but I'll get that information for you." Then be certain to follow up with an answer.

6. Encourage the patient and family to discuss their feelings or anxieties regarding the surgical procedure and anticipated results.

a. Motivate and assist the patient and family to gain perspective, objectivity, awareness, and insight. A skilled professional nurse will know how to discourage wishful thinking for miraculous cures while also communicating an understanding of their fears and wishes for an uncomplicated, fast recovery.

b. Observe emotional reactions.

Addressing Patient Needs

1. As an interviewer be objective about personal feelings. Listen to what the patient is asking without feeling threatened. Do not superimpose personal feelings onto what the patient is actually expressing. Empathy is appropriate in this environment.

a. Acknowledge the effect of the procedure on the patient's sexuality if appropriate. Allow the patient to express personal feelings without evoking shame or guilt. Include the family or significant others as the patient desires. Adolescent patients may not want to talk about personal issues in front of parents.

b. Try to help the patient solve his or her own problems when possible. Ask open-ended questions that help explore a subject or feelings, but do not probe to elicit specific responses. Do not destroy the patient's coping mechanism; encourage an appropriate one. The visit is not a structured psychiatric counseling session.

c. Listen to the anxieties of the patient, family, or significant others in a realistic time frame, and get others to follow through as necessary. Do not attempt too full an agenda, but sort out what is legitimate. You cannot solve all problems in 20 minutes. For example, say, "I'll share this information with someone who can help you with this problem." Use a colleague's expertise to assist you or to make a proper referral.

d. Comfort the patient and convey a sense of security and trust. Use touch as appropriate. Touch has a positive effect on physiologic parameters, such as respiration and circulation, and it can lower heart rate and blood pressure. Its calming effect can improve perceptual and cognitive abilities. It establishes rapport, provides reassurance, and conveys warmth, empathy, encouragement, and support. Touch should be comfortable. A perceptive nurse can tell when a patient resents being touched; respect the patient's feelings. Patients with decreased visual acuity appreciate the assurance that touch can give, but always speak first to avoid startling the patient. Remember to wash hands after the visit.

e. Reassure the patient that he or she will not be alone but will be constantly attended by competent perioperative team members. Try to increase the patient's trust and confidence in the team as a whole.

f. Allow time to deal with the patient's questions or concerns. Ask the patient, "Do you have any other concerns?" Never bring a patient's feelings into the open and then cut off the conversation. Do not interrupt, interrogate, or belittle an expressed fear or seemingly irrelevant topic. All questions are significant to the patient. Answer the questions honestly, and try to resolve concerns.

2. Identify any special needs of the patient that will alter the plan for intraoperative care. The preoperative visit is the time for a total assessment to guard against a traumatic experience for the patient.

a. Observe any physical characteristics of the patient that might affect positioning or require special setups. The plan of care will include considerations for extra tall, obese, or left-handed patients. For example, an intravenous (IV) infusion should be started in the right arm of a left-handed person to minimize the limitation of manual dexterity unless contraindicated.

b. Observe the patient for physical limitations such as pain on moving, an amputated extremity, paralysis, or sensory loss. This information enables the circulating nurse to anticipate how much cooperation to expect from the patient and how much additional help may be needed. A pad of paper and pencil may be needed to communicate with a patient who is unable to speak or hear. In certain instances an interpreter may be needed.

c. Ask the patient whether he or she wears any type of prosthetic device. Explain, per accepted hospital policy, that the device should be removed before the surgical procedure, either at the bedside or in the OR. Explain that jewelry should be removed to prevent damage or loss. Peripheral swelling of fingers can be complicated by the wearing of rings. Piercings could cause alternative pathway burns when cautery is used and could interfere with the surgical site.

d. Determine how a preexisting medical condition should be managed in the OR. For example, it is important that the circulating nurse know about the presence of an implanted pacemaker or defibrillator. A monopolar electrosurgery unit (ESU) could cause certain models of implanted devices to malfunction; therefore monopolar ESU would be contraindicated and bipolar ESU should be used instead.

e. Know the patient's special requests. Placing a note on the front of the chart or in a special section of the EMR is one method of relaying temporary information about a patient's special requests. These notes are not part of the permanent record.

3. Use educational materials to supplement the interview, if available and appropriate.

a. Written instructions with photographs or drawings are useful for explaining procedures and equipment. These can be presented in a booklet or pamphlet that the patient can keep and share with family members or significant others.

b. Utilization of smart devices, videos, slide/taped programs, or DVDs help reinforce the preoperative teaching.

Preoperative Teaching

Teaching is a function of perioperative nursing practice and embraces perception, thought, feeling, and performance. During the preoperative visit the perioperative nurse supplements the instructions of the other perioperative team members and gives information unique to the patient's specific surgical procedure. Care is taken not to use jargon and explanations the patient does not understand.

The perioperative nurse teaches patients how to participate in their own postoperative recovery. Patients must have a readiness to learn. Preoperative teaching should take place at three levels:

1. *Information:* Explanations of procedures, patient care activities, and physical feelings that the patient may encounter during the perioperative experience help the patient identify what is happening and what to expect. Such explanations also enhance patient satisfaction with care.
2. *Psychosocial support:* Interactions enhance coping mechanisms to deal with anxiety and fears and provide emotional comfort.
3. *Skill training:* Guided practice of specific tasks to be performed by the patient in the postoperative period can decrease anxiety, hasten recovery, and help prevent complications.

Effective Teaching

Patient teaching involves emotional energy on the part of the nurse. It can produce behavioral changes in patients as they become better prepared, both physically and emotionally, for the surgical procedure. They also learn how to use the health care system. Learning self-help has a positive effect. Discharge planning begins during preoperative teaching. The patient knows what to expect and where to go for help after discharge if needed, such as a support group.

Patient teaching may be conducted in an informal, individual manner or in a formal, group instructional setting. In conjunction with other team members the nurse-instructor should first formulate attainable learning objectives with the patient's input. The development of learning objectives is based on the assessed level of the patient's emotional receptivity and mental capacity.

The nurse also assesses, by observation and elicited response, factors such as the patient's developmental level, sight, hearing, and acceptance of his or her problem. Before beginning an explanation, the nurse should verify what the patient already knows, needs to know, and wants to know. An understanding relationship with the patient facilitates the teaching/learning experience.

The nurse assists family members in coping with the situation to the extent of their ability. The success or failure of treatment often depends on what happens after the patient leaves the hospital. The family's knowledge and understanding of the patient's needs, their coping skills, and their willingness to help are important factors in recovery. Teaching should be presented at the family members' level of particular resources and knowledge base. Other points to consider include:

1. Arrange the environment so that a teaching/learning exchange can take place. A quiet, undisturbed environment and proper timing are important.
2. Language is the fundamental tool for education. Use understandable terms. Do not equate intelligence level with educational level. The nurse is accountable for what is taught.
3. Set priorities and teach what is significant and appropriate to the patient's particular needs.
   a. Break down instructions into manageable steps; for example, instruct the patient to breathe deeply and then cough while he or she splints the site of the surgical incision with a pillow.
   b. Put content into a logical sequence of activities to facilitate learning. For example, to avoid the possibility of an inappropriate dosage, instruct the patient to write down the time he or she takes the medication when at home.
   c. Give the reasons for and the benefits of specific activities. For example, the movement of legs and toes and ambulation postoperatively, unless contraindicated, aid circulation and prevent venous stasis.
   d. Adapt the teaching method and timing to the specific situation. The patient may reject teaching not relevant to the immediate present. For example, a patient about to have a heart valve replacement procedure may listen to instructions but may actually be concentrating on the fact that his or her heart is going to be cut open.
   e. Do not overburden the patient with a multitude of facts.
4. Recognize the patient's need to know. This recognition, not pressure, should be the motivating factor in learning.
5. To evaluate understanding, ask the patient to repeat in his or her own words what has been explained during the instructional session and to demonstrate deep breathing and leg exercises.
6. Written information is helpful in reviewing verbal instruction. Go over the material with the patient, and test his or her comprehension by asking questions. A patient who is experiencing pain or anxiety or who is under the influence of medication may not fully understand verbal communication.
7. As the resource person, be consistent, concise, and organized. Repeat instructions to help the patient retain them.

Patients who receive preoperative instructions from and interact with the perioperative nurse may experience less apprehension, better tolerate the surgical procedure, and seem more secure and comfortable postoperatively. Patients usually remember what has been taught. They react more positively to their perioperative experience than do patients who have not been given the benefit of this interaction.

At the end of the preoperative assessment and teaching session the perioperative nurse should not depart from the patient abruptly but should briefly summarize the events that have taken place. The nurse should give the patient time for any questions before leaving. The patient should be left with the understanding that a postoperative visit may be made after the procedure if this is the policy.

Preoperative Visit by the Anesthesia Provider

The anesthesia provider is knowledgeable in the pathophysiology of disease as it pertains to anesthetic agents. Participation in the patient's preoperative preparation can reduce intraoperative complications. If the patient has been admitted the evening before the surgical procedure, the anesthesia provider usually assesses the patient if he or she is scheduled for anesthesia. Otherwise the patient may be seen before admission in the preoperative testing center, in the same-day procedures unit, or in the preoperative holding area. All patients should be evaluated before any anesthetic is administered.

Judgment and skill are important in the selection of agents and the administration of anesthesia, but firsthand knowledge of the patient is extremely valuable. The anesthesia provider visits the patient to seek information and establish rapport, inspire

confidence and trust, and alleviate fear. Preparation for anesthesia begins with this visit.

Before meeting the patient, the anesthesia provider reviews the patient's past and present medical records. If recent laboratory or other test reports are not in the chart, all decisions and the surgical procedure are delayed until all essential information is available. Special attention is given to past surgical procedures and any disease or complicating processes, especially those involving vital organs or administration of anesthesia drugs.

After introducing himself or herself to the patient, the anesthesia provider performs the following tasks:

1. Obtains a history pertinent to the administration of anesthetic agents by questioning the patient about past anesthetic experiences, allergies, adverse reactions to drugs, and habitual drug usage (Fig. 21.3). Tranquilizers, cortisone, heart and blood pressure medications, alcohol, herbal preparations, and recreational drugs, for example, influence the course of anesthesia. Smoking habits, genetic and metabolic problems, and reactions to previous blood transfusions also influence the choice of anesthetic.

   Patients are advised to report all herbal supplements, because they can cause serious complications such as bleeding (Table 21.1 describes common herbs and dietary supplements). The American Society of Anesthesiologists (ASA) cautions about herbal remedies and the serious complications that can ensue.
2. Evaluates the patient's physical, mental, and emotional status to determine the most appropriate type and amount of anesthetic agent(s).
   a. Examines the patient as necessary to obtain the information desired, with particular interest in the heart and lungs.
   b. Palpates the needle insertion site and observes for skin infection if a regional block anesthesia is contemplated.
   c. Assesses the patient's mental state and cognitive ability subjectively and observes for signs of anxiety.
3. Investigates the patient's cardiac reserve and observes for signs of dyspnea or claudication.
4. Asks the patient about his or her teeth. If indicated, explains that dental work may be damaged inadvertently during airway insertion.
5. Evaluates the patient's physique for possible technical difficulties in the administration of the anesthetic. The patient will be asked to move the head and neck in a natural range of motion. The oropharynx will be assessed.
   a. A short, stout neck may cause respiratory problems or difficult intubation. A stiff neck or unstable cervical spine such as from rheumatoid arthritis can make intubation difficult or dangerous, especially in a geriatric patient. Fiberoptic laryngoscope and/or awake intubation may be necessary.
   b. Active athletic and obese patients require more anesthetic than do inactive patients.

• **Fig. 21.3** The anesthesia provider assesses the patient and plans the anesthetic for the surgical procedure.

TABLE 21.1 Examples of Common Herbal and Dietary Supplements and Potential Complications

Herbal or Dietary Supplement	Action and Potential Complications	Notes on Patient Usage
St. John's wort	Prolonged sedative effect, photosensitivity, peripheral neuropathy, interferes with metabolism of some antibiotics, calcium channel blockers, and warfarin	Antidepressant, antiinflammatory, possibly antiviral
Ginkgo biloba	Bleeding, anticoagulant	Improves circulation and memory
Ginseng	Hypertension and tachycardia, hypoglycemia, bleeding	Boosts vitality, stimulant, enhances sexuality
Vitamin E	Bleeding, slows wound healing and collagen repair	Prevents heart disease
Vitamin A (beta carotene converts to vitamin A in the body)	Can cause complications in pregnancy	Reverses the adverse effects on wound healing caused by steroid use, enhances healing, boosts immune system, fights infection, fights inflammation
Vitamin C	Potential for kidney stones and anemia in toxic state; can interfere with vitamin B_{12}; water-soluble; excreted readily via kidneys	Enhances wound healing
Garlic	Bleeding, hypotension, hypoglycemia, antithrombotic, antiplatelet	Lowers cholesterol, prevents heart disease, fights infection

TABLE 21.1 Examples of Common Herbal and Dietary Supplements and Potential Complications—cont'd

Herbal or Dietary Supplement	Action and Potential Complications	Notes on Patient Usage
Fish oil	Bleeding, hypotension	Prevents heart disease
Bromelain (found in pineapple stems)	No known complications	Antiinflammatory, digestive aid
Echinacea	Liver complications, interferes with immunosuppression, can cause transplant rejection	Antiinfective, fights common cold, enhances wound healing
Ephedra (also known as ma huang)	Cardiovascular instability, palpitations, hypertension, seizures	Appetite suppressant, respiratory treatment, boosts energy
Kava	Prolonged sedative effect, liver toxicity	Sedative, antiepileptic
Valerian	Prolonged sedative effect, can go through withdrawal, potentiated by alcohol, nausea	Sedative, sleep aid, muscle relaxant
Black cohosh	Bradycardia, peripheral dilation, hypotension	Alternative to estrogen replacement
Ginger	Bradycardia, bleeding, hypotension	Antiemetic, digestive aid, cough suppressant, relieves menstrual cramps
Licorice	Hypokalemia and dysrhythmia, hypertension, bleeding, can affect electrolytes, edema	Digestive aid
Dong quai	Can increase the risk for bleeding	Used to treat menstrual issues
Green tea	Can increase the risk for bleeding, may elevate heart rate and blood pressure	Stimulant
Saw palmetto	Can increase the risk for bleeding	Used to treat urinary retention in men with benign prostatic hypertrophy and hair loss
Chaparral	Liver complications	Alternative anticancer therapy
Chamomile	Potential allergy, bleeding, can affect electrolytes	Digestive aid, antiinflammatory, antiinfective

   c. The patient's accurate weight should be known in both kilograms and pounds because the dosage of many medications is calculated from body weight. Most dosages are calculated in milligrams per kilogram.
6. Explains his or her preference of anesthetic, pending the surgeon's approval, and informs the patient what to expect concerning anesthesia. The patient's wishes are considered, if expressed.
7. Tells the patient or asks about restricted or prohibited oral intake before anesthesia, and gives the reasons for these restrictions. IV therapy is explained.
8. Discusses preoperative sedation in relation to the time the surgical procedure is scheduled to begin. Antibiotic administration is discussed if indicated 1 hour before the incision is made.
9. Reassures the patient that constant observation will be maintained during the surgical procedure and in the immediate postoperative period. Also explains the methods of monitoring vital functions.
10. Explains the risks of anesthesia without causing the patient undue stress.
11. Answers the patient's questions and allays his or her fears related to anesthesia.

Anesthesia Plan of Care

After this visit with the patient, the anesthesia provider performs the following list of steps:

1. Estimates the effect of the necessary positioning during the surgical procedure on the patient's physiologic processes.
2. Records preliminary data on the anesthesia chart.
3. Writes preanesthesia orders, including times for medication administration.
4. Writes a summary of the visit and the proposed anesthetic management of the patient on the physicians' progress note. This summary has medicolegal value if a problem subsequently develops, and it is also necessary for regulatory accreditation, such as for the state or The Joint Commission (TJC).
5. Assigns the patient a physical status classification for the purpose of anesthesia, as per the taxonomy adopted by the ASA.
   a. Class I theoretically includes relatively healthy patients with localized pathologic processes. An emergency surgical procedure, designated E, signifies additional risk. For example, a hernia that becomes incarcerated changes the patient's status to Class I-E.
   b. Class II includes patients with mild systemic disease (e.g., type 2 diabetes controlled by oral hypoglycemic agents or diet).
   c. Class III includes patients with severe systemic disease that limits activity but is not totally incapacitating (e.g., chronic obstructive pulmonary disease or severe hypertension).
   d. Class IV includes patients with an incapacitating disease that is a constant threat to life (e.g., cardiovascular or renal disease).
   e. Class V includes moribund patients who are not expected to survive 24 hours with or without the surgical procedure. They are operated on in an attempt to save their life; the surgical procedure is a resuscitative measure, as in a massive

pulmonary embolus. The patient may or may not survive the surgical procedure.

f. Class VI includes patients who have been declared brain dead but whose organs will be removed for donor purposes. Mechanical ventilation and life support systems are maintained until the organs are procured.

6. Consults with the surgeon and other physicians (e.g., cardiologist) about a patient who has been assigned a Class III, IV, or V status. Considers the critical nature of the surgical procedure in relation to the risks of anesthesia.
   a. In elective situations, the surgical procedure is postponed until anesthesia will be less hazardous (e.g., after acute respiratory infection or cardiac decompensation).
   b. In emergency situations, ideal practices may be altered or disregarded to meet the exigencies of the situation. For example, if a patient is hemorrhaging, there is no time to wait to replace a low red blood cell count. A multiple trauma victim with a full stomach may need a nasogastric tube inserted and suction applied, an endotracheal intubation while awake, or spinal anesthesia as applicable, and he or she may undergo a surgical procedure despite food ingestion.

In addition to the preoperative assessment of the patient and the administration and maintenance of the intraoperative anesthetic, the anesthesia provider may see the patient postoperatively. He or she has a responsibility to inform the patient of any unfavorable reaction to a medication or agent so that the patient is forewarned and can report these reactions to other physicians and anesthesia providers in future experiences.

Before Taking the Patient to the Operating Room

Before the patient goes to the OR suite, his or her physical and emotional status and vital signs should be assessed and recorded by the nurse on the surgical unit or in the same-day admission unit. Any untoward signs and symptoms and extreme apprehension are reported to the surgeon because they could affect the patient's intraoperative course. The following list outlines the preparations:

1. The patient puts on a clean hospital gown. The surgeon permits some patients to wear underpants or pajama pants if the lower body segment is not part of the surgical site. This is helpful in adolescents and patients who are embarrassed and uncomfortable. Any clothing removed in the OR should be placed in a clear plastic bag and labeled with the patient's name, date, and surgeon's name.

   Menstruating patients should use a sanitary napkin if they will be under general anesthesia for more than 2 hours. Tampons can be used if they will not remain in place for more than a few hours total. The presence of a tampon should be clearly noted in the chart so it is not forgotten if the surgery becomes more extensive and longer in duration. The circulating nurse should be informed verbally about the patient's menses so confusion does not arise if vaginal bleeding is noted.
2. Jewelry is removed for safekeeping. If a wedding ring cannot be removed, it is taped loosely or tied securely to prevent loss. The patient may be permitted to keep a religious symbol, but the patient should understand that it may be removed during the surgical procedure. Document the personal items and their disposition in the chart before, during, and after the procedure.
3. Unless otherwise ordered, dentures and removable bridges are removed before the administration of the general anesthetic to safeguard them and prevent them from obstructing respiration. Dentures are permitted during local anesthesia, especially if the patient can breathe more easily with them in place.

   Some anesthesia providers prefer that securely fitting dentures be left in place to facilitate the airway maintenance. Dentures are necessary to retain facial contours for some plastic surgery procedures. Dentures removed in the OR should be labeled and taken to PACU for placement in the patient's mouth during the postprocedure period.
4. All removable prostheses (e.g., eye, extremity, contact lenses, hearing aids, spectacles) are removed for safekeeping. In some instances the patient may be permitted to wear spectacles or a hearing aid to the OR. The circulating nurse safeguards them and sends them to the PACU with the patient. Contact lenses are removed before the administration of a general anesthetic because they may become dry and cause corneal abrasions.

   The patient's personal property is safeguarded to prevent loss or damage. Jewelry and valuables can be given to the family or sent to the hospital security department and locked in a safe. The clothing of ambulatory surgery patients can be stored in a locker. The clothing of TCI patients can be sent to the room or unit where the patient will be admitted postoperatively. Be sure that all items are bagged and clearly marked with the patient's name and date. Document the disposition of all patient belongings.
5. Long hair may be braided. Wigs should be removed or, in special cases, covered with a surgical cap. Hairpins are removed to prevent scalp injury.
6. Antiembolic stockings may be ordered for the lower extremities to prevent embolic phenomena. The stockings are applied before abdominal or pelvic procedures; for patients who have varicosities, are prone to thrombus formation, or have a history of emboli; and for some geriatric patients. They also are often applied for long procedures.
7. The patient voids to prevent overdistention of the bladder or incontinence during unconsciousness. This is especially important for abdominal or pelvic procedures in which a large bladder may be traumatized or may interfere with adequate exposure of the abdominal contents. The time of voiding is recorded. Double-check that a urine specimen is not needed before having the patient void. When indicated, an indwelling Foley catheter is inserted in the OR after the patient has been anesthetized. Some urologic procedures require a full bladder, such as urodynamics with cystometrography, or electromyography; therefore the patient should not void preoperatively.
8. If ordered, an antibiotic is given 1 hour preoperatively to establish and reach a therapeutic blood level of antibiotic prophylaxis intraoperatively. This may be a one-time dose or may be continued into the postoperative period. If cultures or specimens are obtained during the surgical procedure, a notation should be made on the pathology specimen sheet to indicate antibiotic use.
9. Preanesthesia medications are given as ordered. Their purpose is to eliminate apprehension by making the patient calm, drowsy, and comfortable. Patients who receive a preanesthesia medication should be cautioned to remain in bed. Many of the drugs cause drowsiness, vertigo, or postural hypotension. Therefore the side rails on the bed should be raised and the call bell placed within the patient's reach.

10. The patient, bed, and chart are accurately identified, and identifications are fastened securely in place. Allergies should be prominently noted on the chart and patient's wristband.

A preoperative checklist helps ensure the patient has been properly prepared. If preparation is inadequate, the surgical procedure may be canceled. All essential records, including the plan of care, must accompany the patient.

Emotional Preparation

By fulfilling spiritual and psychosocial needs, the caregiver helps provide the preoperative patient with as much peace of mind as possible. Understandably, the patient's tension level rises as the time for the surgical procedure approaches. An emotionally prepared patient will have a smoother postoperative course. If the patient has not seen his or her cleric or the hospital chaplain and makes such a request, the nurse should make every effort to contact that person for the patient.

Family members or significant others should be permitted to stay with the patient until he or she goes to the OR suite. Some hospitals permit parents to accompany infants and children into the OR suite. After leaving the patient, the family should be escorted by transport staff to the waiting area.

Transportation to the Operating Room Suite

Patients may be taken to the OR suite via a transport stretcher or wheelchair. If a stretcher is used, it should be pushed from the head end so the patient's feet go first. Rapid movements through corridors and around corners may cause dizziness and nausea, especially if the patient has been medicated. The attendant at the head end can observe for vomiting or respiratory distress. The patient may be more comfortable if the head end of the stretcher is raised.

If transporting by wheelchair, the patient should be instructed not to help with door opening and to keep hands on the lap. A blanket or sheet should be placed on the seat of the chair and a cover over the lap for modesty. It is inappropriate for bare buttocks to be seated on the uncovered surface of the wheelchair. Take care with tubing such as IV lines or catheters so they do not get tangled in the wheels. Urinary drainage bags should be maintained below the level of the bladder to prevent reflux infection.

Some ambulatory patients may be permitted to walk to the OR. They are given foot protection such as slippers to prevent injury. The slippers should be skid-proof on the bottom. Paper slippers may be unsafe. They do not protect from injury or slippage. The slippers may need to be removed for the procedure but should be retained until the end of the procedure and returned to the patient for use within the facility.

Ideally certain elevators are designated "For OR Use Only," which ensures privacy and minimizes microbial contamination. The patient should be comfortable, warm, and safe during transport. Side rails are raised and restraint straps are applied. The patient should be instructed to keep his or her arms, hands, and fingers inside the side rails during transport to avoid injury when going through doorways.

IV solution bags hung on poles during transportation are attached securely and placed at the foot of the bed away from the patient's head; this minimizes the danger of injury to the patient if the container should fall. Gentle handling is indicated to prevent dislodging IV needles or indwelling catheters.

Parent(s) sometimes are permitted to accompany a child. If the patient has a language barrier or is profoundly deaf, an interpreter may accompany him or her to the OR and stay until the induction of anesthesia. Persons accompanying the patient should be appropriately attired in cap, mask, and scrubs or jumpsuit before entering the OR suite.

Admission to the Operating Room Suite

Presurgical Holding Area

The patient is brought through the outer corridor to the **presurgical holding area** by transport personnel 30 to 45 minutes before the scheduled time of the surgical procedure, where he or she remains until taken to the OR. In some facilities this holding area is in the PACU in a designated space on one end of the unit that is not occupied by patients who are recovering from anesthesia. This can be an advantage because many of the nurses in the holding area also perform patient care in the PACU area. This can promote familiarity between the patient and the nurse.

Some conditions justify bringing patients to the OR suite in their beds. Such conditions include patients on pressure-reducing air mattresses, patients in traction, or cardiac patients who cannot be moved until transferred to the OR bed. The surgeon chooses the course that best benefits the individual patient.

Personnel stabilize beds, stretchers, and frames by locking the wheels when a patient is moved or is permitted to move from one surface to another. Mattresses also should be stabilized. An adequate number of personnel and a transfer device should be available to ensure patient safety during transfer between surfaces. The patient's head, arms, and legs are protected. When using a transfer roller or other device, a minimum of four people is required to control the head, foot, and both sides of the patient.

Some hospitals have individual rooms for anesthesia induction. The patient waits in this room and is administered an anesthetic before being taken into the OR.

Admission to the Presurgical Holding Area

The holding area nurse greets the patient by name and introduces himself or herself. The nurse stands next to the midsection of the stretcher so the patient can comfortably see him or her. The holding area nurse performs the following steps and documents them on the surgical checklist:

1. Places a warm blanket on the patient, verifies patient identification (checking wrist band information) by name and date of birth, and notifies the individual at the surgery control desk that the patient is in the holding area.
2. Verifies the surgical procedure, site, and surgeon verbally with the patient and/or family, as appropriate. The surgical site is validated by observing the indelible ink of the surgeon's initials. Hospital policy is followed for identification of surgical sites that cannot be marked.
3. Reviews the patient's chart and EMR for completeness (Fig. 21.4).
   a. Medical history and physical examination
   b. Laboratory reports
   c. Consent forms and documentation of consents
      (1) Informed consent data
      (2) General consent to treat
      (3) Anesthesia consent
      (4) Blood or blood products consent
      (5) Living will and DNR order
4. Measures the vital signs and blood pressure.
5. Verifies allergies, sensitivities, and medication history.
6. Checks skin tone and integrity.

• **Fig. 21.4** The holding room nurse reviews the patient's chart for completeness.

7. Verifies physical limitations.
8. Notes the patient's mental state.
9. Puts a cap on the patient to protect his or her hair, for purposes of asepsis, and to help minimize hypothermia. Patients who are bald are required to wear a head covering to prevent heat loss and scalp dander shed.
10. Notifies the individual at the surgery control desk when the patient and surgical team is ready for transport to the OR.[5] The patient is under constant observation by the patient care staff until transported from the surgical department to another patient care unit or discharged.

The holding area nurse records pertinent findings in the perioperative patient care record and on the surgical checklist. If a perioperative patient assessment has not been performed, the holding area nurse will assess the patient, formulate the nursing diagnoses and expected outcomes, and prepare an individualized plan of care.

Preanesthesia Preparations

The anesthesia provider or surgeon may wish to talk with the patient before sedation is given. The patient should be informed about all procedures before they are initiated. The following list of procedures may need to be completed before the induction of anesthesia; some or all of these procedures can be performed in the preoperative holding area if there are adequate facilities for patient privacy:

- Removal of body hair, if ordered.
- Marking of surgical incision sites such as for plastic surgery of the face and torso.
- Insertion of IV access. Be sure the placement does not interfere with the surgical site. Avoid the operative side of the body if possible.
- Insertion of invasive hemodynamic monitoring lines, as appropriate.
- Administration of the preanesthesia medication and other drugs, such as preoperative antibiotics, as ordered. The preanesthesia medication can precipitate respiratory depression and hypotension, and the perioperative nurse should be alert and take prompt action for airway maintenance if necessary. The holding area should be equipped for cardiopulmonary resuscitation. An emergency or code blue button should be accessible to summon help at all times.

The anesthesia provider may perform regional blocks in the holding area. All procedures performed in the holding area are documented on the patient's record.

Despite the activities around them, patients may feel more alone in a holding area than in any other location. Time passes slowly, causing a possible increase in anxiety. An anxious patient looks to the nurse for comfort, reassurance, and attention. A compassionate expression in the eyes and voice and a reassuring touch of the hand can convey concern and understanding to the patient.

If the patient is drowsy, unnecessary conversation should be avoided. The nurse should answer questions and see to the patient's comfort. The patient should be kept warm, or the blanket should be turned down if he or she is too warm. An extra pillow should be placed under the patient's head or under the knees. Dry lips should be moistened, if appropriate. Any delay or unusual circumstances should be explained to the patient and family.

A quiet, restful atmosphere enables the patient to gain full advantage of the premedication. Some holding areas and ORs have piped-in recorded music, which diverts attention from the many other sounds in the environment. Music with a slow, easy rhythm and a low volume is most conducive to relaxation. Familiar music is more pleasing and relaxing, because the patient can associate it with pleasant experiences. Some facilities provide earphones or headsets so patients can listen to the music of their choice. Earphones also muffle extraneous noises and conversations. Ideally the patient should have a choice in selecting the music or in having no music at all; this is the advantage of individual headsets over piped-in systems.

Transfer to the Operating Room

When the OR is ready the circulating nurse comes to the holding area for the patient. A hand-over report is given by the holding room nurse to the circulating nurse. The surgical checklist is one way to assure an accurate exchange of information is given as patient care changes hands. The circulating nurse will in turn continue documenting on the checklist for continuity and relay the information to the PACU nurse when the surgical procedure is completed and patient care is transferred for postanesthesia recovery.

It is advantageous if the circulator is the perioperative nurse who made the preoperative visit; the patient will appreciate seeing a familiar face. Before transporting the patient into the OR, the circulating nurse has several important duties to fulfill:

1. Greet the patient, and validate his or her identity (Fig. 21.5).
   a. The circulating nurse should introduce himself or herself if he or she has not previously met the patient. The patient should be addressed as Mr., Mrs., or Ms.—not by the first name. It is appropriate to ask the patient to state and/or spell his or her name. The patient should be asked his or her full name and date of birth.
   b. When the patient arrives at the facility, an identifying wristband is put on in the admitting office. The holding room nurse checks the band before the patient leaves for the OR. The circulating nurse compares the information on the wristband, including the identification number, with the information on the medical record and with the information on the surgical schedule: name, anticipated surgical procedure, time, and surgeon. An allergy band and other notification band (e.g., Do Not Resuscitate [DNR])

• **Fig. 21.5** The circulating nurse greets and identifies the patient.

should be checked at the same time. A discussion of the order should take place between the surgeon, anesthesia provider, and patient if requested.

c. Identification on the stretcher or bed ensures the patient's return to the same stretcher or bed after surgery, if this is the procedure. If the patient is an infant or child, the identification bracelet may be on the ankle. Any tag on the crib should be out of his or her reach. Always validate the identity of a child with a parent or legal guardian. Ask what procedure is being performed. Validate the surgical site marking as appropriate.

d. Verification of the surgical procedure, site, and surgeon with the patient provides reassurance that this is the correct patient. The patient's own words should be documented on the chart. The circulating nurse should note the presence of the surgeon's identifying mark on the surgical site. If the patient is heavily sedated, the surgeon may be asked to help identify the patient.

2. Check the side rails, restraining straps, IV infusions, and indwelling catheters.
3. Observe the patient for any reaction to the medication.
4. Observe the patient's anxiety level.
5. Check the history and physical data, laboratory tests, x-ray reports, and consent form(s) or documentation in the patient's medical record.
6. Review the plan of care and the surgical checklist.
   a. Pay particular attention to allergies and any previous unfavorable reactions to anesthesia or blood transfusions.
   b. Become familiar with this patient's unique and individual needs.

The patient is taken into the OR after the surgeon sees him or her and the anesthesia provider is ready to receive the patient. The main preparations for the procedure should be complete so the circulating nurse can devote undivided attention to the patient.

Before the Induction of Anesthesia

The anesthesia provider also has immediate preanesthesia duties, such as the following[6]:

1. Checking and assembling equipment before the patient enters the room. Airways, endotracheal tubes, laryngoscopes, suction catheters, labeled prefilled medication syringes, and other items are arranged on a cart or table.
2. Reviewing the preoperative physical examination, history, and laboratory reports in the chart.
3. Making certain that the patient is comfortable and secure on the OR bed.
4. Checking for denture removal or any loose teeth.
5. Checking to be certain that contact lenses have been removed.
6. Asking the patient when he or she last took anything by mouth, including medications.
7. Checking the patient's pulse, respiration, and blood pressure to obtain a baseline for the subsequent assessment of vital signs while the patient is anesthetized.
8. Listening to the heart and lungs and then connecting ECG monitor leads and attaching the pulse oximeter and other monitoring devices (Fig. 21.6).
9. Starting the IV access. This may be done in the holding area or an induction room. Some patients arrive with an IV line in place.
10. Preparing for and explaining the induction procedure to the patient. If properly premedicated, the patient should be able to respond to simple instructions.

• **Fig. 21.6** The anesthesia provider prepares for induction of anesthesia.

Circulating Nurse's Role During Induction

The patient's welfare and individual needs take priority over all other activities before and during the induction of anesthesia. The patient is the most important person in the OR. If the circulating nurse gives more attention to the equipment than to the patient, the patient may feel abandoned. In addition, the monitoring equipment is not the best indicator of patient condition. At this time of stress the patient wants the physical presence of a trusted, competent, and compassionate person.

The patient expects the circulating nurse to be cognizant of his or her problems and conditions and willing to help relieve them. The patient will perceive the circulating nurse's attitude as one of either acceptance or rejection. Consequently, the behavior of the circulating nurse affects the patient in either a positive or a negative way. Positive actions include staying close to the patient, paying attention to the patient's needs and comfort, looking directly at the patient when he or she speaks, touching the patient with kindness, and appearing poised, confident, and professional.

Human beings react through their senses. The positive effect of touch is a helpful nonverbal communication in establishing nurse-patient rapport within a short time. Touch communicates caring. A gentle touch can bridge a language barrier by establishing human contact. Holding a patient's hand warmly or laying a hand on an arm during the induction of anesthesia or a painful procedure can do much to alleviate anxiety and elicit trust.

A smile has been called the universal language. Even though the circulating nurse is wearing a mask, his or her eyes can convey a smile or hope. Likewise they can reveal anger or hostility. Physiognomy, the ancient Chinese art of discovering qualities of the mind and temperament from the expression of facial features, still has relevance. Facial expressions, eye contact, and body movements have either a positive or a negative effect on the patient. Warmth and caring can be conveyed by a pleasant manner and the expression of the eyes.

Although routine procedures for care and teaching have been established, each patient deserves personalized care in the face of a disruptive life experience. The circulating nurse should not become insensitive to patients because of depersonalized procedures and routines or his or her own prejudices.

The patient must not be treated as inanimate or anonymous or categorized by the disease or surgical procedure. The patient is a living, feeling person, not "Dr. Brown's hysterectomy," "the cardiac in Room 4," or "the arthritic I need help to move." Jargon such as this is depersonalizing, demoralizing, offensive, and unacceptable. The goal of perioperative patient care is to combine efficiency with caring.

The protection of modesty, dignity, and privacy is essential regardless of whether the patient is conscious or unconscious. Unnecessary exposure should be avoided. The gown and cotton blanket protect modesty and keep the patient warm. The OR door should be kept closed for privacy; this is also important in terms of aseptic technique. Surgical procedures may be viewed only by authorized personnel who have a definite function. All privileged information is kept confidential.

Patients are unnerved by stimuli such as strange odors and disturbing sights. A used, unclean OR, with its soiled linen, instruments, equipment, unconscious patients, and bright lights, can be frightening. Patients feel isolation amid the hustle and

bustle of activity, and a lack of team preparedness increases the patient's stress level. The patient may feel embarrassment from body exposure, and loud noises such as voices, inappropriate conversation, staff disagreements, clattering instruments, crumpling paper, and sterilizer noises contribute to the atmosphere of fear perceived by the patient.

Anxiety and preoperative sedation tend to alter the patient's ability to interpret events objectively. The patient may relate everything heard to himself or herself, even though he or she may not actually be the subject of the conversation, and he or she may misinterpret or react unfavorably. Hearing is the last sense lost when becoming unconscious. It is not known at precisely what moment a person can no longer hear and interpret what is said, but it is known that patients remain aware of their environment much longer than their seemingly unconscious state would indicate.

A lack of consideration can destroy the patient's confidence in the team. An overheard thoughtless comment can create a lasting traumatic memory and fear. Negative recall can induce anxiety in similar future experiences. Therefore team members should think before speaking and should not converse near the patient while excluding him or her from the conversation. Sedation does not imply exclusion. The patient may be aware of conversation, even if he or she appears to be asleep! Out of the patient's hearing, conversation should pertain only to the work at hand. The OR is not the place for social discourse.

Time is of the essence to keep anesthesia and procedure time to a minimum, and it is a protective factor to provide as little disturbance to physiologic homeostasis as possible. However, efficiency and safety must not be sacrificed for speed. Safety is the prime concern.

The OR imposes a high degree of vulnerability on patients and the entire staff. Patients lack the power to defend and protect themselves during a surgical intervention; therefore the circulating nurses are their advocates and protectors. They provide supportive care and safeguard patients from emotional and physical harm by maintaining constant vigilance. Circulating nurses can minimize the potential hazards in the following manner:

- *Never leave a sedated patient unguarded.* In addition to causing mental anguish from a feeling of abandonment, an unattended patient may fall or be injured by equipment.
- *Correctly identify patients, surgical sites, and medications.* An incorrect surgical procedure on a patient or an error in medication is usually the result of inadequate identification. Validation of the planned procedure is signified by a time out wherein the patient's identity is confirmed along with the surgical site, physiologic conditions (allergies), and the presence of necessary equipment, scans, implants, and materials for the procedure. The patient is included in the time out as condition permits. The time out is documented on the surgical checklist.
- *Create, maintain, and control an optimally therapeutic environment in the OR.* This involves control of the physical environment, such as temperature, humidity, and personnel. Traffic flow in and out of the room should be kept to a minimum. The more movement and talking, the greater the microbial count in the room. The OR should be kept quiet once the patient is there so the effects of sedation are not counteracted. A tranquil, relaxed atmosphere is conducive to team concentration and orderly functioning so all can go well. The standards of ethical conduct should be strictly enforced.

The effect inherent in any type of surgical intervention can be reconciled when the patient has hope and confidence in the caregivers. Nurses are the central figures in patient care and can do much to relieve fear and provide security. Preoperative preparations can influence the outcome of the surgical procedure.

Diagnostics, Specimens, and Oncologic Considerations

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- List several invasive diagnostic tests.
- List several noninvasive diagnostic tests.
- List several interventional procedures that incorporate diagnostics.
- Describe several aspects of patient care associated with diagnostic testing.
- Discuss the role of diagnostics in oncology.

KEY TERMS AND DEFINITIONS

Anaplasia Change in cellular differentiation and orientation that causes a more primitive structural appearance and function. Anaplastic cell changes are characteristic of malignancy.

Benign tumor Aggregation of cells that closely resemble those of the parent tissue of origin. The tumor usually grows slowly by expansion, is localized, and is surrounded by a capsule of fibrous tissue.

Biopsy Procedure for obtaining a representative tissue sample for gross and/or microscopic examination. The specimen can be obtained surgically or by other means.

Brachytherapy Placement of radioactive material inside of or close to a tumor. Radioactive elements are introduced through catheters inserted into the tumor.

Cancer Broad term that describes any malignant tumor within a large class of diseases. More than 100 different forms of cancer are known to exist, each with histologic variations. Cancerous tumors are divided into two broad groups, benign and malignant.

Carcinoma Malignant tumor of epithelial origin that affects glandular organs, viscera, and skin.

Chemotherapy Use of chemical or pharmacologic agents to treat diseases, such as cancer.

Contrast medium Use of a substance in the creation of density on a radiographic imaging device; radiopaque contrast injected or instilled to outline an organ or a structure. A radiolucent substance, such as air, can help define a hollow space, such as a ventricle of the brain.

Cytoreductive surgery Mechanical reduction in cell volume at the tumor site by sharp or blunt tissue dissection. Vessel- and nerve-sparing procedures include the use of an ultrasonic aspirator and hydrostatic pulsed lavage.

Immunotherapy Use of agents that stimulate or activate the body's own host defense immune system to combat disease.

Interventional radiology Invasive procedures performed under radiologic control. Examples include balloon angioplasty, coronary artery stent placement, and inferior vena cava filter placement.

Malignant tumor Progressively growing tumor that originates from a specialized organ such as the lung, breast, or brain, or a tumor localized to a specific body system such as bone, skin, lymph nodes, or blood vessels.

Neoplasm Atypical new growth of abnormal cells or tissues, which may be malignant or benign.

Nuclear medicine study Diagnostic test performed using radioactive substances to image a body part or system.

-oma Suffix denoting a tumor or neoplasm.

Palliation Measures taken to decrease the negative effects of a terminal or moribund condition. This is not considered a cure, but rather a temporary solution to a problematic situation. Examples include removing an obstruction or attempts to preserve fertility in the face of cancer.

Pathologic examination Series of tests and examinations conducted by a pathologist to determine the cause of changes in the structure or function of a body part or tissue.

Percutaneous Directed through the skin and tissues of the external body surface. Diagnostics, treatments, or tissue removal can be performed by direct percutaneous routes.

Plethysmography Procedure to determine variations in blood flow between parts.

Sarcoma Malignant tumor of mesenchymal origin that affects bones, muscles, and soft tissue.

Scintigraphy Recording of the emissions of radiologic substances as they are collected or secreted by tissues and/or organs in the body.

Smear Sample of tissue cells or fluid aspirated or scraped from a mucous membrane or a potentially pathologic site. The material is stained and studied for cellular components to make a diagnosis.

Stereotaxis Computerized localization of a lesion.

Tomography Computerized method of imaging a structure in layers.

Tumor Any neoplasm in which cells are permanently altered but have the capability of growth and reproduction. A tumor consists of two elements: the tumor cells themselves and a supporting framework of connective tissue and vascular supply.

Diagnosing Pathology

Diagnosis of a pathologic disease, anomaly, or traumatic injury is established before a surgical procedure is undertaken. Many modalities and techniques help surgeons assess each individual patient problem, guide them through the surgical procedure, and help them verify the results of surgical intervention. The term *diagnosis* refers to the art or the act of determining the nature of a patient's disease. Diagnostic procedures can be classified as follows:

- *Noninvasive:* Noninvasive techniques use equipment placed on or near the patient's skin but outside body tissues.
- *Invasive:* Invasive techniques use equipment placed into a body cavity or vessel and/or use substances injected into body structures.
- *Interventional:* Interventional techniques involve invasive diagnostics and procedures performed in a specialty department, such as in radiology.

Perioperative nurses and surgical technologists should be familiar with the modalities and equipment necessary to assist with diagnostic procedures in the operating room (OR) and interventional departments.

Patient Care Considerations for Diagnostic Procedures

1. Patients should be assessed for their physical condition and any metal implants, pacemakers, infusion pumps, sensitivities, and allergies. Patients who will be administered contrast media should be evaluated for kidney function before testing.
2. Clear instructions should be given verbally and in writing before the test is performed.
3. Preprocedure preparations should be confirmed before the patient begins testing. A "time out" process that includes the pertinent patient and procedure information should be conducted by the team.
4. Explanations of procedures should be given to patients to allay fears and ensure their understanding of the value of the procedure in making a diagnosis. Before the procedure begins, an explanation should be given of the equipment being used.
5. Sterile and aseptic techniques of invasive procedures are strictly observed.

Specimens and Pathologic Examination

Clinical pathology is the use of laboratory methods to establish a clinical diagnosis of a disease by examining body fluid, tissue, and organs. Surgical pathology is the study of alterations in body tissues removed by surgical intervention.

Cultures and Smears

Cultures

Aerobic or anaerobic cultures may be obtained before or during the surgical procedure. If obtained before the procedure, the culture must be done before the skin prep. Cultures should be refrigerated or sent to the laboratory immediately. The culture tube and plastic transport bag should be labeled with the patient's identification, date, and site of culture.

The sterile culture tube and swab are prepackaged in a peel pouch and are dispensed to the sterile field. The culture tube has a small sealed plastic media chamber at the bottom that preserves the material obtained from the patient on the swab. Nothing other than the fluid or tissue to be cultured should touch the sterile swab.

The sterile swab is withdrawn from the tube by the sterile team member and dipped into the area to be cultured. The swab is replaced into the culture tube and seated tightly. The media chamber at the bottom of the tube is crushed to release the culture media and immerse the tip of the swab. The scrub person can drop the closed culture tube into a small plastic bag held by the gloved circulating nurse, who will affix the patient's identification label and biohazard sticker.

Cultures for suspected anaerobic microorganisms require immediate attention. Exposure to room air may kill anaerobes in a few minutes. The purulent material can be aspirated into a sterile disposable syringe through a disposable needle. This needle is removed with a hemostat and placed with counted sharps on the instrument table. The aspirated material may be transferred into a sterile specimen cup and sent immediately to the laboratory in a plastic bag with a biohazard sticker affixed to the outside.

Smears

Cells and small pieces of tissue are suspended in liquid and smeared on glass microscope slides. The specimen is "fixed" by being sprayed with fixative or immersed in liquid. The fixed slide is then stained and examined under a microscope by the pathologist or specially trained technician. This technique is useful for the examination of fine needle aspirate or scrapings. **Smears** can be examined within minutes after they have been obtained from the patient. Instant diagnosis is possible in many cases.

Biopsies

The removal of tissue or fluid for diagnosis is referred to as a **biopsy**. Biopsy specimens can be obtained by several invasive methods. The

pathologist determines and/or confirms the diagnosis by histologic examination (the study of tissue) and cytologic analysis (the study of cells).

Aspiration Biopsy

In an aspiration biopsy, fluid is aspirated through a 22 to 25-gauge needle placed in a lesion, such as a cyst or abscess, or in a joint or body cavity. Fine needle aspiration biopsies are done most commonly to obtain cells from solid lesions in the breast, thyroid, neck, lymph nodes, or soft tissues. The needle is manipulated in the mass while suction is placed on the syringe. Several hundred cells are drawn into the syringe. The cells can be chemically fixed and then examined under the microscope. Aspiration biopsies can be performed under computed **tomography** (CT) or ultrasonic guidance with minimal local anesthesia.

Bone Marrow Biopsy

For a bone marrow biopsy a trocar puncture needle or aspiration needle is placed into bone, through a small skin incision or percutaneous puncture. The sternum and iliac crest are common sites for bone marrow aspiration. Patients with abnormal blood counts or unusual blood morphology can benefit from cytologic studies of bone marrow.

Local anesthesia to the level of the periosteum is necessary. In obese patients a spinal needle may be needed to reach this depth. After satisfactory anesthesia, a larger bore needle is introduced into the marrow space and the specimen is aspirated. The aspiration may feel painful to the patient because the bone is not numb. A core sample of bone may be obtained at this time for **pathologic examination**.

Percutaneous Needle Biopsy

With percutaneous needle biopsy, tissue is obtained from an internal organ or solid mass by means of a hollow needle inserted through the body wall. **Percutaneous** puncture into a lesion may be guided by fluoroscopy under image intensification, by ultrasound, or by CT scanning.[1] Special needles are used; some types are disposable.

Punch Biopsy

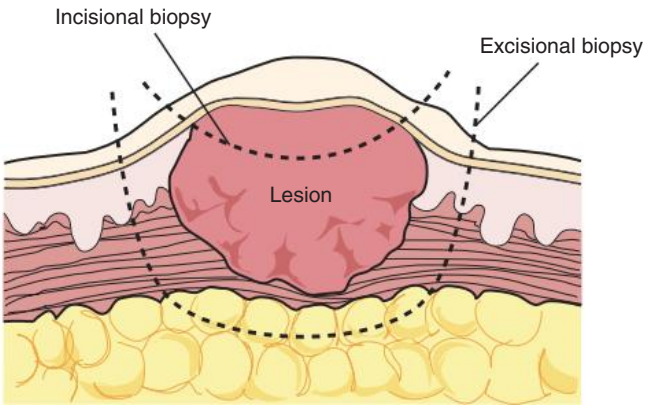
For a punch biopsy, an instrument with a 3 to 4-mm circular, sharp, hollow tip is used to sample skin lesions in a cookie-cutter manner. The plug of tissue is sent for pathologic study. Dermatologists or plastic surgeons use this method for skin biopsy.

Brush Biopsy

In brush biopsy, stiff brushes of nylon or steel are passed through an endoscope to the interior of the respiratory tree or urinary tract. Tissue samples are collected as the brush rubs against the target organ. Smears are made on glass slides; the tip of the brush is then cut off and placed in formalin for a minimum of 1 hour for fixation. The slides and fixed tissue are subjected to histologic studies for diagnosis.

Excisional Biopsy

A mass or entire structure is cut from the body in an excisional biopsy. The advent of fine needle aspiration has decreased the need for full excisional biopsy with the exception of a friable organ or a breast mass. In cases of suspected lymphoma an entire lymph node is necessary for adequate diagnosis. Some excisional biopsies can be performed endoscopically (Fig. 22.1).



• **Fig. 22.1** Comparison between incisional and excisional tissue biopsies.

Incisional Biopsy

A portion of a mass is removed during incisional biopsy. Soft tissue masses incised for diagnosis include muscle, fat, or other connective tissue (see Fig. 22.1).

Frozen Section

Special preparation and examination of tissue can determine whether it is malignant and whether regional nodes are involved. When the surgeon removes a piece of tissue and wants an immediate diagnosis, it is placed in a basin or specimen container without any added preservative, such as formalin or normal saline solution.[2] Formalin or normal saline solution will alter the freezing process used in the specialized pathologic study. The circulating nurse should alert the pathologist that a frozen section will be sent. When the tissue examination is complete, the pathologist will report the results directly to the surgeon in the OR.

The patient's level of consciousness should be considered during report of pathologic results, especially if the patient is awake. The use of speakerphones should be avoided for patient confidentiality. If a malignant lesion is present and the individual situation calls for it, the surgeon proceeds with a radical resection of the affected organ or body area. In some situations, additional tissue is needed for diagnosis.

Permanent Section

The specimen is placed in fixative, commonly formalin, for several hours to cause the cells to become firm. The fixed specimen is placed in a machine that removes all of the water from the tissues, replacing it with paraffin. When this process is complete, the specimen is embedded into a block of wax. It is placed in a microtome and is sliced tissue-paper thin and floated in a water bath. The slices are placed on glass slides, where the paraffin is dissolved with solvent and the water is restored to the tissue on the slide. The slices readily accept dyes and stains used for diagnosis. Permanent section is the best diagnostic biopsy tool. Box 22.1 lists several tissue dyes and stains used in diagnostic procedures.

Collecting Surgical Specimens

All tissue removed during the surgical procedure is sent to the pathology laboratory for verification of the diagnosis. Any unidentifiable or unusual item removed from a patient should be

sent for identification by the pathology department. Some examples include removal of retained surgical items, such as instruments, sponges, and towels. Any questionable item should be sent to the laboratory and documented by the circulating nurse. Facility policy and procedure should delineate disposition of all surgical specimens.

Tissue specimens may be stored in a refrigerator in the laboratory or some other location within the OR suite until they are taken to the pathology department at the end of each day's schedule of surgical procedures or at intervals during the day.

Correct solutions for storage and correct labeling of specimens are critical for accurate diagnosis. Table 22.1 lists types of specimens for pathologic study.

Specimen containers may be plastic containers, waxed cardboard cartons, or glass jars with preservative solution. AORN (Association of periOperative Registered Nurses) recommended practices suggest that the specimen container be part of the sterile setup so the container can be closed on the field, thereby minimizing the handling of biohazardous material. The closed, labeled container is placed into a plastic bag or additional container with a biohazard sticker for transport to the laboratory. The double-packaged specimen should be handled while wearing gloves.

The handling of specimens should be kept to a minimum and only while wearing gloves and appropriate personal protective equipment (PPE). Use care to avoid contaminating the outside of a specimen container. If it is contaminated, wipe it with an antiseptic solution. Always wash hands thoroughly after removing gloves that have been worn to handle specimens. If instruments are used for handling, be careful not to tear, crush, or damage tissue. The routine care for each type of tissue specimen may vary, as follows:

- Pathology tissue specimens should not be allowed to dry out. Saline or a solution of aqueous formaldehyde (10% formalin) is commonly used as the fixative until the specimen is processed further in the laboratory. Formalin is flammable and

TABLE 22.1 Specimen Types and Considerations for Handling

Specimen Type	Test	Preparation	Example
Fluid	Bacteriology	Anaerobic or aerobic on culture swab in sterile tube	Exudate
	Virology	Fresh, in sterile container	Cerebrospinal fluid
	Cytology	Fresh or added solution of pathologist's choice in sterile container	Cell washings, urine
	Genetic studies	Fresh, in sterile container	Amniotic fluid
	Cell count	Fresh, in sterile container	Semen for infertility study
Tissue	Permanent section	Fresh or added solution of pathologist's choice in sterile container	Diseased organ
	Frozen section	Fresh, in sterile container; No saline	Margin of malignant lesion
	Biopsy	Fresh or solution of pathologist's choice in sterile container	Suspicious lesion
	Hormonal assay	Fresh, in sterile container	Breast tissue
	Donor tissue	Fresh or added solution of pathologist's choice	Cadaver skin
	Calculi	Dry, in sterile container	Gallstone
	Ova	Fresh or added solution of surgeon's choice	Human egg for preservation
	Muscle	Fresh, extended in special clamp in sterile container	Test for malignant hyperthermia
Nonbiologic specimen	Foreign body Projectile from crime scene	Fresh, in sterile container Dry, in nonmetallic container	Glass fragments Bullet
	Clothing of crime or accident victim	Dry, in porous paper	Underclothes of rape victim
	Explanted prosthesis	Dry, in sterile container	Orthopedic screws or plates

should not be stored in the OR. The formalin is added after the specimen is in the container. Dropping the specimen into a prefilled container can cause a splash.
  - Some pathology laboratories prefer moistening the specimen with sterile normal saline. Check for the preference of the laboratory that will be examining the specimen.
  - Fresh tissue and frozen sections are not placed in preservative solution or saline unless instructed otherwise by the laboratory personnel.
- Stones are placed in a dry container so they will not dissolve. Organs containing stones, such as the gallbladder, may be placed in saline or formalin.
- Foreign bodies should be sent for accession according to policy, and a record is kept for legal purposes. The description and the disposition of the object are recorded. A foreign body may be given to the police, surgeon, or patient, depending on legal implications, policy, or the surgeon's wishes. A chain of specimen custody slip should be signed by all persons handling the specimen.
- Forensic evidence, such as bullets or knife blades, should be placed in a dry plastic container. Do not allow the item to contact metallic basins because ballistic evidence could be altered. Chain of custody documentation should accompany the specimen at all times to protect the evidence.
- Amputated extremities are wrapped in plastic before sending them to a refrigerator in the laboratory or morgue. Avoid placing the amputated limb in the patient's field of vision. Most patients needing amputation have spinal or epidural anesthesia for the procedure. The sight of the body part may cause emotional distress in the patient. The patient may request that an amputated extremity be sent to a mortuary for preservation for burial with his or her body after death. This request must be noted on the requisition sent to the laboratory. Refer to institutional policy and procedure for the care of amputated limbs.

Radiologic Examination

An x-ray is a high-energy electromagnetic wave capable of penetrating various thicknesses of solid substances and affecting photographic plates. X-rays are generated on a vacuum tube when high-velocity electrons from a heated filament strike a metal target (anode), causing it to emit x-rays.

The image obtained by the use of x-rays may be referred to as an x-ray, roentgenogram, radiograph, or other -gram or -graph name associated either with the specific technique used to obtain the photograph or the anatomic structures identified (e.g., mammogram, x-ray, or radiograph).[3] Most facilities have eliminated the use of x-ray film and have changed to a digital viewing format.

X-rays are also used for diagnostic imaging with fluoroscopy, CT, and digital radiography.[4] Computerized radiologic images may be stored on diskettes.

Types of Radiologic Equipment and Accessories

Many hospitals have one or more rooms within the OR suite that are equipped for diagnostic as well as intraoperative radiologic procedures. In some facilities, OR personnel are cross-trained to assist with diagnostic and interventional procedures in the radiology department.

Contrast Media

Agents composed of nonmetallic compounds or heavy metallic salts that do not permit the passage of radiant energy are radiopaque. When exposed to x-rays the lumen of a body structure filled with these agents appears as a dense area. Radiopaque contrast media frequently used for the procedures to be described are listed in Box 22.2.

Patients with renal disease are given contrast media if necessary at the lowest possible dose.[5] Studies have shown that contrast agents are excreted in breast milk in small amounts. Contrast agents cross the placenta and are excreted by the fetal kidneys into the amniotic fluid. Sensitization of the infant has not been shown. The contrast is cleared by the mother's circulation within 24 hours. She may wish to abstain from breastfeeding during that period. Refer to the product package insert for specific information.

Some contrast agents are fluorescent dyes. Most contain iodine, either bound or unbound. The contrast media is designated low osmolarity or high osmolarity. Low osmolarity is associated with fewer reactions to contrast. Few patients have an immediate reaction; however, a small population of patients may react several hours later. Known reactors may be given prednisone and Benadryl (diphenhydramine) several hours before the anticipated use of any contrast agents.

A history of systemic sensitivity to substances that contain iodine, such as shellfish, or other allergies is obtained before these agents are injected. True shellfish allergies are not related to iodine but to specific proteins in the fish. True allergy is not a common event. Studies have shown that other allergies, such as milk and egg, both high in protein, may play a role. Precautionary administration of prednisone and Benadryl minimizes the risk. The use of low-osmolarity contrast helps decrease reactions.

• BOX 22.2 Radiopaque Contrast Media

Barium sulfate for gastrointestinal studies

  - Cardiografin for angiography and aortography
  - Hypaque-M, 30%, for urography and computed tomography (CT)
  - Hypaque-M, 60%, for urography, cerebral and peripheral angiography, aortography, venography, cholangiography, hysterosalpingography, and splenoportography
- Diatrizoate sodium, injectable:
  - Hypaque sodium, 25%, for urography and CT
  - Hypaque sodium, 50%, same uses as for Hypaque Meglumine, 60%
- Diatrizoic acid, injectable, used as meglumine and sodium salts:
  - Hypaque-M, 75%, for angiocardiography, angiography, aortography, and urography
  - Renografin for cerebral angiography, peripheral arteriography and venography, cholangiography, splenoportography, arthrography, discography, urography, and CT
  - Renovist for aortography, angiocardiography, peripheral arteriography and venography, venacavography, and urography

Ethiodized Oil (Ethiodol) for Splenoportography and CT
- Iodipamide meglumine, injectable:
  - Cholografin meglumine for cholangiography and cholecystography
  - Renovue for IV excretory urography
  - Sinografin for hysterosalpingography
- Iohexol (Omnipaque) for myelography
- Iophendylate (Pantopaque) for myelography
- Ioversol (Optiray) for arteriography and CT
- Metrizamide (Amipaque) for myelography and CT
- Propyliodone (Dionosil) for bronchography
- Sodium iothalamate (Angio-Conray) for arteriography

Iodine allergy information may be unreliable because studies have shown that immediate reactions to contrast are nonimmunologic. This means that the adverse reaction is not caused by allergy. The patient's immunoglobulin E (IgE) is not activated. True allergic reactions to any contrast agent ingredient stimulate IgE, and the patient can exhibit hives, angioedema, respiratory difficulty, and cardiovascular collapse.

A test dose of 1 or 2 mL may be given before the dose required for x-ray study to rule out a potential reaction. The patient should be observed for symptoms of reaction throughout the procedure. Signs of reaction may include the following:

- Red rash over face and chest
- Extreme agitation
- Sudden elevation of body temperature
- Complaints of muscle, joint, and back pain
- Respiratory distress
- Tachycardia
- Hypotension
- Blood-tinged urine
- Convulsions
- Loss of consciousness
- Cardiac arrest

Radiolucent Gases

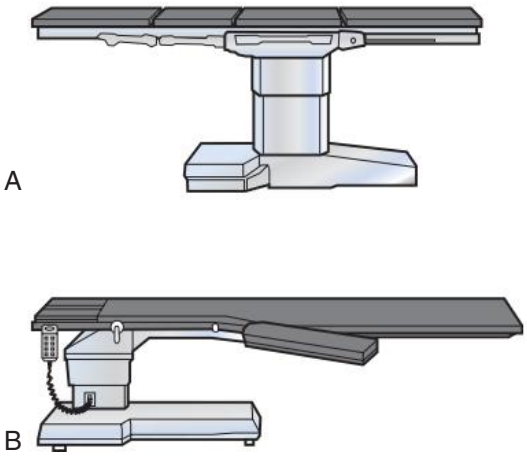
Filtered room air, oxygen, nitrogen, carbon dioxide, or a combination of gases may be injected into body spaces or structures that normally contain fluid other than blood. Gases are radiolucent (i.e., transparent to x-rays). Thus gas-filled spaces appear less dense on x-rays than do surrounding tissues.

Radiologic Table

The tabletop the patient lies on is made of acrylic or some other radiolucent material (Fig. 22.2). Some OR beds have a Bakelite top that fits over the length of the table and permits insertion of the x-ray cassette at any area. For fluoroscopy with image intensification, the entire top must be radiolucent because the image intensifier is positioned underneath the table. If the entire OR bed is not radiolucent, the foot section can be lowered and a radiolucent extension attached that will accommodate specialized x-ray machinery.

Cassette

The lightproof holder for x-ray film is referred to as a *cassette.* The patient is positioned between the x-ray tube and the cassette.



• **Fig. 22.2** Pedestal Bases. **A,** Central. **B,** Eccentric for C-arm image intensifier placement.

Holders for cassettes may be built into or attached to the OR bed. Intraoperative x-rays may require the use of a sterile disposable cassette cover. If a sterile cover is unavailable, a sterile Mayo stand cover may be substituted. In some circumstances a cassette may be slid under a patient on the OR table. Care is taken not to contaminate the sterile drapes. Many facilities have discontinued the use of x-ray film and have converted to a digital viewing format.

Processing Equipment

Conventional x-ray equipment projects a black-and-white image on x-ray film that is developed by a chemical process. Some OR suites have a darkroom where x-ray film is developed after exposure so that the surgeon can see results of the study without excessive delay. An automatic processor in which film can be developed within 90 seconds to 3 minutes may be available.

Fixed X-Ray Equipment

A fixed overhead x-ray tube with housing may be mounted on a ceiling track for unrestricted movement of the x-ray beam into the desired position over the patient. When not in use it can be moved against a wall and retracted toward the ceiling. Some units are fixed to specially designed tables, such as the urologic table for cystoscopic examinations. The controls are in an adjacent room or behind a lead shield and are activated by the radiologist or radiology technician.

Portable X-Ray Machine

An x-ray tube mounted on a portable electric- or battery-powered generator of a nonexplosive design may be moved from one room to another in the OR suite and postanesthesia care unit (PACU). A portable x-ray machine offers the advantages of flexibility in scheduling procedures and availability for when and where it is needed.

Portable x-ray machines can be a source for cross-contamination. All portable equipment should be thoroughly disinfected before being brought into the OR/PACU and again after use. It should be stored within the perioperative environment between uses. Portable x-ray machines are used for intraoperative angiography, cholangiography, orthopedic localization, and urologic contrast procedures.

Intraoperative images require the x-ray machine to be in proximity to the sterile field and could cause contamination. A few options to prevent contamination include draping the machine with a specialized drape or temporarily placing a sterile towel over the site to be imaged. Extreme care is taken to prevent contamination when the towel is removed. Reasons for intraoperative x-ray imaging include performing diagnostic examinations with contrast media or looking for a lost surgical object.

In the PACU the portable x-ray machine is used for immediate (stat) chest and kidney, ureter, and bladder (KUB)/flat plate films. X-ray films can be used to check the location of implants and delayed passage of **contrast medium** through an organ system.

Fluoroscope

Similar to an x-ray generator, a fluoroscope has an additional screen, composed of fluorescent crystals, which lies in contact with a photocathode. When an x-ray beam passes through this screen, it fluoresces. Fluorescent light sets electrons free from an adjacent photocathode to produce an electron image. Rather than this image of body structures being photographed on x-ray film, it is reproduced as a digital image on a luminescent screen. Known as fluoroscopy, examination under a fluoroscope allows

visualization of both form and movement of internal body structures. Fluoroscopy is used frequently for both preoperative and intraoperative procedures.

It is an invasive technique because a fluorescent substance must be injected or a radiopaque device inserted. When exposure time is prolonged to perform a procedure with visual fluoroscopic control (e.g., cardiac catheterization), fluoroscopy exposes the patient and personnel to radiation at higher levels than do conventional x-rays. Personnel must wear lead aprons during fluoroscopy, even though a lead shield is part of the installation. Patients in the vicinity should be protected with gonad and thyroid shields.

Image Intensifier

The image intensifier is used with the fluoroscope. It amplifies the image onto a monitor screen. The surgeon activates the image intensifier with a foot pedal. Clarity of the image is an aid in diagnosis, particularly of vascular, urologic, neurologic, and bone disorders. The surgeon can observe the progression of an injected fluorescent substance as it moves through internal structures or the placement of a device, such as a catheter, into the body. When connected to other closed-circuit television facilities, the image can be transmitted to other rooms for teaching purposes. In addition, the image can be videoed for a permanent record and teaching. The monitoring screen may be mounted on the ceiling and positioned over the OR bed to save space in the OR, or it may be portable.

C-Arm Image Intensifier

Designed primarily for orthopedic procedures, foreign body and calculi localization, and catheter placement, mobile image intensifiers offer the same advantages and disadvantages of portable x-ray machines. The C-arm, so named because of its shape (see Fig. 13-4), keeps the image intensifier and x-ray tube in alignment; the intensifier is directly under the tube. It can be moved from an anterior to a lateral position. Utility of the mobile C-arm image intensifier is enhanced when the system is capable of making electronic x-rays for permanent records. An additional formatting device is required for this function.

Computerized Digital Subtraction Processor

After intravenous (IV) injection of a radiopaque contrast medium, the computerized digital subtraction x-ray imaging system visually records perfusion within the cardiovascular system (e.g., extracranial and intracranial vessels). The procedure is known as Digital Subtraction Angiography (DSA).

Initially, before contrast medium is injected, fluoroscopic body images are converted to digital data for storage in a memory unit in the processor. Termed the *mask image,* these digitized data are integrated into single or multiple video frames. The video signal is logarithmically amplified and digitized. The mask image is electronically subtracted from subsequent images with the contrast medium. This process removes unwanted background, thus providing optimal visualization of vessels with contrast density that cannot be achieved by other image intensifiers. The resultant images (digital x-rays) are displayed on a video screen and can be recorded on CD or other peripheral media.

Radiologic Diagnostic Procedures

Chest X-Ray

Most surgeons consider a chest x-ray film as an extension of the patient's history and physical examination if it is clinically necessary. An x-ray study of the chest may be part of the admission procedure for elective surgical patients to rule out unsuspected pulmonary disease that could be communicable or would contraindicate the use of inhalation anesthetics.

This procedure may be routine for patients older than 40 years. It is always a part of the diagnostic workup in patients with suspected or symptomatic pulmonary abnormalities if they will be undergoing general anesthesia.

X-Ray Studies for Trauma

In addition to being an aid in determining the extent of traumatic injury, x-ray films and scans may be entered as legal evidence in a court of law to establish injuries sustained by the patient or to justify medical care given. Conventional noninvasive x-ray images will show the following features:

- Bone fractures
- Presence and location of some types of foreign bodies (e.g., bullets)
- Air or blood in the pleural cavity
- Gas or fluid in the abdominal cavity
- Outline of abdominal and chest organs and any deviation from normal size or location

Mammography

A technique for projecting an x-ray image of soft tissue of the breast, mammography is the most effective screening method for early diagnosis of small, nonpalpable breast **tumors**.[6] Mammography may be performed in conjunction with ultrasonography if the woman has fibrocystic breasts and difficult-to-palpate masses less than ¼ inch (0.5 cm) in diameter. Patients with a family history of breast cancer may have a genetic blood test for a mutation in the *BRCA1* or *BRCA2* gene. This genetic defect may contribute to the risk for ovarian cancer.

Three views of each breast are exposed to conventional x-rays and developed on film. The use of three-dimensional technology (3-D breast tomosynthesis mammography [DBT]) takes pictures from the front and side angles of the breast, and the digital images are viewed on a computer screen. The images can be enlarged on a computer screen for better viewing, especially for dense breast tissue. Images can be electronically sent to a health care provider and easily stored in the computer. The procedure may be somewhat painful for the woman, because compression is needed for radiologic imaging. Tumors appear on the mammogram as opaque spiculated (star-shaped) areas or, occasionally, as areas of calcification. The radiologist places a small, BB-like radiolucent bead with crosshairs over a suspicious area. Another x-ray view of this area is obtained. Fine needle aspiration may be performed under ultrasonic guidance to gather cells for cytologic study.

Patient Teaching

The American Cancer Society recommends that women 40 years of age have a baseline screening mammogram. Between the ages of 45 and 54 years, they should have additional screening x-rays yearly or recommendations by their physician. After age 54 women should have a mammogram every 2 years. Women with a family history of breast cancer may be recommended to have a mammogram well before the age of 40. The use of magnetic resonance imaging (MRI) may be suggested along with mammography.

Mammography is not contraindicated in women with breast implants. The technician obtaining the x-ray should be informed of previous breast surgeries, hormone replacement therapy, and augmentation mammoplasty. Special breast-imaging techniques

are used to displace an implant or obtain an x-ray view of extremely dense breast tissue.

Men with suspicious breast lesions or pronounced gynecomastia should have mammographic screening to rule out cancerous tissue.

Every patient should be taught breast self-examination and practice it every month as a baseline diagnostic test. Early diagnosis is the best chance for a cure. Fig. 22.3 depicts the average sizes of masses discovered in patients who do and do not practice breast self-examination.

Stereotactic Core Breast Tissue Biopsy

A needle biopsy device may be used in conjunction with mammography to obtain a tissue specimen from a lesion seen on the mammogram. The patient is positioned prone on a special table with her breasts placed through a biopsy porthole. Stereotactic imaging equipment is used to isolate breast lesions that may not be palpable. Percutaneous needle biopsies are performed with the patient under local anesthesia.

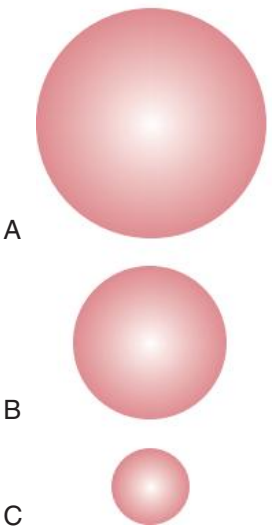
Computed Tomography

In CT, special complex and expensive equipment uses an x-ray in conjunction with a computer. Because the x-ray beam moves back and forth across the body to project cross-sectional images, the technique is referred to as computed tomography, computed axial tomography (CAT), or, simply, scanning. It produces a highly contrasted, detailed study of normal and pathologic anatomy.

The x-ray tube and photomultiplier detectors rotate slowly around the patient's head, chest, or body for 180 degrees in a linear fashion along the vertical axis. The computer processes the data and constructs a two- or three-dimensional picture on a black-and-white monitor or in colors that correspond to the density of tissue. Structures are identified by differences in density. This picture is photographed for a permanent record. The computer also prints out on a magnetic disk the numerical density values related to the radiation-absorption coefficients of substances in the area scanned. The radiologist uses this printout to determine whether a substance is fluid, blood, normal tissue, bone, air, or a pathologic lesion. The exact size and location of lesions in the brain, mediastinum, and abdominal organs are identified.

CT becomes an invasive procedure when a radiopaque contrast medium is injected IV to enhance visualization of the vascular and renal systems. Oral diluted barium contrast can be used to examine the gastrointestinal tract when a perforated organ is not suspected. Tissue biopsy can be performed under CT guidance. Needle aspiration can be performed under direct CT visualization.

CT exposes the patient to ionizing radiation and a potential allergic reaction to contrast medium, if used. To ensure proper use of this complex equipment, as well as to protect the patient from excessive or unnecessary radiation, the procedure is done under the supervision of a qualified radiologist.



• **Fig. 22.3** Average-Size Lumps Found by Breast Self-Examination (BSE). **A,** Woman not practicing BSE. **B,** Woman practicing occasional BSE. **C,** Woman practicing monthly BSE. (From Fortunato NM, McCullough SM: *Plastic and reconstructive surgery,* St. Louis, 1998, Mosby.)

Ventriculography

Ventriculography is the x-ray study of the ventricles after injection of gas, radionuclide, or contrast medium directly into the lateral ventricles of the brain. It may be used to evaluate a patient with signs of increased intracranial pressure as a result of blockage of cerebrospinal fluid circulation. Ventricular needles or catheters are inserted into one or both lateral ventricles through holes made in the skull. The ventricular needle has a blunt, tapered point that prevents injury to the brain as it is inserted into the ventricle. Openings on the side near the point permit removal of spinal fluid and injection of agent. If the patient is an infant whose suture lines in the skull are not yet closed, needles are inserted through these.

The entire ventriculographic procedure may be done in the OR. Otherwise the holes are drilled and the ventricular needles or an intraventricular catheter is inserted and the patient is then transferred to the radiology department or an interventional room within the OR suite. If a lesion is identified, the diagnostic procedure may be followed immediately by a surgical procedure because of the possibility of a further increase in intracranial pressure. If the patient is returned to the unit after the procedure, sterile ventricular needles should accompany the patient. If intracranial pressure becomes too great after injection, a needle can be inserted to remove the gas, radionuclide, or contrast media.

Arthrography

Arthrography is the study of a joint after the injection of gas or contrast medium into it. Conventional x-ray views show only the bony structure of a joint. Through injection of a dye or gas, injury to cartilage and ligaments may be visualized. A double-contrast study uses both gas and contrast, which is particularly useful in knee arthrograms.

Angiography and Arteriography

Angiography is a comprehensive term for studies of the circulatory system after injection of a radiopaque substance to permit visualization of the venous blood vessel system. These procedures are useful in the differential diagnosis of arteriovenous malformations, aneurysms, tumors, vascular accidents, or other circulatory abnormalities caused by traumatic injury or an acquired structural disease.

Intraoperative studies often are essential to assess the results of vascular reconstruction. Angiography is one method of assessment to confirm the position and patency of an arterial or venous graft or the quality of a restored vessel lumen. Intraoperative angiography frequently is indicated for these assessments in the peripheral vessels of extremities. After insertion of a bypass graft or endarterectomy, patency of the graft or vessel is checked by

pulsations and also by arteriography to examine the arterial blood vessels of the circulatory system.

Angiography is also used at the time of the surgical procedure to identify vascularity or the exact location of some types of lesions in the extremities, brain, and thoracic and abdominal cavities. After venous injection of radiopaque contrast medium, radiologic studies are done. Techniques and equipment to be used will vary according to the specific procedure, but all types of angiography have the following list of features in common:

1. Access to the vessel (either an artery or vein) to be injected with a radiopaque contrast medium may be made by a percutaneous puncture or a cutdown.
   a. Cannulated needles with or without a radiopaque plastic catheter, similar to those used for IV infusions, may be used for a percutaneous puncture to penetrate an artery or vein. To prevent backflow of blood, cannulated needles have an obturator that remains in place until the contrast medium is injected. Long catheters have a guidewire to assist threading through the vessel.
   b. A Seldinger (18-gauge) needle has a sharply beveled inner cannula and a blunt outer cannula. The blunt end of the outer cannula prevents trauma to the vessel. After insertion, the inner cannula is replaced with a guidewire and the outer cannula is removed. A 20-cm vessel dilator sheath (which is approximately 8 inches long) is threaded over the guidewire to create a track for a radiopaque catheter.

      After the dilator sheath is removed, the catheter is positioned and the guidewire is withdrawn. This method is generally preferred for angiography because blood vessels other than the one punctured can be injected with contrast medium.
   c. A Cournand needle has a curved, flanged guard that contours to the body. It is particularly useful in carotid arteriography to hold the needle in position in the neck during injection.
   d. A Robb cannula is blunt, with a large lumen and a stopcock at the hub. It is inserted via a cutdown and is used with a Robb syringe that has a large opening in the tip for fast injection.
   e. A Sheldon needle has an occluded point with an opening at 90 degrees to the lumen. When the vertebral artery is entered, a right-angle injection is made into the lumen of the artery.
2. The amounts of radiopaque contrast substances injected into blood vessels are computed for infants and children according to weight. In adults the amount is measured so that it can be repeated safely for more exposures if necessary.

   Aortic imaging may require the use of full-strength contrast media because of the size of the structure. Radiopaque agents dissipate very rapidly in the bloodstream.
3. Radiopaque contrast material should be warmed to body temperature to prevent precipitation and reduce viscosity. Cold contrast is thicker and requires more pressure to infuse into smaller vessels. The risk for extravasation exists if the vessel perforates.
4. If awake, the patient should be told to expect a warm feeling and possibly a burning sensation when the contrast medium is injected. Procedures may be done with the patient under local anesthesia.
5. Sterile plastic tubing, 30 inches (76 cm) long with a syringe on one end and an adapter on the other is connected to the needle or catheter in the vessel to prevent jarring from the pressure of injection and to keep the hands of the operator out of the x-ray beam.
6. An automatic injector may be used instead of injecting contrast medium by hand. This device correlates injection and x-ray exposure. When an automatic injector is used, special high-pressure nylon tubing is used that does not pull apart with pressure. When this tubing is used, a stopcock is placed on the end for closing it off at the syringe connection, because nylon tubing cannot be clamped.

   The consistency of pressure associated with a power injector minimizes the risk for air bubbles in the line and possibly air embolization. In the event of air embolus the patient should be immediately placed in a left lateral position. Large quantities of air may need to be removed through a catheter inserted into the right atrium of the heart. Removing the air from the heart is known as the Durant procedure. The anesthesia provider can perform this procedure. Some patients respond well to hyperbaric oxygen treatments.
7. Automatic radiologic equipment takes rapid multiple exposures while the contrast medium is in sufficient concentration to visualize the vessels. It can be set at 0.5 to 2-second intervals to take multiple pictures in succession.
8. Digital subtraction angiography converts the x-ray beam into a video screen image. A small amount of contrast medium is injected IV. Vessel catheterization is unnecessary, and less contrast medium is used. This procedure may be done on an ambulatory basis.

Bronchography

Study of the tracheobronchial tree is performed by instillation of a contrast medium to aid in the diagnosis of bronchiectasis, cancer, tuberculosis, and lung abscess or to detect a foreign body. The location of a lesion can be determined and the surgical procedure planned accordingly. The procedure should be explained in detail to the patient, because cooperation is necessary to accomplish the desired result. This radiologic study may be done in conjunction with bronchoscopy. In most patients, bronchoscopy is performed alone without the use of a bronchographic contrast medium.

Cholangiography

In addition to preoperative diagnostic x-ray studies, some surgeons routinely request radiologic studies in conjunction with cholecystectomy or cholelithotomy to identify gallstones in the biliary tract. Other surgeons selectively include cholangiography at the time of the surgical procedure in patients in whom they suspect stones might be present or retained in the bile ducts. Conventional x-ray equipment or an image intensifier may be used for these intraoperative studies.

The basic difference between preoperative and intraoperative cholangiography is the site of administration of the radiopaque contrast medium. For preoperative invasive cholangiography, the contrast medium injected IV through percutaneous venipuncture is excreted by the liver into the bile ducts. During open surgical procedures, the medium is injected directly into bile ducts.

Gastrointestinal X-Ray Studies

Studies are performed to identify lesions in the mucosa of the gastrointestinal tract, such as an ulcer, stricture, or tumor. Inflammatory lesions and partial or complete obstructions also may be identified. Barium sulfate is either swallowed by the patient or instilled by enema to outline the lumen of segments of the tract to be studied if the bowel is intact, not perforated. These studies are done in the radiology department, but surgeons often refer to views during the surgical procedure. Care is taken not to use natural latex rubber enema tubing for this procedure if the patient is sensitive to latex.

Myelography

Lesions in the spinal canal are studied by myelography. It is helpful to localize a filling defect, spinal cord tumor, or herniated nucleus pulposus. Most surgeons do not rely entirely on this method of diagnosis; the patient's symptoms and signs are important in making a final diagnosis. Arachnoiditis is a potential complication of intrathecal injection of iophendylate (Pantopaque). Therefore a water-based contrast medium such as metrizamide (Amipaque) may be preferred.

Urography

Urography is a comprehensive term for radiologic studies of the urinary tract. Most procedures are performed in the radiology department, but some are done in conjunction with cystoscopic examinations. Urographic studies are described as follows:

- *Cystography:* The study of the bladder after instillation of a contrast medium. It is valuable in detecting ureterovesical reflux, a malfunction of the sphincter valves.
- *Cystourethrography:* The study of the bladder and urethra to determine whether there is an obstruction or abnormality in contour or position. X-ray views may be taken as contrast medium is injected into the bladder or when the patient voids the material.
- *Intravenous pyelography (IVP):* The study of the structures of the urinary tract and kidney function. Contrast medium is introduced into the circulatory system by rapid IV injection or slow IV infusion drip. It is excreted through the kidneys. X-ray views are taken at carefully timed intervals. If the medium is poorly excreted through the kidneys, the last view may be taken as late as 24 hours after injection. Tomograms also may be taken while the contrast material is still in the urinary tract. These procedures are done in the radiology department rather than in the cystoscopy room.
- *Retrograde pyelography:* The study of the patency, shape, and position of the kidneys and ureters. Contrast medium is injected through catheters placed in each ureter. This procedure is used to visualize the renal pelves and calyces.
- *Voiding cystourethrography:* The study of the contour and patency of the urethra. Contrast medium may be instilled into the bladder. X-ray views are taken as the patient voids. The medium must flow well but be viscous enough to distend the urethra and provide good detail on the x-ray view. If the patient is anesthetized, a very viscous contrast medium is injected into the urethra and then views are taken. Because the female urethra is rather short, the latter technique is of little value in female patients.

Incidental X-Ray

An unanticipated need for an x-ray view occurs when a sponge, needle, or instrument is unaccounted for at the time the final count is taken during wound closure. An x-ray view will confirm whether the item is still inside the patient. Unless the patient's condition demands immediate wound closure, an x-ray should be taken before closure is completed.

A simple, noncontrast x-ray of the abdomen is referred to as a flat plate. Another name for a flat plate is KUB, which stands for kidneys, ureters, and bladder.

Interventional Radiology

The radiologist may work in collaboration with the surgeon to insert catheters for infusion of cytotoxic and pharmacologic drugs, dilation, or embolization of vessels or organs. Cardiac catheterization, angioplasty, and stent placement are performed in an **interventional radiology** department. Biopsies may be performed percutaneously under radiologic C-arm control.[4] Foreign bodies and thrombi may be extracted.

Interventional radiologic procedures are performed with the patient positioned on a fluoroscopic table equipped with an image intensifier for x-ray visualization of anatomic structures as the surgical procedure progresses. Positioning aids should be used as compatible with the machinery.

The x-ray equipment that will extend over the surgical site should be free from dust. It should be damp-dusted with a disinfectant solution before the patient arrives and the surgical procedure begins. It may be covered with a sterile drape or sleeve before it is moved over the sterile field.

Time, distance, and shielding are the key factors in minimizing ionizing radiation exposure. Personnel should stand at least 6 ft (2 m) away from the radiation source and wear lead aprons with thyroid, sternal, and gonad shields. Patients should be protected with gonad shields if possible. C-arm imaging sends the ionizing radiation from under the patient's body; therefore the shielding should be placed under the patient for adequate protection.

A stock of routine supplies should be kept on a portable cart if procedures are done in the radiology department or other interventional area. In general the following list of items should be readily available:

1. Sterile tray for the specific procedure
2. Skin preparation tray and solutions
3. IV administration sets and solutions
4. Local anesthetic agents, needles, and syringes
5. Radiopaque contrast material
6. Sterile gowns, gloves, drapes, and dressings

The following list of emergency equipment should be readily available:

1. Cardiac resuscitation equipment, including a defibrillator and emergency medications
2. Oxygen supply, Ambu bag, endotracheal tubes, and tubing

Patients should be carefully observed and monitored during all procedures for any change in condition. If a procedure is done with the patient under local anesthesia, a qualified registered nurse should monitor the patient's vital signs. A stand-by anesthesia provider should be available to check the patient's physiologic status as needed.

Magnetic Resonance Imaging

MRI was introduced in U.S. hospitals in 1981. Unlike CT scanning, MRI does not use radiation. The patient lies flat inside a large electromagnet. In this static magnetic field the patient is exposed to bursts of alternating radiofrequency energy waves. The magnetic nuclei of hydrogen atoms in the water of body cells are stimulated from their state of equilibrium. As nuclei return to their original state, they emit radiofrequency signals. These signals are converted by a digital computer into two-dimensional color images displayed on a monitor and recorded on video. Cross-sectional views of the head and all body soft tissue planes can be obtained. A computer software system is also available that produces three-dimensional images.

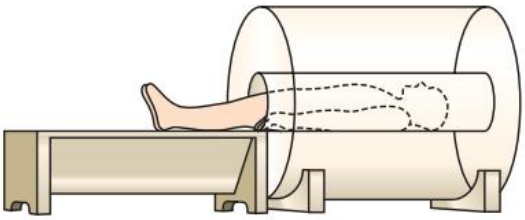
MRI is based on the magnetic properties of hydrogen in the body rather than on the radiodensity of calcium, which is the basis of radiology. MRI looks at both the body's structure and function. It defines soft tissues in relationship to bony and neurovascular structures. It distinguishes among fat, muscle, compact

bone and bone marrow, brain and spinal cord, fluid-filled cavities, ligaments and tendons, and blood vessels. The major applications of MRI are detection of tumors, inflammatory diseases, infections, and abscesses and evaluation of functions of the cardiovascular and central nervous systems and other organs.

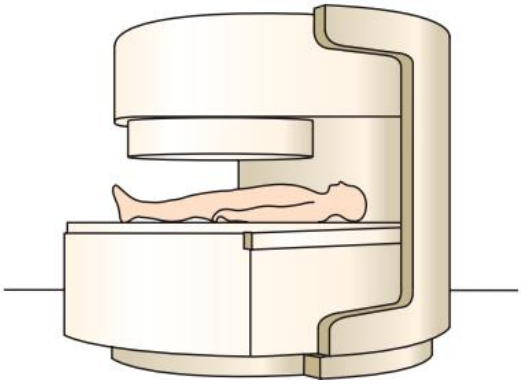
MRI paramagnetic IV contrast media, such as gadopentetate, gadoterate, or gadoteridol are sometimes used to localize tumors in the central nervous system. These media do not contain iodine, and allergic reactions are rare. All metals can cause artifacts that distort MRI scans—some more so than others. Titanium ligating clips, for example, create less distortion than do ferromagnetic (iron) or stainless steel clips. Iron-containing (ferrous) pigments used in tattoos and permanent eyeliner can alter the image produced and generate heat. The magnetic field can cause ferromagnetic components of implants, such as pacemakers and cochlear implants, to malfunction. The magnetic field will also disable metallic devices in the area, such as cardiac monitors, infusion pumps, and wristwatches.

Some patients feel a sense of claustrophobia in a conventional MRI machine (Fig. 22.4). The procedure lasts from 30 to 90 minutes, and the patient must remain still. As the magnets switch on and off, a banging noise echoes through the chamber. The use of ear plugs and head phones helps reduce the sound. Newer open MRI technology has decreased the feeling of being closed in and has decreased the noise level caused by the scanning (Fig. 22.5).

MRI is used during select neurosurgical procedures since the advent of open units. Dedicated MRI interventional rooms permit the use of MRI during the actual surgical procedure. It is critical to prevent any magnetic metallic equipment or instrumentation from being used in the vicinity of the MRI. The literature reports instances of severe patient injury caused by objects such as a metal oxygen tank being pulled into the field by the powerful magnets. Patients are required to change into a facility-approved gown to prevent injuries from metal buttons or items in pockets. Some types of fabrics contain copper or other metals that can cause burns.



• **Fig. 22.4** Conventional closed magnetic resonance imaging.



• **Fig. 22.5** Open magnetic resonance imaging.

Nuclear Medicine Studies

Radionuclides

Radioactive isotopes used in **nuclear medicine studies** are referred to as *radionuclides.* A nuclide is a stable nucleus of a chemical element, such as iodine, plus its orbiting electrons. A nuclide bombarded with radioactive particles becomes unstable and emits radiant energy; it becomes a radionuclide.

Radionuclides that emit electromagnetic energy are used for diagnostic studies to trace the function and structure of most organs of the body. They may be given by the oral, intracavitary, or IV route, including slow IV infusion. These agents may be used to visualize specific areas rather than radiopaque contrast media in some of the procedures previously described. They are particularly useful in studies of the bone marrow, liver, spleen, biliary tract, thyroid, brain, urinary tract, and peripheral vascular system. Because they provide better quantification of arrival times for vascular perfusion above and below lesions, radionuclides may be a more accurate index of the functional significance of a lesion than are other radiopaque contrast media.

Total-Body Scanning

Total-body scanning does not refer to CT but to a radiologic scanning procedure after IV injection of a radionuclide material. Uptake of the radionuclide within the tissues depends on blood flow. Therefore the imaging procedure may be delayed for several hours after the dose is given—not because it takes long for the material to localize in a tumor or inflammatory lesion, where the uptake is high, but because differentiation is achieved after washout from normal structures.

Scanning may include the whole body or only areas of specific interest. Total-body scanning includes identification of structures in the skeletal and vascular systems for diagnosis of a pathologic process such as metastatic bone tumors or thrombotic vascular disease. The scanner can be angled for many views of the same structure.

Scintigraphy and Lymph Node Mapping

Distribution of gamma radioactivity, such as from gallium-67 citrate or radiotracer, may be determined by an external scintillation detector. This is referred to as **scintigraphy**; the record produced is a scintigram or scintiscan. A sterile probe may be used intraoperatively to count gamma emissions from cancer cells. A radionuclide, such as iodine-125, and specific antibodies for antigen-producing tumors are injected approximately 2 to 4 hours before the surgical procedure. The computerized display unit emits an auditory signal when the probe detects radioactivity in tissue.

Lymphoscintigraphy (Sentinel Node Sampling)

Spread of cancer from the primary tumor starts with cells entering an adjacent lymph node, referred to as the sentinel lymph node. Some patients have multiple sentinel nodes in some areas of the body. The degree of tumor progression is measured, and the prognostics of the disease can be predicted by evaluating the findings in the sentinel node(s). It is possible to detect spread to other nodes in the area. If the sentinel node is disease free, it can be assumed that the cancer has not spread to other nodes in the area.

Lymphoscintigraphy uses technetium-99m sulfur colloid, which is an isotope that emits gamma rays as it spontaneously degrades. The isotope is injected around the primary tumor and taken up by the lymphatics. A high-resolution gamma camera follows the isotope's path. Images are captured on digital media until the sentinel node is visualized. An excisional biopsy is performed in the OR.

Some surgeons prefer to use isosulfan blue dye, which is selectively picked up by lymphatic vessels, to visually observe the location of the sentinel node. The dye is injected 1 hour before the excisional biopsy. Care is taken not to transect the lymphatic vessels that carry the dye, because nontarget tissue could be stained and the location of the node in question would be obscured. The excised specimen is sent to the laboratory for fixation or frozen section. Before permanent slides are made, the specimen is stored in the nuclear medicine department for 2 or 3 days until the isotope has degraded to normal. At this point the permanent slide is sent to the pathology department for further diagnosis.

Positron Emission Tomography

Positron emission tomography (PET) is a form of nuclear imaging that combines elements of CT scanning and nuclear scanning to create a picture representing the brain or other organ structure. The radioisotopes used emit positrons that cause pairs of gamma rays to be discharged. The rays are detected by the scanner and are relayed to a computer that converts them into cross-sectional, three-dimensional color images. PET studies provide detailed measurements of biochemistry and physiologic activity. They are used to study blood flow and metabolic functions, primarily in the brain and heart. Higher metabolic activity appears red, lesser activity appears yellow, still lesser activity appears green, and the least activity appears blue.

A PET scan can be used with fludeoxyglucose-F18 to identify and localize lymph node activity. Metastasis can be detected, and/or the patient's response to therapy can be assessed. This method is costly because the radioisotopes have a short half-life. The patient is placed on a table that slides into a tube-like opening. A similar form of scan is the single-photon emission computed tomography (SPECT) scan, which is done with a rotating gamma camera and is commonly used in brain, liver, and cardiac imaging.

Ultrasonography

Ultrasonography uses vibrating high-frequency sound waves in the frequency of 20,000 to 10 billion cycles per second—beyond the hearing capability of human ears—to detect alterations in anatomic structures or hemodynamic properties within the body. The basic component of any diagnostic ultrasound system is its specialized transducer, which is a piezoelectric crystal. The transducer converts electrical impulses to ultrasonic waves at a frequency greater than 1 million cycles per second. These ultrasonic frequencies are transmitted into tissues through a transducer placed on the skin.

A water-soluble gel is applied to the skin to maintain airtight contact between the skin and the transducer, because ultrasonic waves do not travel well through air. A portion of the transmitted ultrasonic waves is reflected back as real-time images to a receiving crystal. The transducer, connected to a microprocessing computer, is held on the skin long enough to obtain a graphic recording of the reflected high-frequency sound waves. Uniform imaging of a wide range of body tissues is possible. Ultrasound is not effective in the presence of bone or gases in the gastrointestinal tract.

Whether used as a preoperative or intraoperative diagnostic technique, ultrasonography is a rapid, painless, noninvasive procedure that distinguishes between fluid-filled and solid masses.

Ultrasonic frequencies are reflected when the beam reaches target anatomic structures of different densities and acoustic impedance. The reflected signal is picked up by the transducer/receiver as an echo. The intensity of the returning echo is determined not only by the angle formed between the ultrasound beam and the reflecting surface of the anatomic structure, but also by the acoustic properties of that surface. The resulting echo is described in terms of time and intensity and displayed on a computerized monitor for immediate interpretation of movements and dimensions of structures.

The image can be recorded on video or printed to provide a permanent record known as an *echogram* or *sonogram.* Sonograms can be obtained on multiple planes. Ultrasonography is a useful adjunct in the diagnosis of the following conditions:

- *Space-occupying lesions in the neonatal brain:* The echoencephalogram will show a shift of the brain caused by tumor.
- *Lesions in the breast, thyroid, and parathyroid glands and in abdominal and pelvic organs:* Ultrasound can distinguish between a cystic and a solid tumor mass in the kidney, pancreas, liver, ovary, and testis. It is the best imaging method in patients with gallbladder disease.
- *Emboli (air, blood, or fat):* Ultrasonography is particularly useful in the early diagnosis of pulmonary embolism. Fat embolus syndrome can develop after long bone fractures.
- *Fetal maturation:* Fetal head size is an aid in the determination of fetal maturation. This can be measured by ultrasound before an elective cesarean section (C-section) or to determine the need for a C-section if the head is too large for vaginal delivery. Ultrasonography is also used to determine the position of the fetus and placenta, identify sex, and detect fetal abnormalities.
- *Cardiac defects:* Structural defects, insufficient valvular movement, and blood flow volumes within the heart chambers and myocardium can be detected. This diagnostic technique is known as *echocardiography.* The echo probe is inserted into the esophagus to obtain a transesophageal echocardiogram (TEE) or placed over the chest for a two-dimensional effect. The esophageal method is useful during open-heart surgery.

Doppler Studies

Blood flow velocity and pressure measurements are possible with ultrasound because moving blood cells produce a sufficient interface with surrounding vessels to independently reflect high-frequency sound waves. The Doppler ultrasonic velocity detector emits a beam of 5 to 10 megahertz (MHz) that is directed through the skin into the bloodstream. A portion of the transmitted ultrasound is reflected from moving particles in the blood. Known as the Doppler effect, the reflected sound wave changes in frequency because the source of the sound is in motion. This shift in frequency is proportional to the velocity of the blood flow.

Originally introduced for use in detecting obstruction in arterial blood flow, the Doppler instrument is used extensively to locate and evaluate blood flow patterns in peripheral arterial and venous diseases or defects, such as the following:

- *Arterial disease:* Detection of altered hemodynamics in arterial flow is significant in diagnosis of obstructive or occlusive arterial

lesions. For example, the Doppler will indicate regions in the neck where carotid artery blood flow to the brain is obstructed by atherosclerosis.

- *Obstruction, ischemia, and aneurysms:* A surgical procedure can be performed to remove or bypass the obstruction to prevent the patient suffering a cerebrovascular accident (stroke/brain attack). It also may help the surgeon determine the appropriate level of lower extremity amputation for ischemia caused by peripheral arterial occlusive disease.[7] It is useful in diagnosis of aortoiliac aneurysms.
- *Venous disease:* Occlusion of superficial or deep veins and the presence of incompetent valves can be located and identified by sounds made by the flow of blood through the peripheral venous system. This qualitative information of abnormal venous hemodynamics in patients with varicose veins and thrombotic disease helps the surgeon plan surgical intervention.

Intraoperative Ultrasonography

A sterile ultrasound transducer probe or scan head may be placed on tissue to evaluate vascularity or density. A pathologic condition can be diagnosed or localized. The handheld transducer must make an acoustic coupling with tissue. Tissues are moistened with sterile normal saline solution, sterile water-soluble jelly, sterile acoustic gel, or peritoneal fluid (if the transducer is placed on the abdomen). The flexible transducer cable is attached to the ultrasound machine, which has a visible display screen.

Permanent recordings of images may be immediately printed or saved on a CD incorporated into the machine. The sound waves may be either continuous or pulsed. A transducer can range from 2 to 15 MHz. A three-dimensional transducer has a frequency between 7.5 and 11 Mhz. Ultrasonography is less time consuming and requires less tissue manipulation than do other intraoperative diagnostic procedures and does not expose the patient to radiation and contrast medium.

Hemodynamics

Ultrasound imaging is used to evaluate the adequacy or restoration of blood flow during vascular reconstruction procedures, such as of peripheral vessels in the lower extremities, hepatic and portal shunts, and carotid arteries. A TEE (transesophageal echo) may be obtained during coronary revascularization by placing the transducer in the esophagus. Doppler instruments are frequently used to assess blood flow through reconstructive tissue flaps and grafts and microvascular anastomoses.

Air Embolus

The Doppler instrument can be used to monitor patients during neurosurgery, open-heart surgery, or procedures on the great vessels in the chest to detect the escape of air into the circulation. Whenever the surgical site is higher than the right atrium the risk for venous air embolism is possible. Air entering an artery to the brain (cerebral air embolism) or venous system may cause anoxic brain damage or death. A venous air embolus of 50 mL causes severe cardiac dysrhythmias by blocking blood flow through the right atrium of the heart; however, 300 mL can be fatal. If an air embolus is detected at the time it occurs, the Durant procedure to evacuate the air can be initiated immediately by the anesthesia provider.

In the Durant procedure the right atrial air embolus is treated by placing the patient's head lower than the heart in steep Trendelenburg's position and elevating the right side of the table or rolling the patient into left lateral position. A multilumen right atrial catheter is inserted through a central venous line into the superior vena cava and into the right atrium of the heart. The air can be manually removed by the anesthesia provider with a large syringe.

Localization of Lesions

Ultrasound imaging is used for intraoperative localization of subcortical brain lesions, spinal cord lesions, pancreatic and hepatic tumors, pelvic masses, and lesions in other soft tissues to determine whether the lesion is resectable. The exact location of gallbladder and kidney stones also can be identified.

Percutaneous Puncture

The direction and depth of needle punctures to locate lesions in various abdominal organs, such as a pancreatic cyst, can be determined by following the ultrasound that is continuously visualized on the monitor. The echo from the tip of the needle is easily visible on the scope when the lesion is entered. These procedures are performed to aspirate cytologic specimens for diagnosis.[4]

Sensory Evoked Potential

Sensory evoked potential (SEP) measures neural pathways and involves placement of multiple recording electrodes over peripheral nerves or the scalp and ears. The evoked potentials generated in response to stimulation are recorded. Components of the computerized system provide sensory stimulation; acquisition, amplification, and filtering of electrophysiologic signals; signal processing; and display, measurement, and storage of SEP waveforms. These noninvasive measurements may be taken preoperatively to assist in the diagnosis of a pathologic condition, such as acoustic neuroma. The techniques also may be used for intraoperative monitoring to assess the status of the central nervous system. Multimodality evoked potentials aid in assessment of patients with trauma. Three modalities are used:

1. *Somatosensory evoked potential (SEP):* An objective evaluation of peripheral and central neural pathways. Pairs of surface or needle skin or scalp electrodes are placed in desired patterns over the appropriate peripheral nerves and areas of the spinal cord and cerebral cortex. These electrodes record somatosensory responses elicited on application of electrical stimuli, such as to the peroneal peripheral nerve at the knee or from over the spinal column or scalp. These impulses along neural pathways are charted to determine whether the nerve is functioning properly or a lesion is impeding impulses to the brain. Testing time can range from 45 minutes to 4 hours, depending on the number of peripheral nerves stimulated and sites necessary to assess neural pathways.
2. *Auditory brainstem evoked potential:* A test of the eighth cranial nerve and the auditory pathway to the cerebral cortex. The patient, wearing headphones or earphones, responds to auditory clicks or tones. Multiple electrodes on the scalp and ears record responses. This study is used to assess the physiologic condition of the brainstem and the patient's hearing threshold.
3. *Visual evoked potential:* A test of responses to visual pattern-reversal stimulation of the optic nerve and its associated pathways to the cerebral cortex. The patient receives stimuli via a television monitor or special eye goggles. Multiple electrodes on the scalp and ears record the evoked potentials.

Plethysmography

In **plethysmography**, pressure-sensitive instruments placed on an organ or around an extremity record variations in volume and pressure of blood passing through tissues. Pen-recorded tracings reflect pulse wave impulses transmitted from moving currents within arteries and veins. These impulses may be measured, computed by electronic circuits, and displayed as digitized data. Plethysmography does not identify the exact anatomic location, extent, or characteristics of vascular disease. It will quantitatively measure the rate of blood flow or degree of vascular obstruction. The following four techniques are used:

1. *Oculoplethysmography:* A technique for determining hemodynamically significant carotid artery stenosis or cerebrovascular obstruction. The instrument is placed on each eyeball to record pulse waves emanating from the cerebrovascular system.
2. *Strain-gauge plethysmography:* A technique to evaluate altered venous hemodynamics in deep venous thrombosis and varicose veins. Two pneumatic cuffs are placed on the leg snugly around the thigh and calf or the ankle and great toe. A mercury strain gauge attached to the plethysmograph is secured around the leg or foot between the two cuffs. Cuffs are inflated sequentially for distal arterial occlusion and proximal venous occlusion. Changes in blood flow volume are measured as the gauge detects changes in the circumference of the calf or foot caused by sequential inflation and deflation of the pneumatic cuffs.
3. *Venous impedance plethysmography:* A technique to measure venous reflux in the lower extremity. Impedance electrodes are attached to the calf under a pneumatic boot. As the boot is inflated, blood is forced proximally out of the veins. Tissues are compressed, causing a concomitant increase in impedance and decrease in calf volume.
4. *Cutaneous pressure photoplethysmography:* A technique to identify peripheral arterial occlusive disease. An infrared light source in a handheld photoplethysmograph probe is applied to the skin with increasing pressure until the pulse is occluded. Infrared light is absorbed by blood. The intensity of the reflected light changes as the volume of blood increases as pressure is released. The probe measures the ability of the vascular system to force arterial blood into skin tissue.

Endoscopy

Direct visualization within body cavities and structures aids in determination of the appropriate course of therapy for many conditions. Diagnostic endoscopy frequently is performed in conjunction with radiologic studies or to obtain specimens for pathologic examination. A tissue staining dye and/or radiopaque contrast material may be injected through the endoscope or an accessory before radiologic studies. Fluid and secretions may be withdrawn for culture or chemical analysis. Biopsy specimens are frequently obtained.

Direct visualization alone may confirm the presence or absence of a suspected lesion or abnormal condition. This may be enhanced by an ultrasonic transducer at the end of a flexible fiberoptic scope. Endoscopic diagnosis often provides the information necessary to proceed with an open procedure or to cancel an anticipated surgical procedure. Small video capsules can be swallowed to allow visualization of the small intestine.

Endoscopy is described in detail in Chapter 32, and specific endoscopic procedures are discussed in subsequent chapters when they are pertinent to diagnostic and surgical procedures in the appropriate surgical specialties.

The Patient with Cancer

Oncology is the study of scientific control over neoplastic growth. It concerns the etiology, diagnosis, treatment, and rehabilitation of patients with known or potential neoplasms. A **neoplasm** is an atypical growth of abnormal cells or tissues that may be a benign or **malignant tumor**.

Cancer is a broad term that encompasses any malignant tissue change. The exact cause of cancer is unknown. Cancerous tumors can be caused by exposure to chemical toxins, ionizing radiation, chronic tissue irritation, tobacco smoke, ultraviolet rays, viral invasion, and genetic predisposition. Studies have shown that immunosuppression may contribute to the incidence of cancer by altering biochemical metabolism and cellular enzyme production. Other research has shown that dietary influences, such as nitrates, salt-cured or smoked foods, and high-fat diets, may contribute to cancer in certain individuals.

Both malignant and benign neoplasms consist of cells that divide and grow uncontrollably at varied rates. The stimulus for growth can be intrinsic (e.g., hormonal) or extrinsic (e.g., exposure to external elements). Neoplastic overgrowth or the invasion of surrounding tissue causes dysfunction and may eventually cause the death of the patient.

Table 22.2 compares the characteristics and effects of benign and malignant tumors. Four characteristics distinguish malignant from **benign tumors**, with a malignant tumor having characteristics as follows:

- It is anaplastic. Cancer cells resemble normal cell forms but are morphologically and functionally differentiated from the normal tissue of origin. They vary in size, shape, and texture.
- It infiltrates and destroys adjacent normal tissue.
- It grows in a disorganized, uncontrolled, and irregular manner, usually increasing in size both rapidly and perceptibly within weeks or months.

TABLE 22.2 Comparison of Benign and Malignant Tumors

Benign	Malignant
Characteristics	
Expansive	Invasive
Localized	Spreads to distant sites
Encapsulated	No capsule
Slow growth	Rapid growth
Resembles parent tissue	Varied differentiation
Normal cell reproduction	Disorganized cell reproduction
Organized mitoses	Abnormal mitoses
Effect on Patient	
Pain uncommon	Severe pain common
Little nutritional effect unless mechanical obstruction is involved	Cachexia, nausea, and vomiting

- It has the power to metastasize. Cancer cells migrate from the primary focus to another single focus or to multiple foci in distant tissues or organs via lymphatic or vascular channels.

Clinical Signs and Symptoms of Cancer

According to the American Cancer Society, the following are the clinical signs and symptoms of cancer:

- Palpable mass or abnormal thickening of tissue
- Abnormal bleeding or discharge
- Obvious change in a wart or mole
- Lesion that does not heal
- Steady decrease in weight, appetite, and energy
- Chronic cough
- Change in bowel or bladder habits

Potential Causes of Cancer

The early detection of cancer decreases the incidence of morbidity and mortality. A screening examination may identify a neoplasm before clinical symptoms develop. Recommended cancer screening examinations are listed in Table 22.3. (More screening information can be found on the American Cancer Society website at www.cancer.org.)[7]

Risk-Related Factors

Risk factors for cancer include the following:

- Age, sex, or racial, genetic, or hereditary predisposition. Table 22.4 identifies neoplasms associated with familial cancer syndromes.
- Exposure to carcinogens (cancer-producing agents) such as tobacco smoke, coal tar, ionizing radiation, ultraviolet rays, and chemicals. Table 22.5 lists examples of chemical carcinogens.
- Predisposition from specific environmental conditions or acquired conditions or diseases. Table 22.6 gives examples of viral-mediated carcinogens.

Extent of Disease

Carcinoma in Situ

In **carcinoma** in situ, normal cells are replaced by anaplastic cells but the growth disturbance of epithelial surfaces shows no behavioral evidence of invasion and metastasis. This cellular change is noted most often in stratified squamous and glandular epithelium. Carcinoma in situ is also referred to as *intraepithelial* or *preinvasive cancer.* Common sites for in situ carcinoma include the following:

- Uterine cervix
- Uterine endometrium

TABLE 22.3 Cancer Screening Examinations

Sex	Age	Frequency of Examination
Pelvic Examination by Palpation and Inspection		
Female	21-29 years Ages 30 and up	Every 3 years Every 5 years
Pelvic Examination by Palpation and Inspection, Including Pap Smear and HPV Testing		
Female	Start at age 21 or at age of onset of sexual activity if younger. HPV screening every 3-5 years for women 30-65 years	May be performed less frequently on advice of physician.
Endometrial Tissue Sample		
Female	At menopause or sooner at recommendation of physician	Sample for baseline in high-risk patient Age 35 and over
Breast Self-Examination		
Female and male	Start at age 18 and throughout life span	*Female:* monthly after menses or at same time each month after menopause *Male:* monthly
Clinical Breast Examination		
Female	Start at age 21 and throughout life span	Corresponds with pelvic examination sequence unless patient has a previous history of breast disease or is at high risk for breast disease
Mammography		
Female	Baseline at age 40, yearly after age 40-49	Frequency after baseline is individualized according to age, health, and risk factor analysis by physician; mammography, when performed, should precede clinical breast examination so that data analysis will be complete

TABLE 22.3 Cancer Screening Examinations—Cont'd

Sex	Age	Frequency of Examination
Testicular Self-Examination by Palpation and Inspection		
Male	Start at age 16 and throughout life span	Monthly
Prostate		
Male	More than age 50; start at age 40 for men at high risk	Yearly, prostate-specific antigen (PSA) blood test
Digital Rectal Examination		
Male and female	Over age 50; start at age 45 for risk factors	Yearly; frequency may vary according to individual risk factors or the recommendation of physician
Stool Guaiac Examination		
Male and female	Over age 45	Yearly; age and frequency may vary according to symptoms and the recommendation of physician
Sigmoidoscopy or Colonoscopy		
Male and female	Over age 45	Every 5-10 years or according to the advice of physician; age and frequency may vary in the presence of risk factors or individual symptoms; colonoscopy may be advised according to risk factors
Generalized Physical with Health Counseling		
Includes palpation of thyroid, gonads, and lymphatics, as well as inspection of oral mucosa		
Male and female	Over age 20	Every 3 years
Male and female	Over age 40	Every year

HPV, Human papillomavirus.

- Vagina
- Anus
- Penis
- Lip
- Buccal mucosa
- Bronchi
- Esophagus
- Eye
- Breast

Localized Cancer

Localized cancer is contained within the organ of its origin.

Regional Cancer

In regional cancer the invaded area extends from the periphery of the organ or tissue of origin to include tumor cells in adjacent organs or tissues (e.g., the regional lymph nodes).

Metastatic Cancer

In metastatic cancer the tumor extends by way of lymphatic or vascular channels to tissues or organs beyond the regional area. The cancer cells multiply erratically (**anaplasia**) and move to other areas of the body. Anaplasia implies that the cancer cells have taken on unusual shapes and reproduce in unpredictable patterns.

Disseminated Cancer

In disseminated cancer, multiple foci of tumor cells are dispersed throughout the body.

Tumor Identification System (TNM)

A standardized tumor identification system, which includes classification and staging, is essential for establishing treatment protocols and evaluating the end result of therapy. Hospitals maintain a tumor registry of patients to evaluate therapeutic approaches to specific types of tumors. Classification includes the anatomic and histologic description of a tumor, whereas staging refers to the extent of the tumor. There are three basic categories of the tumor identification system:

- Primary **T**umor
- Regional **N**odes
- Distant **M**etastases

The TNM categories are identified by pretreatment clinical diagnosis, tissue biopsy, and/or histopathologic examination after surgical resection of the tumor. Numeric and alphabetical characters are

TABLE 22.4 Familial Cancer Syndromes

Syndrome	Associated Neoplasm
Autosomal Dominant Gene	
Familial polyposis coli	Adenocarcinoma of colon, adenomatous polyps
Gardner syndrome	Adenocarcinoma of colon, musculoaponeurotic tumors
Peutz-Jeghers syndrome	Adenocarcinoma of small intestine, colon, ovary
Neurofibromatosis	Neurofibroma, neurogenic sarcoma, pheochromocytoma
Multiple endocrine neoplasia (MEN type I), or Wermer's syndrome	Pituitary, pancreatic islet cells, parathyroid glands
Multiple endocrine neoplasia (MEN type IIA), or Sipple's syndrome	Thyroid, parathyroid glands, pheochromocytoma
Multiple endocrine neoplasia (MEN type IIB)	Thyroid, parathyroid, pheochromocytoma, mucosa ganglioneuromas
Autosomal Recessive Gene	
Xeroderma pigmentosum	Basal and squamous cell carcinoma of skin, malignant melanoma
Ataxia-telangiectasia	Acute leukemia, lymphoma, some gastric cancers

TABLE 22.5 Examples of Chemical Carcinogenesis

Chemical	Site of Neoplasm
Alkylating Agents	
Nitrogen mustard, cyclophosphamide, chlorambucil	Leukemia, urinary bladder
Vinyl chloride	Angiosarcoma of liver
Polycyclic Hydrocarbons	
Tar, soot, oils	Skin, lung
Aromatic Amines and Azo Dyes	
α-Naphthylamine, benzidine	Urinary bladder
Food Products	
Saccharin	Urinary bladder
Aflatoxin (mold on peanuts)	Liver
Betel nuts	Oral mucosa
Medication	
Androgenic metabolic steroids	Liver
Diethylstilbestrol	Vagina
Phenacetin	Renal pelvis
Inorganic Compounds	
Chromium	Lung
Nickel	Lung, nasal sinuses
Asbestos	Serosal membranes, lung
Arsenic	Skin
Mercury	Fetal growth and development abnormalities

used to describe the findings; for example, bronchogenic carcinoma T1 N0 M0 means a primary tumor in the lung without positive regional nodes or distant metastases. If a positive lymph node is identified in the area, it is indicated in an abbreviated sequence (e.g., T1 N1 M0). If a metastatic site also is diagnosed, it too is indicated in the same format.(e.g., T1 N1 M1).

The numeric and alphabetic sequence corresponds to the number of separate tumors at the identified primary site, positive lymph nodes, or metastatic sites (Box 22.3). Other staging systems are referred to in the literature as stages I, II, III, and IV. After treatment, the estimation of residual tumor volume is indicated by the letter R.

Monitoring Tumor Markers

Tumor markers are serum studies used to measure specific enzymes emitted by tumor cells. Elevated tumor markers in the patient's blood and tissues can help determine the patient's treatment and prognosis. Table 22.7 describes common blood tests for serum tumor markers and their implication in cancer prognostication.

Cancer Treatment

Cancer is a systemic disease and is treated based on location and cell type. Therapy is curative if the disease process can be totally eradicated, but the success of therapy depends largely on early diagnosis. Tumors are classified to determine the most effective therapy. When a cure is not possible, palliative therapy relieves symptoms and improves quality of life but does not cure the disease.

Before beginning therapy a patient with cancer undergoes an extensive pretreatment workup. Each form of cancer therapy has certain advantages and limitations. Several factors affect a patient's response to treatment: host factors, clinical stage of malignancy, and type of therapy. The patient is followed carefully to determine the effectiveness of treatment at routine intervals.

Adjuvant Therapy

Surgical resection, ablation, endocrine therapy, radiation therapy, **chemotherapy**, **immunotherapy**, hyperthermia, or combinations of these procedures are used in the treatment of cancer. The surgeon or oncologist determines the most appropriate therapy for each patient. When determining the most appropriate therapy, the following parameters are considered:

- Type, site, and extent of tumor and whether lymph nodes are involved
- Type of surrounding normal tissue
- Age and general condition of the patient, including nutritional status and whether other diseases are present
- Whether curative or palliative therapy is possible

TABLE 22.6 Viral-Mediated Carcinogenesis

Viral Family	Type of Neoplasm
DNA-Associated	
Papilloma (condyloma)	Squamous papilloma and squamous cell carcinoma
Hepatitis B	Hepatocellular carcinoma
Herpesvirus	
Epstein-Barr	Burkitt's lymphoma, nasopharyngeal carcinoma
Cytomegalovirus	Kaposi's sarcoma
Herpes simplex type II	Uterine cervical carcinoma
RNA-Dependent	
Human T cell lymphotropic type 1 (retrovirus C)	T cell leukemia, lymphoma

DNA, Deoxyribonucleic acid; *RNA*, ribonucleic acid.

TABLE 22.7 Common Serum Tumor Markers

Test	Value	Indication
Carcinoembryonic antigen (CEA)	0-2.5 ng/mL	Colorectal
Alpha-fetoprotein (AFP)	10 ng/mL	Testicular, liver
Ca-125	<35 U/mL	Ovarian
Human chorionic gonadotropin (HCG)	0-1 ng/mL	Choriocarcinoma testicular
Prostate-specific antigen (PSA)	0-4.0 ng/m/L (>40 yr)	Prostate

• BOX 22.3 Tumor Identification Scale

Primary Tumor

TX	Primary tumor discovered by the detection of malignant cells in secretions or cell washings but not directly visualized
T0	No evidence of primary tumor
Tis	Tumor (carcinoma) in situ
T1	Tumor is 2 cm or less at largest dimension
T2	Tumor is larger than 2 cm at largest dimension
T3	Tumor directly invades surrounding tissue
T4	Tumor invades surrounding tissue and adjacent structures, such as blood vessels or bone

Regional Lymph Nodes

NX	Unable to assess nodes
N0	No regional lymph node metastasis
N1	Metastasis to ipsilateral nodes or direct extension to nodes
N2	Metastasis to contralateral nodes

Distant Metastasis

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis confirmed

Posttreatment Residual Tumor

RX	Unable to assess residual tumor
R0	No residual tumor
R1	Microscopic residual tumor
R2	Macroscopic residual tumor

Surgical Resection and Palliation

Surgical resection is the modality of choice to remove solid tumors. The resection of a malignant tumor is, however, localized therapy for what may be a systemic disease. Each patient is evaluated and treated individually, and the surgical procedure is planned appropriately for the identified stage of disease. Depending on localization, regionalization, and dissemination of the tumor, the surgeon selects either a radical curative surgical procedure or a salvage palliative surgical procedure.

Surgical debulking or **cytoreductive surgery**, in which the tumor is partially removed, may be the procedure of choice for some types of surgically incurable malignant neoplasms. With surgical debulking the intent is not to cure but to make subsequent therapy with irradiation, drugs, or other **palliative** measures more effective and thereby extend survival. In planning the surgical procedure the surgeon considers the length of expected survival, the prognosis of surgical intervention, and the effect of concurrent diseases on the postoperative result.

Accessible primary tumors are often treated by excision. An extremely wide resection may be necessary to avoid recurrence of the tumor. The pathologist is able to make judgments about questionable margins by evaluating frozen sections while the surgical procedure is in progress. The pathologist's findings guide the surgeon during resection so that residual tumor is not left in the patient. The specimen is also tested after permanent section fixation in the pathology laboratory. Final results are available in 2 to 3 days.

Many surgical procedures are performed for ablation of tumors by primary resection. In addition, a lymphadenectomy (removal of local lymph nodes) may be performed as a prophylactic measure to inhibit the metastatic spread of tumor cells via lymphatic channels. These nodes are tested to determine the extent of tumor cell spread. Other modalities of therapy may be administered preoperatively, intraoperatively, and/or postoperatively to reduce or prevent a recurrence or metastasis.

Preservation of Reproductive System

Females and males of reproductive age with cancer who are facing radiation therapy are at risk for becoming sterile as a result of treatment. Gonadal shields are used whenever possible. Males can donate sperm for cryopreservation and later use it for in vitro fertilization or artificial insemination. In some circumstances females can have a laparoscopic procedure to relocate their ovaries to a deeper or medial location in the pelvis where they will experience little or no exposure to radiation. Other palliative surgical interventions are described in Box 22.4.

Endocrine Therapy

Tumors arising in organs that are usually under hormonal influence (e.g., breast, ovary, and uterus in female patients; prostate and testes in male patients) may be stimulated by hormones

• BOX 22.4 Palliative Oncologic Surgical Procedures

- Reduction of tumor to prevent obstruction (debulking)
- Reduction of tumor cells to aid effectiveness of chemotherapy
- Treatment of oncologic emergencies such as hemorrhage or compression
- Removal of enlarged organs such as the spleen
- Repair of perforations in irradiated parts such as the rectum
- Removal of a hormone-producing part such as a gonad or other gland
- Removal of a diseased organ such as the uterus, prostate, or breast
- Insertion of a nutritional support device such as a feeding gastrostomy or total parenteral alimentation line
- Pain control such as nerve blocks or the severing of a neural pathway or receptor site

produced in the endocrine glands. Cellular metabolism is affected by the presence of specific hormone receptors in tumor cells: estrogen and/or progesterone in females and androgens in males.

Certain breast, endometrial, and prostatic cancers depend on sex hormones for growth and maintenance. Therefore the recurrence or spread of disease may be slowed by therapeutic hormonal manipulation. Endocrine manipulation does not cure, but it can control dissemination of the disease if the tumor progresses beyond the limits of effective surgical resection or radiation therapy.

Hormonal Receptor Site Studies

Identifying the hormonal dependence of the primary tumor through studies of the receptor site is a fairly reliable way of selecting patients who will benefit from preoperative or postoperative endocrine manipulation. After a positive diagnosis of cancer, either by a frozen section biopsy or pathologic permanent sections, the surgeon will probably request a receptor site evaluation of a primary breast, uterine, or prostatic tumor.

The tissue specimen removed by surgical resection should be sent fresh or in saline. It should not be placed in formalin preservative solution because doing so will alter the receptor cells enough to negate the hormonal study.

Endocrine Ablation

Since 1896, surgeons have described positive clinical responses in patients with metastatic breast cancer after treatment by endocrine ablation—the surgical removal of endocrine glands. If the surgeon plans to eliminate endocrine stimulation surgically in a patient with a known hormone-dependent tumor, all sources of the hormone should be ablated chemically, hormonally, or surgically.

- *Bilateral adrenalectomy and oophorectomy.* Both adrenal glands and/or ovaries may be resected to prevent the recurrence of endocrine-derived cancer. These may be removed as a one-stage surgical procedure (i.e., bilateral adrenalectomy/oophorectomy). If two separate surgical procedures are preferred, the bilateral oophorectomy precedes the bilateral adrenalectomy, except in menopausal women in whom only the latter surgical procedure may be indicated.
- *Bilateral adrenalectomy and orchiectomy.* After prostatectomy for advanced carcinoma of the prostate, both testes may be removed (i.e., bilateral orchiectomy) to eliminate androgens of testicular origin. Bilateral adrenalectomy also may be indicated.

Hormonal Therapy

Hormones administered orally or via injection can alter cell metabolism by changing the systemic hormonal environment of the body. For hormones to be effective, tumor cells must contain receptors. Hormones must bind to these receptors before they can exert an effect on cells.

- *Antiestrogen therapy:* Patients with medical contraindications to endocrine ablation may receive antiestrogen therapy. An estrogen antagonist deprives an estrogen-dependent tumor of the estrogen necessary for its growth. Nafoxidine and tamoxifen (Nolvadex) are synthetic nonsteroidal drugs that inhibit the normal intake of estrogen at estrogen receptor sites; they are taken orally.
- *Corticosteroids:* Prednisone, cortisone, hydrocortisone, or some other preparation of corticosteroids may be administered as an antiinflammatory agent along with the chemotherapeutic agents given to control disseminated disease.

Photodynamic (Laser) Therapy

For photodynamic therapy (also referred to as *photoradiation*), an argon tunable dye laser is used to destroy malignant cells by photochemical reaction. A photosensitive drug, either hematoporphyrin derivative (HPD) from bovine blood (porfimer [Photofrin]) or purified dihematoporphyrin ether, is absorbed by malignant and reticular endothelial cells.

The photosensitive drug is injected intravenously via venipuncture or Hickman's catheter 24 to 48 hours before the photodynamic therapy and is taken up by cells to make them fluorescent and photosensitive. It remains longer in malignant cells than in normal cells before being excreted from the body. When exposed to light from an argon laser, the tunable rhodamine B dye laser produces a red beam of approximately 630 nm. Other dyes, such as dicyanomethylene, may produce different wavelengths.

HPD in cells absorbs the laser light, which leads to a photochemical reaction that causes tissue-oxygen molecules to release cytotoxic singlet oxygen and destroy tumor cells. Depending on tumor site, the laser can be delivered interstitially, endoscopically, externally, or retrobulbarly.

Photodynamic therapy may be used to debulk tumors of the eye, head and neck, breast, esophagus, gastrointestinal tract, bronchus, and bladder. The tunable dye laser also may be used to diagnose tumor cells. The OR should be darkened or have shades to block outside daylight during the laser treatment. The patient is cautioned to avoid exposure to sunlight or other sources of ultraviolet light both after injection of the dye and postoperatively. Photosensitivity is the primary side effect of the dye and may last 4 to 6 weeks.

Radiation Therapy

Radiation is the emission of electromagnetic waves or atomic particles that result from the disintegration of nuclei of unstable or radioactive elements. The treatment of malignant disease with radiation may be referred to as *radiation therapy,* brachytherapy, or *radiotherapy.* Ionizing radiation is used for this type of therapy, which involves the use of high-voltage radiation and other radioactive elements to injure or destroy cells. Like surgical resection and photodynamic therapy, radiation therapy is localized therapy that is applicable for a limited number of specific tumors.

Ionizing Radiation

Ionization is the physical production of positive and negative ions capable of conducting electricity. Ionizing radiation is radiation with sufficient energy to disrupt the electronic balance of an atom. When disruption occurs in tissue cells or extracellular fluids, the effect can range from minor changes to profound disturbances.

Radiation may come either from particles of the nuclei of disintegrating atoms or from electromagnetic waves that have no mass. Types of ionizing radiation include the following:

- *Alpha particles:* Alpha particles are relatively large particles that have a very slight penetrating power. They are stopped by a thin sheet of paper. They have dense ionization but can produce tremendous tissue destruction within a short distance.
- *Beta particles:* Beta particles are relatively small, are electrical, and travel with the speed of light. They have greater penetrating properties than do alpha particles. Their emissions cause tissue necrosis, and they produce ionization, which has destructive properties.
- *Gamma rays and x-rays:* Gamma rays and x-rays are electromagnetic radiations of short wavelength but high energy, and they are capable of completely penetrating the body. They affect tumor tissue more rapidly than normal tissue. These types of rays are stopped by a thick lead shield. Protons ranging in energy from 30 kilovolts (kV) to 35 million electron volts (eV) are available for the treatment of various cancers. Gamma rays are emitted spontaneously from the nucleus of an atom of a radioactive element.

Implantation of Radiation Sources

All radiation sources for implantation are prepared in the desired therapeutic dosages by personnel in the nuclear medicine department. Many types of sources are used to deliver maximum radiation to the primary tumor. No single type is ideal for every tumor or anatomic site.

Interstitial Needles. Interstitial needles are hollow sheaths that are usually made of platinum or Monel metal. Radium salts or radionuclides are encased in platinum or platinum-iridium short units or cells, which in turn are sealed in the metal sheath of the needle for implantation into tumor tissue. A needle may contain one or several short units or cells of the radiation source, depending on the length of needle to be used. Needles vary in length from 10 to 60 mm, with a diameter of 1 to 2 mm. The choice of length depends on dosage and on the area involved. Dosage is measured in milligram-hours, which can be converted to rads.

The interstitial needles, which usually contain cesium-137, are implanted in tumors near the body surface or in tissue accessible enough to permit their use (e.g., vagina, cervix, tongue, mouth, neck). In certain patients, stereotactic techniques are used to implant needles for the irradiation of brain tumors.

In the OR these needles are inserted at the periphery of and within the tumor. One end of the needle is pointed, and the other end has an eye for a heavy (size 2) suture. Needles are threaded to prevent loss while in use and to aid in removal. After the surgeon inserts the needles, the ends of the sutures are tied or taped together and are taped to the skin in an adjoining area or secured to buttons.

Depending on the anatomic site, a template may be used to position and secure the needles. A template consists of two acrylic plates separated by rubber O-rings and held together with screws. The plates have holes for insertion of the interstitial needles. The template remains in place until the needles are removed. Depending on the planned dosage to the tumor bed, needles are usually left in place for hours to several days.

Interstitial Seeds. Sealed radionuclide seeds may be implanted permanently or temporarily. Because they have a short half-life, gold seeds are permanently implanted, most commonly into the prostate, lungs, or pancreas. Seeds containing cesium-137, iridium-192, or iodine-125 implanted directly into tumor tissue are removed after the desired exposure.

Seeds are useful in body cavities, localized areas, and tumors that are not resectable because of their location near major vessels or the spinal cord. Because they are small, the seeds can be placed to fit a curved area without requiring immobilization. However, they may move about if there is much motion.

Radionuclide seeds are 7 mm or less in length, are 0.75 mm in diameter, and have a wall 0.3 mm thick. The length of the seed depends on the desired dosage. Seeds can be inserted with or without an invasive surgical procedure. They may be strung on a strand of suture material or placed in a hollow plastic tube with sealed ends. With a needle attached, the strand or tube is woven or pulled through the tumor.

Seeds in a plastic tube may be inserted through a hollow needle, such as a catheter through a trocar. Empty tubes may be inserted in the OR and afterloaded (i.e., the seeds are put into the tube at a later time and place). A microprocessor-controlled machine that pulls wire attached to radioactive material through the tube may be used for remote afterloading.

Brachytherapy. The term **brachytherapy** comes from a Greek term meaning "short-range treatment." Tiny titanium cylinders that contain a radioactive isotope are implanted to deliver a dose of radiation from the inside out that kills cancer cells while sparing healthy tissue. Brachytherapy is performed for many types of cancers, including breast and prostate (see Fig. 7-5).

Brachytherapy is useful for delivering higher cell-killing doses in shorter periods than conventional radiation treatments. The capsules are placed under ultrasound guidance. A rapid delivery system that uses a catheter with a balloon on the tip has been developed to treat breast cancer smaller than 3 cm. The catheter is placed into the breast tissue during tumor excision, and the balloon is expanded with water. Twice per day for 4 to 5 days a high-dose radiation pellet is placed inside the catheter to treat the tissue. When the treatment period is complete, the catheter and pellet are removed. Patient selection includes those with clear tumor margins and with fewer than three affected lymph nodes.

Intracavitary Capsules. A sealed capsule of radium, cesium-137, iodine-125, yttrium-192, or cobalt-60 may be placed into a body cavity or orifice. The capsule may be a single tube of radioactive pins fixed in a tandem loader or a group of individual capsules, each of which contains one radioactive pin. Commonly used to treat tumors in the cervix or endometrium of the uterus, a capsule is inserted via the vagina for treatment of the uterine body.

In a patient with cervical cancer an instrument such as an Ernst applicator is used. A metal or plastic tube with radioactive pins is inserted in the uterus. Metal pins are used in conjunction with heat. The tube is attached to two vaginal ovoids, each of which contains a radioactive pin, that are placed in the cul-de-sac around the cervix. This type of application delivers the desired dosage in a pear-shaped volume of tissue, which includes the cervix, corpus, and tissue around the cervix but spares the bladder and rectum from high doses of radiation.

A blunt intracavitary applicator is used to position the parts. The applicator is held securely and remains fixed to ensure proper dosage to the tumor without injuring the normal surrounding structures. For stabilization, the surgeon may suture the applicator to the cervix, and vaginal packing also is used. Two different methods of application are used for inserting the radiation source: afterloading techniques and preloading techniques.

Afterloading Techniques. Afterloading techniques afford the greatest safety for OR personnel. In the OR a cold, unloaded, hollow plastic or metal applicator, such as the Fletcher afterloader, is inserted into or adjacent to the tissues that will receive radiation.

After x-ray verification of correct placement, the radiation source is loaded into the applicator at the patient's bedside.

Preloading Techniques. Preloading techniques require insertion of the "hot" radiation capsule in the OR by the surgeon. OR personnel should not be permitted in the OR during this procedure. To deliver a uniform dose to the desired area, the surgeon inserts an adjustable device designed to hold the radiation source in proper position in the tissues (e.g., the Ernst applicator). The bladder and rectum are held away from the area with packs to avoid undesired irradiation. To calculate the necessary dosage, the surgeon uses x-ray views of the pelvis to check the position of the radiation source and measure its distance from critical sites.

All preparations for insertion are made by nursing team members before they leave the room. (They wait in the substerile room during insertion.) Preparations include setting the sterile table with vaginal packing, antibiotic cream for packing, radiopaque solutions for x-ray studies, and a basin of sterile water; placing the x-ray cassette on the OR bed and notifying the radiology technician; obtaining the radiation source; positioning the patient; and putting a radiation sheet on the patient's chart and a card on the stretcher.

Intracavitary Colloidal Suspensions. Sterile radioactive colloidal suspensions of gold or phosphorus are used as palliative therapy to limit the growth of metastatic tumors in the pleural or peritoneal cavities. Radioactive colloidal gold-198 is most commonly used; it has a half-life of 2.7 days. It also may be instilled within the bladder. The effect of these suspensions is caused by the emission of beta particles that penetrate tissue so slightly that radioactivity is limited to the immediate area in which the colloidal suspension is placed. A trocar and cannula are introduced into the pleural or peritoneal cavity, and the colloidal suspension is injected through the cannula from a lead-shielded syringe. After use, these instruments are stored in a remote area until the decay of radioactivity is complete.

Intraoperative Radiation Therapy

During a surgical procedure, a single, high dose of radiation may be delivered directly to an intraabdominal or intrapelvic tumor or tumor bed to provide an additional palliative or localized means of control. Normal organs or tissues can be shielded from exposure. Radiation also may be used after resection of the bulk of the tumor.

An orthovoltage unit may be installed in a lead-lined OR for performing intraoperative radiation therapy. The sterile Lucite cone is placed directly over the tumor site. All team members leave the room during treatment. In some hospitals the patient is transported from the OR to the radiation therapy department. After exposure to a megavoltage electron beam, the wound may be closed in the treatment area or the patient may be returned to the OR for further surgery and/or wound closure. The open wound is covered with a sterile drape during transport, and sterile technique is used for closure.

Stereotactic Radiosurgery

Gamma knife technology was developed in Sweden in the early 1950s by surgeon Lars Leksell and Börje Larsson, MD, a radiobiologist. They experimented with guiding devices and proton beams. Cobalt-60 was found to be most effective in the treatment of brain tumors and was selected as the energy source for the gamma knife. In 1975 the device was used to treat brain tumors in humans.

With stereotactic radiosurgery, fiberglass fixation pins are used to apply a base ring (the Leksell head frame) to the patient's head preoperatively. Two small rods are placed in the ear canals to stabilize the head frame during fixation. Care is taken not to injure the ear canal or tympanic membrane during this process. A calibrated ring is affixed to the frame to form X, Y, and Z coordinates to localize the brain lesion. The frame and ring sit within a larger helmet that aims the radiation at the tumor.

The gamma knife delivers highly concentrated doses of gamma rays to inoperable or deep-seated vascular malformations or brain tumors 1 to 10 cm^3 in size. The localized area is determined by precision **stereotaxis**. The neurosurgeon places the patient's head, with the Leksell head frame and localizing ring, into the collimator helmet so that the focusing channels direct 201 pinpointed cobalt-60 beams to the tumor. (The radiation sources are located in a large spherical chamber that is located within a special room.) Other styles of frames are available that attach in the front and back of the head or use markers to pinpoint the direction of gamma rays.

The patient is placed on a sliding bed that accommodates and aligns with the helmet as it enters the spherical chamber. The gamma knife process lasts 3 to 4 hours. During the procedure the patient is in video and voice communication with the perioperative team. All personnel leave the room during treatment because of the intensity of the radiation and its cumulative effects.

Effects of Radiation Therapy on the Perioperative Patient

The patient may be undergoing several treatment modalities and may experience the specific tissue and systemic effects of each. The perioperative nurse should understand how radiation affects the patient and how it affects the attainment of desired outcomes. The plan of care should include consideration for the potential side effects of radiation therapy. Box 22.5 describes the patient's responses to the physiologic effects of radiation.

• BOX 22.5 Physiologic Effects of Radiation Therapy

External Beam

- Gastroenteritis
- Nausea and vomiting
- Diarrhea
- Menstrual irregularities
- Miscarriage
- Sexual dysfunction
- Fatigue
- Cystitis
- Erythema
- Skin desquamation
- Headache
- Decreased circulation

Internal Implants

- Bleeding tendency
- Increased infections
- Sexual dysfunction

Intracavitary Implants

- Bleeding
- Infection
- Sexual dysfunction

Intraoperative Radiation

- Anorexia
- Nausea and vomiting

Chemotherapy

Either alone or in combination, a variety of chemotherapeutic agents are capable of providing measurable palliative remission or regression of primary and metastatic disease, with a decrease in the size of the tumor and no new metastases. In some instances a complete response, with the disappearance of all clinical evidence of the tumor, is achieved.

The trend is toward earlier and greater use of adjuvant chemotherapy. More than one agent may be administered to enhance the action of another cytotoxic or antigenic substance. Adjuvant therapy is designed to maximize the benefits of each agent in the combination while avoiding overlapping toxicities. The following factors are important in determining the ability of tumor cells to respond to chemotherapy:

- *Size and location of the tumor:* The smaller the tumor the easier it will be to reach cells. The mechanism for the passage of drugs into the brain differs from that for other body organs.
- *Type of tumor:* For example, cells of solid tumors in the lung, stomach, colon, and breast may be more resistant than cells in the lymphatic system.
- *Combinations of adjuvant therapy:* In select patients, chemotherapy may be used as an adjunct to all other types of therapies. Precise scheduling of dosages is necessary to attain effective results.
- *Specific biochemical requirements of the tumor:* Agents are selected according to the appropriateness of their structure and function. More than one agent is usually given.
- *State of life cycle of the cancer cells:* Cancer cells and normal cells go through the same life-cycle phases. An understanding of this phenomenon is necessary for understanding chemotherapy.

Indications for Chemotherapy

Patients who are at risk for or who have systemic signs of advanced or disseminated disease (generally indicated by extranodal involvement) may be candidates for preoperative, intraoperative, or postoperative chemotherapy.

Preoperative Chemotherapy. The objective of preoperative chemotherapy may be to shrink the tumor sufficiently to permit surgical resection. Adjuvant radiation therapy may be used in combination with chemotherapy to increase tumor regression and necrosis. Agents may also eliminate subclinical microscopic metastatic disease.

Intraoperative Chemotherapy. Chemotherapeutic agents can be instilled during a surgical procedure. The agent may be heated to encourage absorption by the tissues. Care is taken during the process because chemotherapeutic agents are considered hazardous materials.

Postoperative Chemotherapy. Surgical resection followed by regional chemotherapy often can control local disease to keep a tumor in remission. Residual metastatic disease may be treated with systemic chemotherapy to cure the patient or to prolong life. Multiple doses may be given over a long period (several months to a year or more) to delay or eliminate recurrence of the tumor.

Delivery Devices for Chemotherapeutic Agents

The method of chemotherapy administration depends on the extent of dissemination or localization of the tumor cells and on the agent or combination of agents selected. Agents can be instilled locally into a target site by continuous infusion, injected intramuscularly (IM) or intrathecally, infused by IV push or drip, or ingested orally (PO).

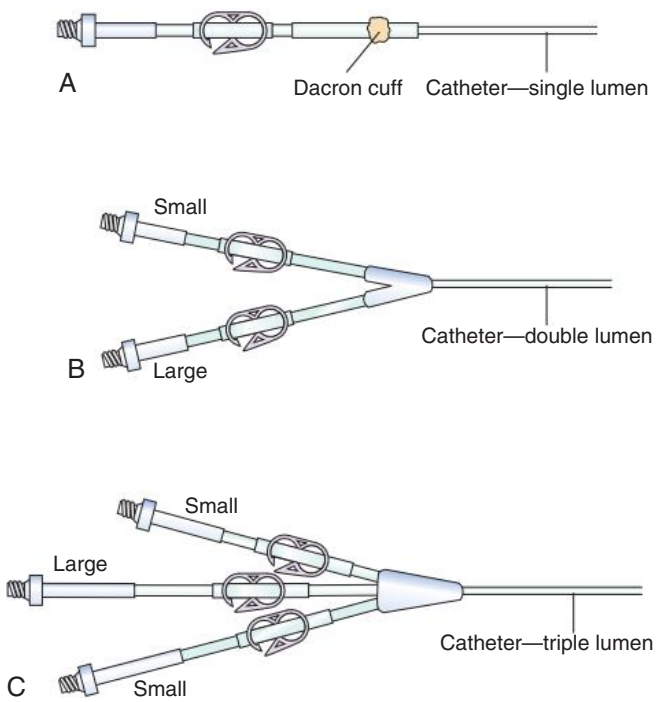
A patient with widely disseminated metastatic disease usually receives systemic chemotherapy via the IV, IM, or PO route. Agents may be infused regionally for patients whose tumor cannot be removed because of its location (e.g., a primary or metastatic tumor in the liver). The patient may come to the OR for insertion of an indwelling catheter or implantable infusion pump of the brain.

Infusion Catheters. An indwelling infusion catheter may be placed percutaneously or directly into a vein, artery, or body cavity. Continuous or intermittent infusion of the chemotherapeutic agent can be maintained by means of a portable infusion pump attached to the catheter, or the catheter may be used on an intermittent basis.

Central Venous Catheter. Under local anesthesia, a long-term Hickman, Quinton, Groshong, or other central venous catheter is inserted percutaneously through a particular blood vessel and into the right atrium of the heart. The catheter also may be used for hyperalimentation. Varieties include single, double, and triple-lumen styles and require heparinized saline flushes between uses (Fig. 22.6). Groshong catheters have a self-closing distal tip, do not require heparinization, and are available in single, double, and triple-lumen styles. Therefore the Groshong catheter can be used for patients with bleeding tendencies without the same risk associated with added heparinization. Sterile normal saline for injection is used to flush the line between uses.

Short-term subclavian catheters in double- and triple-lumen styles can be used for the administration of chemotherapeutic agents and total parenteral nutrition (TPN). These types of catheters require heparin flushes between uses.

Hepatic Artery Catheter. Hepatic artery catheterization may be performed to establish regional chemotherapy to treat primary or metastatic disease of the liver. With the use of a local anesthetic



• **Fig. 22.6** Intravenous Catheters for Long-Term Intravascular Access. **A,** Hickman and Broviac single-lumen catheter for intravenous (IV) fluids or total parenteral nutrition (TPN). **B,** Hickman and Leonard multipurpose dual-lumen catheter for IV fluids or blood sampling. **C,** Hickman triple-lumen catheter for IV fluids, TPN, and blood administration.

the catheter may be inserted percutaneously into the left axillary artery and threaded into the common hepatic artery. This technique eliminates the need for a laparotomy to cannulate the hepatic arteries. However, some patients have variant anatomy that requires a dual-catheter delivery system.

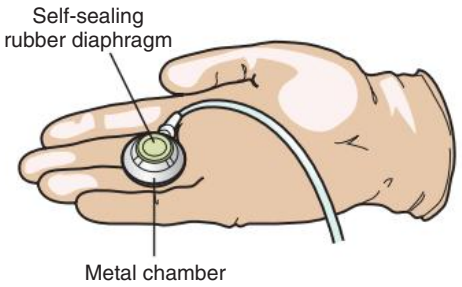
Vascular reconstruction, ligation, and/or occlusion of an artery may be necessary for local/regional perfusion. Regardless of the method of catheterization, an infusion pump is attached to the catheter(s) to deliver the cytotoxic agent to the tumor.

Intraperitoneal Catheter. Intraperitoneal chemotherapy permits the delivery of high concentrations of an agent to an ovarian or colorectal tumor without exposing normal tissues systemically. With the use of a local anesthetic, a Tenckhoff catheter is inserted into the peritoneal cavity. An incision in the anterior abdominal wall is usually located just lateral to the right or left of the rectus abdominis muscle at the level of the umbilicus. The anterior rectus sheath is incised to allow a Verres needle to penetrate the peritoneum. To prevent the catheter from kinking, air is injected before the catheter is placed in the peritoneal cavity. A subcutaneous tunnel is made between the initial incision and stab wound to secure the catheter. A Dacron cuff is embedded in the subcutaneous tissue to anchor the catheter in place. The agent exits the peritoneal cavity via the portal circulation.

Infusion Devices

Devices with reservoirs for the chemotherapeutic agent are implanted into body tissues.

Subcutaneous Infusion Port. With the use of a local anesthetic a venous access device is implanted subcutaneously for continuous or intermittent injections of cytotoxic agent(s), TPN, or blood products. Depending on the manufacturer, the device consists of a plastic or silicone rubber self-sealing port on a plastic or stainless steel reservoir (Fig. 22.7). The catheter attached to the reservoir is inserted into a central vein, hepatic artery, peritoneal cavity, or epidural space. A tunnel is created from the point at which the catheter enters the vessel, cavity, or space to a subcutaneous pocket (Fig. 22.8). The pocket is made wherever necessary to stabilize the port.



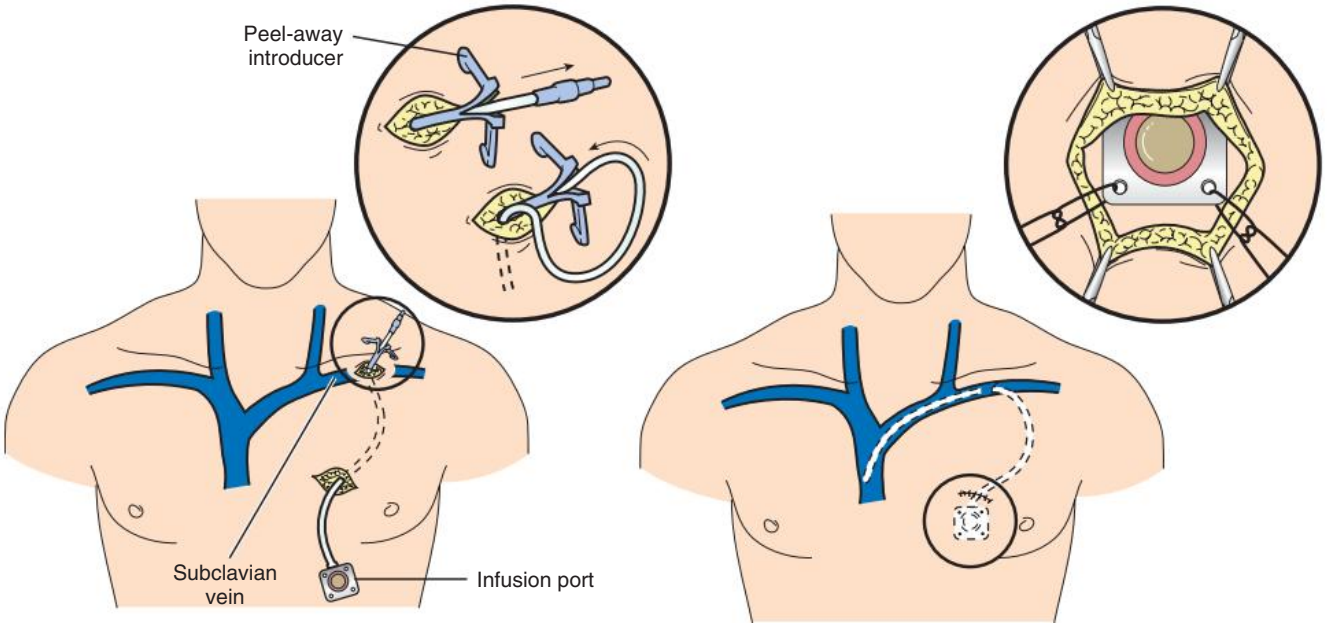
• **Fig. 22.7** Implantable subcutaneous infusion port.

The reservoir is sutured to the underlying fascia. A Huber needle with a 90-degree-angle tip is used to enter the port for heparinizing and infusing agents (Fig. 22.9). Extension tubing may connect the needle to an infusion pump for continuous infusion. After use, the port is flushed with 10 mL of sterile normal saline followed by 3 to 10 mL of heparinized saline (100 units/mL). Thrombosis and infection are potential complications of long-term venous access devices and catheters.

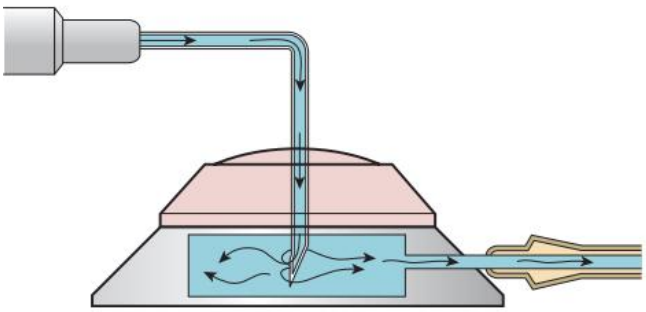
Implantable Infusion Pump. With the patient under local, regional, or general anesthesia, an infusion catheter is placed into an artery, vein, body space, spine, or ventricle for localized chemotherapy to a tumor in the liver, head, neck, or brain. The infusion pump device is implanted in a subcutaneous pocket created in the abdominal wall, beneath the clavicle, or under the scalp.

The titanium, stainless steel, and silicone rubber device resembles a hockey puck and delivers the agent by means of a bellows device (Infusaid) or by radio signals (Medtronic). The inner reservoir is filled with the cytotoxic agent. When the reservoir is collapsed by pressure, the agent is infused into the catheter. The pump is warmed initially to activate the fluorocarbon propellant in the chamber around the reservoir. It is placed over a bony prominence for support when refilling.

The drug is replenished periodically by percutaneous injection. A bolus can be administered through a side port on the pump. These implanted infusion devices also are used to control severe systemic



• **Fig. 22.8** Placement of an implantable subcutaneous infusion port.



• **Fig. 22.9** Huber needle with a 90-degree-angle tip.

conditions such as diabetes, thromboembolic disease, or pain from a malignancy. Insulin, heparin, or morphine is infused, respectively.

Perioperative Care of the Patient with Cancer

Malignant tumor cells can be disseminated by manipulation of tissue. Because of their altered nutritional and physiologic status, patients with cancer also may be highly susceptible to the complications of postoperative infection. To minimize these risks, the following specific precautions are taken in the surgical management of patients with cancer:

1. The skin over the site of a soft tissue tumor should be handled gently during hair removal and antisepsis. Vigorous scrubbing could dislodge underlying tumor cells; this is avoided by the use of "no-touch" techniques. With vascular tumors, manipulation during positioning or skin preparation could cause vascular complications such as emboli or hemorrhage. The no-touch technique means that the tumor is handled as little as possible during its removal. Radiated skin is very fragile.
2. Gowns, gloves, drapes, and instruments may be changed after a biopsy (e.g., a breast biopsy) before incision for a radical resection (e.g., a mastectomy). The tumor is deliberately incised to obtain a biopsy for diagnosis.
3. Instruments placed in direct contact with tumor cells may be discarded immediately after use. Even when the tumor appears to be localized, most cancers have disseminated to some degree. Therefore some surgeons prefer to use each instrument once and then discard it.
4. Some surgeons prefer to irrigate the surgical site with sterile water instead of sterile normal saline solution, which causes the destruction of cancerous cells by crenation. This practice is common during mastectomy.
5. As a prophylactic measure, antibiotics are administered preoperatively, intraoperatively, and postoperatively to provide an adequate antibacterial level to prevent wound infection.
6. Time-honored precautions such as handling tissue gently, keeping blood loss to a minimum, and avoiding an unduly prolonged surgical procedure influence the outcome for the patient.

During a long surgical procedure, messages should be conveyed periodically to the patient's anxiously waiting family members or significant others to reassure them that the patient is receiving care from a concerned perioperative team.

Teaching Patients Risk Avoidance Behaviors

Patient education should include information about avoiding cancer-causing behaviors and how to minimize the risk for cancer. Behaviors to discuss include:

- *Avoiding smoking and exposure to smoke.* The Department of Health and Human Services reports that exposure to cigarette smoke is responsible for 90% of all cases of lung cancer. More than 480,000 people die each year from smoking. Secondhand smoke, referred to as *environmental tobacco smoke,* has been implicated in the development of cancer in nonsmoking people who are exposed to smoke on a regular basis. The use of E-cigarettes and vaping has been on the rise in teens and young adults. Serious respiratory illness and even death have been linked to vaping. The U.S. Food and Drug Administration has rules for retailers who sell tobacco and electronic delivery systems (ENDS). Regulatory requirements and purchasing age are currently changing. Some states have changed the purchasing age from 18 to 21 years old. The FDA has banned fruit flavor and mint products popular with teens.
- *Increasing dietary intake of fiber and low-fat foods.* Antioxidants such as vitamins C and A may reduce an individual's risk for developing cancer. High-fat diets have been implicated in the development of breast, colon, and prostate cancers. According to reports of the American Cancer Society, 45% of cancer deaths are related to dietary causes and are possibly preventable. A desirable weight should be maintained, and obesity should be avoided. Excessive alcohol intake also should be avoided.
- *Minimizing sun exposure, especially between the hours of 10:00 AM and 4:00 PM.* Sun exposure has been shown to be the major cause of skin cancer, especially melanoma. Severe sunburn in childhood may be linked to the development of skin cancer later in life. Certain medications, such as tranquilizers, antidiabetic agents, diuretics, antiinflammatory agents, and antibiotics, can predispose an individual to sunburn. Certain cosmetic products, such as tretinoin (Retin-A) and alpha-hydroxy acid are extremely reactive to sunlight and can increase the risk for sunburn within 30 minutes of exposure. Tanning booths also can be hazardous to the skin.
- *Using a water-resistant sunscreen lotion with a sun-protection factor (SPF) of at least 30.* Water-resistant sunscreen should be applied whenever sun exposure is likely. Sun-blocking products of SPF 30 to 70 are preferred. The sun-blocking product should provide protection from both ultraviolet A and ultraviolet B (UVA, UVB) rays. (UVA rays can increase the damage caused by UVB rays.) Sunscreen should be applied at least 30 minutes before going outdoors and then reapplied every hour thereafter.
- *Scheduling regular checkups, especially yearly checkups after 40 years of age.* Knowing the warning signs of cancer may promote prompt diagnosis and treatment. Signs to consider in young children include frequent swelling (lymphadenopathy) or bruising, unexplained headaches or fevers, dramatic weight loss or gain, and localized pain.
- *Self-examining the skin, breast, and testes.* Examining these areas on a routine monthly basis may reveal an early sign of cancer.

23 Surgical Pharmacology

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Calculate drug dosages in the perioperative environment.
- List common drugs used in surgery.
- Identify drug sources and their effects on patient use.
- Demonstrate drug handling in a sterile environment.

KEY TERMS AND DEFINITIONS

Absorption Drug is taken in by the cells of the body.
Ampule Sealed glass tube containing a drug. Tip is scored for removal by snapping off. Drug is removed by a sterile syringe and filter needle to prevent aspiration of glass shards.
Antagonist One drug is used to alter or stop the effect of another drug.
Contrast medium Radiopaque solution used during radiography or fluoroscopy to define structures on film or digital media.
Conversion Standard scale of equivalents used to measure between metric, English, and apothecary.
Diagnostic chemical Used to perform a medical test or confirm a pathogenic condition.
Diluent Liquid used to decrease the concentration of a substance.
Distribution Drug is evenly absorbed by the entire body.
Dye Colored solution used to identify structures with gross vision.
Excretion Drug is released from the body in naturally excreted substances.
Gas Nonsolid, nonliquid form of a chemical.
Generic Chemically equivalent drugs formulated as substitutes for brand-name products.
Hypodermic Below the skin; subdermal.
Infusion Flow of a drug directly into the circulatory system.
Inhalant Drug that is taken in like a breath, then absorbed through the respiratory tract.
Injection Insertion of a drug directly into the tissues using a syringe and needle.
Loading dose First dose of a series given in a larger quantity than the subsequent doses.
Localized drug effect Physiologic response to a drug is in a select area of the body and not carried to other regions in an effective form.
Metabolism Drug is used throughout the body and broken down by major organs.
Pharmacokinetics Actions and disposition of a chemical in the body. These include absorption, distribution, metabolism, and excretion.
Placebo Inert substance given to a patient to stimulate the power of suggestion of effectiveness. Commonly used as a control in experimental medicine.
Polypharmacy Term used to describe when a patient has multiple prescription medications from one or multiple prescribers.
Potentiation Synergistic action of one drug against another to cause an increased response by the body.
Preventive drug Chemical or biologic preparation given with the intent of avoiding a disease state.
Reaction Physiologic response of the body when exposed to a drug. The response can be positive or negative. Sensitivity refers to when physiologic mechanisms are triggered by exposure to small doses of a given drug. Allergy refers to when physiologic defense mechanisms are triggered by exposure to a drug or chemical, causing a potentially life-threatening response. Anaphylaxis refers to a severe physiologic response to exposure to a drug or chemical, causing a definite threat to the patient's life.
Receptor site Location in the body that acts in response to a chemical stimulus. Some drugs act by blocking a receptor site and prevent naturally produced chemicals from bonding.
Side effect Secondary reaction that occurs in response to administration of a drug.
Stain Chemical used in solution to tint cellular structures for microscopic study.
Systemic effect Physiologic response to a drug is manifest in the entire body.
Tolerance Physiologic response caused by prolonged use of large quantities of a drug that makes average doses ineffective.
Toxic Level of any given drug that causes a negative or possibly fatal physiologic response.
Vial Vacuum-sealed glass or plastic container of medication that is sealed by a rubber stopper. The drug is removed by a sterile syringe and needle.

Pharmacology Baselines

The main purpose of this chapter is to highlight information concerning the drugs specifically used in perioperative patient care. It is not intended to be an all-inclusive pharmacologic resource. Drugs used in diagnostics, surgical procedures, anesthesia, and emergencies in the operating room (OR) are described in more depth in the corresponding subsequent chapters. Drugs used in patient care areas other than the perioperative environment can be reviewed at www.globalrph.com. This site has most of the common drugs and dosages listed in chart form.

Many drugs and pharmaceutical substances require special preparation and handling in the surgical environment. Some of these pharmaceuticals are found only in the OR, and their proper use is based on sterile technique, precise actions, and extreme caution. Correct dosing, mixing, and delivery to the sterile field are important for the safety of the patient and the team.

Safe drug and pharmaceutical administration in the OR is practiced according to the seven rights of medication administration in any setting:

- Right patient
- Right drug
- Right timing (cements/glues, antibiotics)
- Right dose
- Right route
- Right reason
- Right documentation

Patient assessment will provide information about the patient's health and general condition. Knowledge of how a drug acts in the body should be compared with the patient's assessment and current vital sign trend. The patient's weight should be documented in kilograms because many dosages are calculated according to milligrams per kilograms. The patient's history or body size may require a change in the plan of care involving medications for the intraoperative care period. Allergies are assessed and documented, and adverse **reactions** are prevented.

Prescription items in the OR are more than drugs and medications. The effectiveness of surgical drugs and chemicals depends on the desired **localized drug effect** and the specific targeted **receptor sites**. Some drugs are used to decrease consciousness; others are used to alleviate pain. Many drugs cause amnesia. Some drugs are given as a preventive measure against a possible complication. The physiologic drugs have **systemic effects** and are given in larger **loading doses** to induce the desired effect and titrated to maintenance doses to keep the patient's body relaxed and pain-free during the surgical procedure. The patient is carefully monitored for **side effects** and **toxic** levels.

Surgical pharmacology encompasses many chemicals ranging from **dyes** to adhesives, most of which are not used in any other patient care area. All of the specialized items require specific handling within the confines of the sterile field. Other items used in the OR include gaseous materials and surgical-site closure materials.

Avoiding Pharmaceutical Error

Every patient population is at risk for errors during the use of pharmaceutical materials in the perioperative environment. Known and unknown allergies and sensitivities can lead to serious illness or death. Constant patient monitoring can identify signs and symptoms of evolving reactions and permit time to effect treatment. Always investigate when patients report unusual feelings when a drug has been given.

Dosage error can affect any patient, but pediatric, geriatric, or patients with impaired body systems are particularly at risk. Pediatric error is usually related to doses greater than their bodies can tolerate. Geriatric and system-impaired patients metabolize medications at a slower rate. Any drug in their systems can be augmented by additional drugs in a subsequent dose. The end result can be unintentional overdosage. Anticoagulants, antibiotics, and steroidal compounds are the pharmaceuticals most frequently identified as the source of such problems.

Key points in avoiding error include double-checking labels for drug, dose, and method of delivery. The patient should be identified at least twice by name and other identifier approved by facility policy. Allergy and sensitivity alerts should be clear in the record and on the patient's identification wristband.

The risk for pharmaceutical error is high when patients take prescribed or unprescribed medications at home. A patient may use an inhaler for asthma and forget to report its use before surgery. Dietary supplements, herbs, home remedies, and over-the-counter (OTC) drugs are not considered "medication" to some patients, and they may neglect to report their use.

Some patients may hide the fact that they are using additional materials at home for fear of angering the physician. Patients using recreational drugs may hide the fact for fear of punishment. Most facilities do not routinely test for illegal drugs unless prompted by the situation or by a patient who acts suspicious when queried concerning their use. Not only does the use of drugs (legal and illegal) and supplements alter the course of treatment, but they can potentially interact adversely with many forms of anesthesia and physiologic stabilization drugs during surgery or emergency treatment.

Pregnancy, Lactation, and Reproductive Considerations

The safe administration of any drug to a pregnant or lactating woman requires knowledge of how the drug might affect a developing fetus or a breastfed infant. The risks should be identified before any drug is administered to a pregnant or possibly pregnant woman. Previously the U.S. Food and Drug Administration (FDA) had a lettering system concerning safety of a drug during pregnancy. In 2015 the FDA discontinued the use of the lettering system for labeling drugs. The FDA requirements for drug labeling include all persons of reproductive age regardless of sex. The labels should include information about infertility safety and contraception if necessary. Additional information about this required labeling change can be found at www.fda.gov. The labeling requirements for all prescription drugs have been changed as follows:

- *Pregnancy:* Includes labor and delivery
- *Lactation:* Includes nursing mothers
- *Females and males of reproductive potential:* Indicates the need for pregnancy testing, advice about contraception during therapy, and information concerning the potential for infertility

A breastfeeding mother and her infant are at risk if a drug given is transferred by breast milk. Antidepressants, antibiotics, antihypertensives, narcotics, opioids, cardiac drugs, salicylates, psychotropics, some anesthetics, and anticholesterol drugs are examples of some drugs passed in breast milk that can have an effect on the infant. A mother can be advised to pump and store milk preoperatively if a potentially harmful drug will be used in her procedure. The physician will advise when it is safe to resume regular breastfeeding. The mother should be instructed what to look for in her infant after feeding.

Although the labeling of prescription drugs has changed, the labeling of OTC drugs has not been affected by the FDA's new rules.

Drug Development

New drugs take many years to become available for patient use. According to the Office of Research and Development of the Pharmaceutical Manufacturers Association, it takes almost 12 years for a drug to be discovered and placed into use. Safety and efficacy testing on animals and laboratory simulation takes an average of 3½ years to complete. It is estimated that only 1 in 1000 compounds is actually tested in human trials. Each potential drug is filed with the FDA in an Investigational New Drug (IND) application. A series of clinical trials are performed on humans who have given informed consent, as follows:

- *Phase I clinical trial:* 20 to 80 healthy individuals for a period of 1 year. The drug is studied for safety in dosage, duration of action, **absorption**, **distribution**, **metabolism**, and **excretion**.
- *Phase II clinical trial:* 100 to 300 people with actual disease for which the drug is proposed treatment for a period of up to 2 years. The drug is studied for effectiveness and tolerability. Adverse reactions are monitored.
- *Phase III clinical trial:* 300 to 3000 patients in multiple health care settings participate. The drug is monitored to validate effectiveness and safety. The trial phase can take 1 to 4 years.
- *Phase VI postmarket surveillance:* After the drug is on the market, the manufacturer monitors the users for therapeutic and nontherapeutic effects and reports to the FDA.

Clinical trial results are reported yearly to the FDA. Only one in four drugs ever completes the process of the three clinical trials. The long period needed for the clinical trials permits the researchers to observe for long-term effects of the compound. On completion of the clinical trial phases the drug manufacturer submits a New Drug Application (NDA). Once approved by the FDA, the new drug is made available for physicians to prescribe. The approval process takes between 6 and 10 months to complete.

Expedited Drug Approval

The Office of Hematology and Oncology Products (OHOP) has had numerous drugs approved under the expedited drug program.[1] The program looks at the data for drugs and therapies that look promising for diseases with no known cure. Multiple drugs for aggressive cancers, bone marrow stimulants, and drug treatment for neuroblastoma have been approved. The drugs must go through extensive review while treating patients with life-threatening conditions. More information can be found at www.fda.gov

Drug Names

Drugs have three names. The first name is the chemical name and describes the chemical components such as molecular and atomic structure of the drug. It is not commonly used when referencing the drug.

The second name is the official name, referred to as **generic**, and given to the compound by the initial manufacturer. The generic name is derived from the chemical name and is not capitalized. The drugs are listed in the United States Pharmacopeia (USP) and the National Formulary (NF) according to the generic names. The first letter of generic drugs is lower case.

For the third name the drug company who sells the drug will assign a copyrighted trade name, or a brand name, which is proprietary. The trade name is capitalized and designated by a registration mark (®).

Mathematics Baselines

Decimals

Numbers to the left of the decimal are whole numbers. Numbers to the right of the decimal are decimal fractions and are read according to their place value, as follows:

0.1	one tenth
0.01	one hundredth
0.001	one thousandth
0.0001	one ten thousandth

Addition of Decimals

1. Write numbers in a column with the decimals vertically aligned.
2. Place the decimal in the answer beneath the decimal in the problem.

Example: Add 1.33, 4.0, 2.146, and 0.03

$$\begin{array}{r} 1.33 \\ 4.0 \\ 2.146 \\ +\ 0.03 \\ \hline 7.506 \end{array}$$

Subtraction of Decimals

1. Write numbers in column with the decimals vertically aligned.
2. Subtract and place the decimal in the answer beneath the decimal in the problem.

Example: Subtract 0.025 from 15.838

$$\begin{array}{r} 15.838 \\ -\ 0.025 \\ \hline 15.813 \end{array}$$

Multiplication of Decimals

1. Find the product of the numbers.
2. Total the number of decimal places in the multiplicand and in the multiplier.
3. Mark off the total decimal places in the product and insert a decimal.

Example: Multiply 2.05 by 0.2

2.05	(multiplicand)
× 0.2	(multiplier)
0.410	(product with three decimal places marked off [answer])

When the number of decimal places to be marked off goes beyond the numbers in the product, add a zero in each place.

To multiply a decimal by 100, 1000, or 10,000, move the decimal to the right as many places as there are zeros in the multiplier.

Example: Multiply 0.25 by 100. There are two zeros, so move the decimal two places to the right: 025., or 25.

To multiply a decimal by 0.1, 0.01, 0.001, move the decimal to the left as many places as there are decimal places in the multiplier.

Example: Multiply 0.25 by 0.1. There is one decimal place, so move the decimal one place to the left: 0.025.

If the decimal must be moved farther than there are numbers, add a zero for each decimal place.

Division of Decimals

To divide a decimal by a whole number:

1. Write the problem.
2. Place a decimal in the quotient directly above the decimal in the dividend.
3. Solve the quotient.

Example: Divide 0.1 by 50

$$\begin{array}{r} 0.002 \\ \text{(divisor) } 50\overline{)0.100}\text{ (dividend)} \end{array}$$

To divide a whole number or decimal by a decimal:

1. Move the decimal in the divisor to the right until the divisor is a whole number.
2. Move the decimal in the dividend to the right as many places as you moved the decimal in the divisor.
3. Place the decimal in the quotient directly above the (moved) decimal in the dividend.
4. Solve the quotient.

Example: Divide 0.225 by 0.5

$$\begin{array}{r} 0.450 \\ 0.5\overline{)0.225} \end{array}$$

To divide a decimal by 10, 100, 1000, and so on, move the decimal to the left as many places as there are zeros in the divisor.

Example: Divide 0.25 by 1000. There are three zeros, so move the decimal three places to the left: 0.00025.

To divide a decimal by 0.1, 0.01, 0.001, and so on, move the decimal to the right as many places as there are decimal places in the divisor.

Example: Divide 0.25 by 0.1. There is one decimal place, so move the decimal one place to the right: 02.5, or 2.5.

Percent

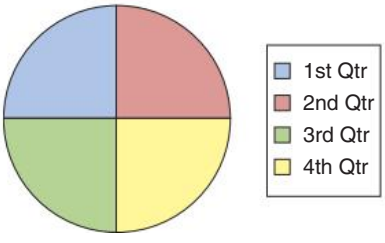
The word *percent* means part of 100. Twenty-five percent (25%) means 25 parts of 100, or 25/100; also written as the decimal 0.25. Percent indicates a fraction in which the denominator is 100.

Fractions

A fraction represents a part of a whole number. If a circle is divided into four equal parts, each part is ¼ of the circle, as seen in Fig. 23.1. The numerator is 1 and the denominator is 4. The line between 1 and 4 means divide.

Common Denominator

Unlike denominators cannot be added or subtracted. Common denominator means the fractions have the same denominator.



• **Fig. 23.1** Parts of the whole (fractions).

Reduce a Fraction to Lowest Terms

Determine the largest number that divides evenly into both numbers; when the fraction cannot be reduced any further, it is considered to be in its lowest terms.

Example: Reduce to lowest terms: 20/80

Both numbers are divisible evenly by 20: 20 × 20 × 1, and 80 × 20 × 4

Therefore the lowest terms of 20/80 are ¼.

Improper Fraction

5/4 is an improper fraction; when reduced to its lowest terms, it becomes 1¼, a mixed number.

Ratio and Proportion

Ratio

We use ratios to compare two things. If we have 6 hemostats and 4 scissors, the ratio is termed 6:4 (stated six to four). Any two sets of quantified items (numbers of things) can be put into ratio format for comparison. The ratio concept can be expressed as "to," a colon, or a fraction.

Example:

6:4

6 to 4

6/4 (six divided by four)

In pharmacology the use of a ratio is expressed in relatively equal terms. For example, 1 ounce of medicine is the same as 30 mL of medicine. It is expressed as (1 oz is to 30 mL) and written as 1 oz : 30 mL. A ratio is one way of saying that 1 oz is equal to 30 mL.

Proportion

When we compare two ratios or need to solve for an unknown quantity to make the ratios balance, the process uses the following format:

1 oz : 30 mL = 2 oz : X mL (stated: 1 ounce is to 30 milliliters as 2 ounces is to X milliliters.)

The outer numbers are referred to as the *extremes* and the inner numbers are referred to as the *means.* The problem is solved by equalizing the formula. That is why an equal sign connects the two ratios.

Notice that the order of the formula follows _____ oz : _____ mL = _____ oz : _____ mL.

The quantities must be expressed in the same order on both sides of the equation.

Here is one method of using ratios and proportions. (1) Multiply the extremes. (2) Multiply the means. (3) Divide the left side by the right side with X. (Note: Think of the phrase *"X goes into"* because the number next to the X goes into the number on the other side of the equal sign to get the answer.)

1 oz : 30 mL = 2 oz : X mL	Multiply the extremes.
1 × X = 2 x 30	Multiply the means.
1X = 60	Divide the number on the right side by the number on the left side with the X.
X = 60	
Therefore:	
1 oz : 30 mL = 2 oz : 60 mL	The product is 60.

Using ratio and proportion is a good way to solve most medication problems for mixing solutions in the OR; however, several measurements from the **conversion** chart must be known

to complete the formula. For example, knowing that 1 ounce is the same as 30 milliliters is important to finding out that 2 ounces is 60 milliliters.

If the ratio is X mL : 2 pints (stated as X milliliters is to 1 pint) the problem is to solve for X or the number of milliliters in one pint. This is how to use ratio and proportion to solve this problem. Knowing the baseline conversion of 500 mL : 1 pint is the key to solving for X. Here is how to set up the formula:

500 mL : 1 pint = X mL : 2 pints

1000 = 1X

(remember the phrase "X goes into") (1000 is divided by 1)

1000 = X

Answer: 500 mL : 1 pint = 1000 mL : 2 pints

Pharmacologic Conversions

Medications are measured in metric, English/household, or apothecary equivalents. Each unit of measure has a designated accepted abbreviation. Standardization of abbreviations is important for prevention of errors in dosage caused by misinterpretation (Table 23.1).

Accepted Abbreviations

Documentation of medication in the OR is done by using a series of abbreviations and symbols. Standardization of the abbreviations used is important for accuracy. Most of these are expressed in Latin terminology.

Weights and Measures

Converting dosages between metric, English/household, or apothecary systems is done by calculating with a standard set of measures (Table 23.2). Tables are commonly used for conversions of units between systems.

TABLE 23.1 Abbreviations for Measurement and Administration of Medications

Measurement	Abbreviation
Centimeter	cm
Dram	dr
Drops	gt or gtt
Foot/feet	ft
Gallon	gal
Grains	gr
Gram	g
Inch	in
Kilogram	kg
Liter	L
Meter	m
Microgram	mcg
Micron	μ
Milligram	mg
Milliliter	mL
Millimeter	mm
Ounce	oz
Pint	pt
Pound	lb
Quart	qt
Tablespoon	tbsp
Teaspoon	tsp

Administration	Measurement
After meals	pc
As desired	ad lib
As needed	prn
Before meals	ac
By mouth	PO
Drop	gt
Four times per day	qid
Nothing by mouth	NPO
Quantity sufficient	qs
Three times per day	tid
Twice per day	bid

Considerations in Surgical Pharmacology

Pharmaceuticals used in the OR are not limited to medicines in the ordinary concept of medication. Sources for surgical pharmaceuticals can be living matter from a biologic source or compounded from some other natural or synthetic mixture. Some surgical pharmacologic materials remain inside the body permanently (e.g., an implant), whereas others are systemically absorbed.

Items procured from the pharmacy require special handling within the sterile field. Care is taken not to expose the patient or surgical staff to an allergen or any substance that can cause a sensitivity reaction.

Handling Drugs and Pharmacologic Materials in Surgery

Drugs and pharmaceuticals are given to the scrub person for use in the field by a physician or circulating nurse who is a registered nurse (RN). The surgeon requests a drug or pharmaceutical either verbally or in writing for use during surgery, and the circulating nurse obtains it from the pharmacy or stock. The circulating nurse validates the integrity of the package or container, checks the expiration date, checks for patient allergy or contraindication, and shows the complete label to the scrub person for verification. Administration routes in the field include **injection**, instillation, irrigation, topical, and spray.

As the drug is dispensed to the field, the circulating nurse should say the drug name and concentration out loud. The drug

TABLE 23.2 Basic Weights and Measures in Pharmacology

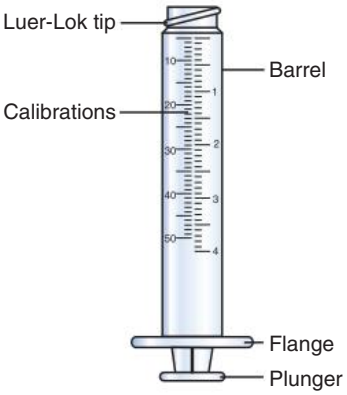
Metric	Household/English Apothecary	Apothecary
Fluid Measure		
4 L/4000 mL	1 gal	1 gal
1 L/1000 mL	1 qt/32 oz/2 pt	32 oz (no plural for pints)
500 mL	1 pt/16 oz/2 cups	16 oz
250 mL	1 cup/8 oz	8 oz
30 mL	1 oz	1 oz/8 dr
15 mL	1 tbsp/3 tsp	225 gtt/m
5 mL	1 tsp	75 gtt/m
1 mL		15 gtt/m
0.0667 mL		1 gt/m
Mass Weight		
1 mg/1000 mcg		1/60 gr
60 mg		1 gr
1 g		15 gr
4 g		60 gr
1000 g/1 kg	2.2 lb	
	16 oz/1 lb	12 oz
Measure of Size		
1 m/1000 mm	3.281 ft	
10 mm/1 cm		
2.54 cm	1 in	
	12 in/1 ft	
	3 ft/1 yd	

or material is dispensed to the sterile field in one of the following ways:

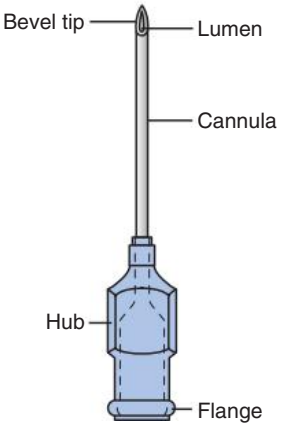
- Solutions for irrigation are poured in their entirety into a sterile basin. If the contents are not completely dispensed, the bottle is not recapped and saved for later use. Once the bottle is opened, the lip of the bottle has rendered the contents unsterile as soon as pouring has started. Do not splash or create an aerosol. Aerosolization can cause anaphylaxis in susceptible patients or staff.
  - Solutions in plastic bottles should be kept in a warmer no longer than 2 weeks between 104° F and 110° F (40° C and 43° C). While in the warmer, the bottle expands. Allowing the solution to reach room temperature after removing from the warmer causes the plastic bottle to contract.
  - Replacing the cooled bottle into the warmer causes the plastic to expand. Several manufacturers advise against allowing the bottle to cool and rewarm because of the potential for contamination via expansion and contraction of micropores on the surface of the bottle that can allow microorganisms to enter.
- Intravenous (IV) solutions are dispensed to the sterile field for use in expandable implants and vascular cases. The IV bag is emptied in its entirety by the circulating nurse into a sterile basin using a bag decanter device.

  The main difference between irrigation solutions and IV solutions is the method of filtering microparticulates. Both solutions used in surgery are sterile. Baxter Corporation prepares irrigation and IV solutions with the same filtration process rendering the bag and bottle contents identical. The main difference is the packaging.
- Products in peel packs may be dispensed directly to the field, or the scrub person can take the item with a forceps from the opened package as it is held open by the circulating nurse. Remember that the edges of the peel pack are not sterile.
- Drugs in **vials** (Fig. 23.2) for injection should be removed from the vial by the circulating nurse, using a syringe (Fig. 23.3) and an 18 or 19-gauge **hypodermic** needle (Fig. 23.4). The scrub

• **Fig. 23.2** Drug vial with rubber stopper and plastic cap in place.



• **Fig. 23.3** Anatomy of a syringe.



• **Fig. 23.4** Anatomy of a hypodermic needle.

person should place a sterile glass or plastic medicine cup near the edge of the table. Metal medicine cups are not advised for some drugs because they may chemically bind with the metallic substance. Popping off the cap of the vial contaminates the lip, and pouring over that lip renders the drug contaminated.

- After the circulating nurse withdraws the drug from the vial with the syringe and needle, the needle is removed and the drug is carefully delivered from the syringe into the medicine cup. The needle is removed because dispensing via the needle creates an aerosol that can cause exposure to an allergen.
- The scrub person should not use a needle and syringe to pierce the rubber stopper on the bottle as the circulating nurse holds it over the field. This places the nurse at risk for needlestick injury. This is an unsafe practice that parallels recapping needles by hand.
- The circulating nurse should use a filter needle when withdrawing drugs from a glass **ampule** (Fig. 23.5). Shards of glass can get into the solution and inadvertently be injected into a patient.

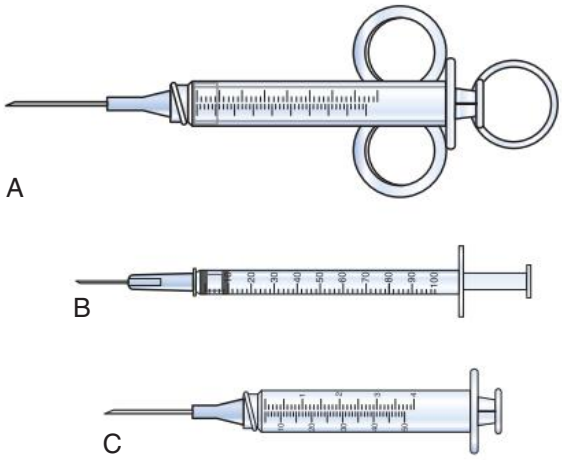
- Ointments and creams should be purchased in unit-dose tubes. Multidose tubes are easily contaminated. If a multidose tube is used, ½ inch of the ointment or cream should be squeezed out into the trash before any is used for the current patient. The sterility is questionable. The drug can be dispensed onto a sponge or other sterile surface. It should be labeled immediately.

The drug or pharmaceutical should be labeled as soon as it is received into the sterile field. Labeling the cup or basin before the drug is dispensed could allow for error if the wrong drug is poured into the wrong cup. The container and the syringe/delivery device (Fig. 23.6) should be clearly marked with the name and concentration of the drug. Sterile labels and sterile marking pens are commercially available and come packed in many custom packs. Some facilities have sterile preprinted labels available. If these types of labels are not used in the facility, wound closure strips, such as Steri-Strips, and a sterile marking pen can be used. All containers of drugs and solutions must be labeled; this includes basins of sterile water and sterile saline.

According to The Joint Commission (TJC), the content of the sterile field drug label should include the first three items on the following list and all five if prepared for use and not yet dispensed to the sterile field:

1. Drug name
2. Strength

• **Fig. 23.5** Drug ampule.



• **Fig. 23.6** **A**, Control syringe. **B**, One-milliliter syringe used for insulin or tuberculosis (TB) testing. **C**, Standard syringe.

3. Amount if not apparent by markings on the container
4. Expiration date if not used within 24 hours
5. Expiration date if expiration occurs within 24 hours

Some facilities require additional labeling on all solutions and drugs such as date, time, and initials of the accepting scrub person. Only facility-approved abbreviations should be used, if abbreviations are used at all. The scrub person should say the name and strength of the drug as the syringe is handed to the surgeon. The circulating nurse documents the delivery of the drug to the sterile field and its usage. The scrub person reports the actual dose given to the patient and recorded on the OR record. The actual dosage is relayed to the anesthesia provider to avoid any incompatibility with medicines given during anesthesia.

Some patients arrive in the OR with peripheral IV access lines in place. These are different from central lines. The circulating nurse takes great care in the access of double or triple-lumen central venous lines. Some of the connectors can be misconnected to a harmful **infusion** if universal adapters are used. Intravascular catheters should not be compatible with other infusion devices.

Surgical Drug and Pharmaceutical Sources

Biologic Sources

Biologic sources for drugs can be found in glands, body fluids, organs, fats, and cells of living entities.

Animal Sources

Animals are used for the manufacturing of drugs. Examples of animals used in the production of pharmaceuticals are found in Box 23.1.

Plant Sources

All portions of plants are used for the manufacturing of drugs. In addition to the anatomic parts of the plant, gums, oils, and bases are used as vehicles for drug administration. Cannabis is an example of an old plant grown for new uses. The cannabis plant (marijuana) is legal in some states and can be purchased in small amounts for recreational use. Cannabis can be purchased legally for medical reasons with a prescription from a doctor. Medical marijuana is grown in a controlled environment, harvested, and processed with the removal of tetrahydrocannabinol (THC),

• BOX 23.1 Animal and Biologic Sources of Drugs

Bovine (Beef Cattle)
- Hemostatic agent
- Blood-based oxygen carrier (Hemopure)
- Insulin
- Serum albumin
- Heparin

Porcine (Pigs)
- Hemostatic agent
- Biologic dressing
- Insulin
- Heparin
- Pancreatic enzymes

Equine (Horse)
- Serum vaccine
- Hormones (estrogen)
- Pericardial implant

Ovine (Sheep)
- Suture
- Lanolin
- Hyaluronidase ophthalmic

Rodents (Hamster)
- Protein used in recombinant thrombin

Avian (Birds)
- Viscoat for eye surgery

Microbes (Fungi and Bacteria)
- Antibiotics

Marine Animals
Snails
- Zinconotide (Prialt) for neuropathy

Fish
- Protamine

Reptilian (Snakes and Lizards)
- Antivenom (antivenin)
- Ancrod
- Exenatide (Byetta)
- Blood pressure drugs (Captopril)

Human
- Blood
- Blood fraction
- Insulin from DNA technology
- Tissue
  - Reconstruction
  - Biologic dressing
- Semen
- Hormones (growth hormone and insulin)
- Human source extraction
  - Human skin equivalent
- Hemoglobin-based oxygen carrier (PolyHeme)

Insects
- Bee's wax: hemostasis as bone wax
- Spider antivenom

• BOX 23.2 Plant Sources of Drugs

- Leaves (atropine from belladonna leaves, indigo carmine, cannabis)
- Blossoms (opium poppy, colchicine from crocus)
- Seeds (arabic, cannabis)
- Fruit (cranberry)
- Tubers/roots (ginseng) and rhizomes (valerian, gentian)
- Oils (camphor, eucalyptus)
- Sap (aloe, gum arabic preservative)
- Bark (aspirin, quinine, cascara)
- Wood extract
- Resin (benzoin)
- Fungi (some antibiotics)
- Herbs (tranquilizers, anticoagulants)
- Cellulose fibers (hemostatic)

• BOX 23.3 Minerals Used as Drugs

- Multivitamins contain calcium, iron, copper, magnesium, selenium, and zinc.
- Potassium is replaced after diuretic administration.
- Iodine is used in contrast media and radioactive markers.
- Zinc is used for wound healing.
- Fluoride strengthens teeth
- Gold salts are used to treat rheumatoid conditions.
- Silver is used for antimicrobial action.
- Iron helps treat anemia.
- Copper is necessary for the use of iron in red cell formation.
- Sulfur found in protein is used for cartilage production
- Tungsten compounds treat AIDS.
- Lithium is used for manic depressive disease.
- Sodium and chloride balance body fluids.
- Talc is powdered magnesium silicate. Used for sclerosis in pleurodesis.

known as the psychoactive component. It is prescribed to relieve pain, reduce seizures, treat anxiety, and reduce inflammation. Examples of plant usage are found in Box 23.2.

Mineral Sources

Many minerals such as calcium, potassium, and chlorides are used intraoperatively. Fibrinogen can be mixed with calcium preparations to form an adhesive that acts as both a sealant and a hemostatic material. Potassium is mixed with other minerals and chemicals to form a cell protectant cardioplegia solution during cardiac surgery when the heart is not beating (Box 23.3).

Synthetic and Semisynthetic Sources

Chemical Sources

Replication of natural drugs from synthetic sources is common. Narcotic pain medications resembling the action of opioids are used for postoperative patients.

Engineered Protein from Plant, Animal, and Chemical Combinations

Skin substitute, pharmaceuticals, and blood products have been manufactured using biologic material as their base. Skin has been cultured for use in wound repair. Blood cells from bovine and human sources have been engineered for use in humans as an oxygen-carrying medium. An oxygen-carrying medium is not intended to replace blood but aims to provide a source of oxygen distribution in the vascular system of the body.

Pharmacologic Forms Used in Surgery

Table 23.3 gives examples of select surgical medications. Drugs used in surgery are found in many forms, ranging from liquids to solids. Routes of drug administration can be found in Box 23.4.

Liquids

A variety of solutions and liquids are used within the sterile field and nonsterile fields before, during, and after the surgical procedure.

TABLE 23.3 Examples of Drugs Used in Surgery

Drug Category	Drug Classifications	Individual Drugs
Anticoagulants and Coagulants		
Antiplatelet agents	Anticoagulant	Aspirin Ticlopidine
Anticoagulants	Anticoagulant	Enoxaparin Heparin Protamine Warfarin
Coagulant hemostatics	Coagulant	Thrombin
Thrombolytics	Thrombolytic	Alteplase
	Streptokinase	
	Urokinase	
Antiinfectives and Antibiotics		
	Aminoglycosides	Gentamicin Kanamycin Neomycin Streptomycin Tobramycin
	Cephalosporins	Cefazolin Cefonicid Cefotaxime
	Lipopeptides	Daptomycin
	Macrolides	Erythromycin
	Oxazolidinones	Ketolides Linezolid Telithromycin
	Penicillins	Amoxicillin Ampicillin Carbenicillin Mezlocillin Penicillin G potassium Ticarcillin
	Quinolones	Ciprofloxacin
	Sulfonamide antimicrobials	Glycylcycline Sulfamethoxazole Tygacil
	Tetracyclines	Doxycycline Tetracycline

Drug Category	Drug Classifications	Individual Drugs
Autonomic Nervous System Agents		
Adrenergic agonists	Alpha- and beta-adrenergic agents	Epinephrine
Adrenergic antagonists	Antidysrhythmics	Isoproterenol Propranolol
Anticholinergics	Muscarinics	Atropine sulfate Glycopyrrolate Scopolamine
Benzodiazepines		
Antianxiety medications	Sedative	Diazepam Lorazepam Midazolam
Central Nervous System Agents		
Analgesic agents	Narcotics	Fentanyl Meperidine Morphine
Surgical Dyes, Contrast Media, Stains		
Dyes		Bismarck brown Brilliant green Congo red Gentian violet Indian ink Indigo carmine Indocyanine green (florescent) Isosulfan blue (radioisotopes) Methylene blue Trypan blue
Contrast media		Diatrizoate meglumine Iohexol Vasovist MRI contrast
Tissue stains		Lugol's iodine solution (Schiller's solution) Monsel's ferric solution

• BOX 23.4 Routes for Administration of Drugs

- Oral
- Sublingual
- Nasogastric
- Gastric tube
- Rectal
- Vaginal
- Topical
- Transdermal
- Inhalation
- Parenteral
- Subcutaneous
- Intramuscular
- Intravenous
- Intraarticular
- Endotracheal
- Intraarterial
- Intracardiac
- Intradermal
- Intraperitoneal
- Intraosseous
- Intrathecal
- Irrigation and instillation
- Umbilical artery or vein

Many of these can be used topically or as an injection. Uses of solutions include the following:

- *Irrigations:* Lactated Ringer's solution, saline, water. The patient can be at risk for fluid overload if the solution accumulates in the body and is resorbed.
- ***Diluents:*** Commonly saline or water (with or without preservative). If large quantities are used, take care to use only preservative-free fluids; the quantity of preservative can pose toxicity in the patient's system.
- *Additives to injections or irrigations:* Vasoconstrictors, anticoagulants, and buffers.
- *Antineoplastics:* Forms of chemotherapy used intraperitoneally.
- *Tumescence:* Fluid mixed with epinephrine, placed under the skin with a special cannula and pressurized delivery system to make the skin firm for liposuction.
- *Expansion media:* Sterile water, glycine, or saline to create a working space for endoscopy. Care is taken to measure how much goes in and how much comes out. The patient can be at risk for fluid overload.
- *Biologic adhesives:* To adhere delicate tissues together.
- *Perfusion:* For cardioplegia (cardiac cell nutrient and preservation during heart stoppage for heart surgery).
- *Preservatives and fixatives:* For tissues and specimens.
- *Medications:* For injection in a sterile field.
- *Caustics:* Phenols to remove cell layers.
- *Skin cleansers and degreasers:* For skin prep. Detergent forms can denude mucous membranes, causing inflammation and irritation. Some have inherent toxicity.
- *Visualization agents:* **Diagnostic chemicals** can be used in the form of **stains**, dyes, or radiopaque **contrast media**. These chemicals permit observation of body structures by adding colorization of the tissues or by the use of x-ray.

Solids

Many preoperative and postoperative oral medications are in pill or tablet form. Patients are instructed in their use and about how much water they are permitted to have to swallow them. Small children can be given a medicated pacifier or lollipop that contains preoperative medication, such as a sedative.

Hemostasis can be obtained using woven sheets of hemostatic material. Other sheets of specialized material can be used for adhesion prevention when placed around internal organs.

Suppositories are sometimes used as an adjunct to rectal surgery. Some surgeons place a belladonna suppository in the rectum to slow peristalsis and allow healing after hemorrhoidectomy. Timed-release medications such as antibiotics can be implanted in bead form in orthopedic cement during prosthetic joint procedures. Gynecologic procedures can include placement of timed-release rings of contraception medication in the uterine cervix.

Orthopedic surgeons commonly use bone cement impregnated with antibiotic pellets or beads when placing implants into bone. Some of these antibiotic beads are timed release.

Powders

Pharmacologic materials in powder form are commonly used in the OR in both dry and diluted forms. Dry powders and fibers used for hemostasis, such as bovine collagen, are applied dry and resorbed by the body in that form. Antibiotic powders are diluted in saline before being used as irrigants in the surgical site or before administration IV.

Sterile talc and tetracycline powder can be placed in solution for a sclerosant action in poudrage of the pleural cavity for the treatment of pleural effusion. These powders are documented in the patient's record. Prepackaged talc has a lot number that should be recorded in the lot log.

Semisolids

Creams and lotions are commonly used during surgical procedures. Ideally the product should be double-wrapped and the inner sterile packaging should be placed directly on the sterile field. Many semisolids are supplied in multidose packages and are dispensed to the field carefully without contaminating the rest of the material in the package or tube. Drugs supplied in multidose tubes should have the first half-inch of the product squeezed out into the trash before dispensing a portion to the field for use.

Lubricants are used for many procedures intraoperatively. Most are water soluble, but those with a petroleum, lanolin, or oil base are not. Postoperatively, petroleum or oil-based nonadherent dressings are placed on some surgical sites.

Gases

Few substances are used in the OR as gaseous forms. If the gas is used in tank form, the tanks are color-coded. Nitrous oxide (blue), nitrogen (black), helium (brown), carbon dioxide (gray), medical air (yellow), and oxygen (green) are the main **gases** found in the OR. Of these five gases, nitrous oxide, medical air, and oxygen are administered to the patient in drug-related form through the respiratory tree as an **inhalant**. Nitrogen is used to power drills and saws, and carbon dioxide is used to create a working space (insufflation) during an endoscopic procedure, but they are not used as drug forms.

In pneumatic retinopexy the ophthalmologic surgeon can use either sulfur hexafluoride (SF_6) or perfluoropropane (C_3F_8) gas injection within the eye to help reposition a torn retina using sterile technique.[2] Medical air can be used if drawn into a 3-mL syringe with a 0.22-μm micropore filter. Between 0.3 mL and 1.2 mL of gas is used to reposition the arc of the retina 45 to 90 degrees in a stable position for healing. The patient is instructed to lie in a certain position to maintain the position of the gas bubble.[2] These gases resorb after a period of time.

Compressed gas cylinders have a valve opening that turns to the left to open (turn on) and to the right to close (turn off). A simple mnemonic to help remember which direction to turn for each function is: Be sure to turn it RIGHT OFF after use and

check to see it's not LEFT ON. Another mnemonic is "righty tighty and lefty loosey."

Volatile liquid substances are passed through special vaporizers and warmers to become gaseous inhalant drugs used during general anesthetic delivery.

Medical Gas Terminology

- *Cylinder:* Metal container designed to hold compressed medical gases at a high pressure.
- *Cryogenic vessel:* Metal container designed to hold liquefied compressed medical gases at extremely low temperatures.
- *Compressed medical gas:* Any liquefied or vaporized gas alone or in combination with other gases.
- *Concentrator:* Stand-alone unit that extracts oxygen from room air and delivers concentrated oxygen at a continuous flow rate.
- *Regulator:* Mechanism that controls the flow of a medical gas.

Potential Complications Caused by Pharmaceuticals and Herbal Medicine

Many patients come to the perioperative environment with comorbidity and **polypharmacy**. Add to this the use of home remedies and folk medicine, and many complications can arise (Box 23.5).

Some surgical drugs and chemicals increase the effect of home remedies. This action is known as **potentiation**. Other medicinal substances act as **antagonists** and interrupt the actions of prescribed drugs. The **pharmacokinetics** of all chemical substances in the body can be altered by drugs given during a surgical procedure. Prolonged use of many physiologic chemicals or drugs can cause the body to develop a **tolerance**, rendering subsequent doses ineffective.

Many ancient herbs and folk remedies are still used today. Although many are useful, many can cause harm when combined with modern drugs. Most people who use herbal remedies do not have knowledge of how much or how often to use them. Serious complications such as anaphylaxis (allergy) can mask the actual cause of disease. The psychologic effects of some self-administered medications have a **placebo** effect that causes the patient to believe that symptoms are relieved or diseases are cured. Medical professionals use the placebo effect as a control to test the efficacy of new drugs before they are introduced to the pharmaceutical marketplace.

The FDA regulates drugs and pharmaceuticals but not dietary supplements made from herbs.[3] The manufacturers may include a disclaimer that the substance is not approved by the FDA, but yet the makers promote their products as treatments for everything from baldness to weight loss. Many of these products have significant effects on the user's physiology, particularly blood pressure and blood function. If a product has been proved to cause serious problems, the FDA intervenes and removes it from the marketplace. One example, ephedra (ma huang), caused serious problems with blood pressure and the cardiovascular system.

• BOX 23.5 Examples of Medications and Herbal Substances That May Promote Postoperative Complications

Products That Contain Aspirin and Cause Bleeding

- Aleve
- Aspergum
- Bufferin
- Congespirin
- Ecotrin
- Empirin
- Excedrin

Analgesics That Have an Aspirin-Like Effect on Bleeding

- Dolobid
- Norgesic
- Oxycodone
- Pepto-Bismol
- Percodan
- Soma
- Talwin
- Voltaren

Medications That Contain Ibuprofen

- Advil
- Midol
- Naprosyn
- Nuprin
- Postel
- Sine-Aid
- Toradol

Anticoagulants

- Coumadin
- Dicumarol
- Heparin
- Panwarfin
- Periactin

Herbal Substances That May Have an Anticoagulant Effect

- Aloe vera
- Chamomile
- Cinnamon
- Clove
- Feverfew
- Garlic
- Ginger
- Ginkgo biloba
- Ginseng
- Licorice
- Some fish oils
- Vitamin E
- Green tea
- Grape seed extract
- Cayenne pepper
- Turmeric

Herbal Substances That Can Increase Blood Pressure

- Ephedra
- Ginseng
- Licorice
- Green tea

Herbs That Can Alter or Prolong Anesthesia

- Kava-kava
- St. John's wort
- Valerian
- Black cohosh

Other natural substances such as tea tree oil and aloe vera are used in astringents and makeup formulas. The National Library of Medicine has a database of more than 3000 herbal dietary supplements. Visit www.nlm.nih.gov/ for additional information.

Anesthesia: Techniques and Agents

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify three methods of general anesthesia.
- Describe the physiologic effects of general anesthesia.
- Discuss the purpose for cricoid pressure.
- Differentiate between general and regional anesthesia.
- List key points in providing safety for the anesthetized patient.

KEY TERMS AND DEFINITIONS

Amnesia Loss of memory.

Analgesia Relief of pain by altering perception of painful stimuli; acts on specific receptors in the nervous system. Does not alter consciousness.

Anesthesia Loss of feeling or sensation, especially loss of the sensation of pain with loss of protective reflexes.

Anoxia Absence of oxygen.

Anticholinergic Antagonist to action of parasympathetic and other cholinergic nerve fibers.

Apnea Suspension or cessation of breathing.

Conduction anesthesia Loss of sensation in a region of the body produced by injecting an anesthetic drug along the course of a nerve or a group of nerves to inhibit conduction of impulses to and from the area supplied by that nerve or nerves (block anesthesia, nerve block anesthesia).

Depolarization Neutralization of polarity; reduction of differentials of ion distribution across polarized semipermeable membranes, as in nerve or muscle cells in the conduction of impulses; to make electrically negative.

Dysrhythmia Ineffective rhythm, as of heart rate or brain waves; term used interchangeably with arrhythmia.

Emergence Return of consciousness, sensation, and reflexes after general anesthesia.

Endotracheal Within the trachea. An endotracheal tube may be placed in the trachea to maintain a patent airway during loss of consciousness.

Epidural anesthesia Loss of sensation below the level of peridural injection of an anesthetic drug into the epidural space in the spinal canal for relief of pain in the lower extremities, abdomen, and pelvis without loss of consciousness.

Extubation Removal of an endotracheal tube.

Fasciculation Abnormal skeletal muscle contraction in which groups of muscle fibers innervated by the same neuron contract together.

Hypercapnia Excessive amount of carbon dioxide in the blood; may also be termed hypercarbia.

Hypnotic Drug or verbal suggestion that induces sleep.

Hypothermia State in which body temperature is lower than the physiologic normal (i.e., below 95° F [35° C]).

Hypoxia, hypoxemia Oxygen deficiency; state in which an inadequate amount of oxygen is available to or used by tissue; inadequate tissue oxygenation.

Induction Period from the beginning of administration of an anesthetic until the patient loses consciousness and is stabilized in the desired plane of anesthesia.

Intrathecal injection Instillation of solution, such as an anesthetic drug, into the subarachnoid space for diffusion in spinal fluid, as for spinal anesthesia.

Intubation Insertion of an endotracheal tube.

Laryngospasm Involuntary spasmodic reflex action that partially or completely closes the vocal cords of the larynx.

Local anesthesia Loss of sensation along specific nerve pathways produced by blocking transmissions of impulses to receptor fibers. The anesthetic drug injected depresses sensory nerves and blocks conduction of pain impulses from their site of origin. The patient remains conscious, with or without intravenous sedation.

Moderate sedation (formerly known as intravenous conscious sedation [IVCS]) Depressed level of consciousness produced by IV administration of pharmacologic agents. The patient retains the ability to continuously maintain a patent airway independently and respond to physical or verbal stimulation. Sedation may relieve anxiety and produce amnesia.

Narcosis State of arrested consciousness, sensation, motor activity, and reflex action produced by drugs.

Narcotic, opioid Drug derived from opium or opium-like compounds, with potent analgesic effects associated with significant alteration of mood and behavior.

Nerve block Loss of sensation produced by injecting an anesthetic drug around a specific nerve or nerve plexus to interrupt sensory, motor, or sympathetic transmission of impulses.

$Paco_2$ Arterial carbon dioxide tension (partial pressure of carbon dioxide in arterial blood). Normal 35 to 45 torr.

Pao_2 Arterial oxygen tension (partial pressure of oxygen in the arterial blood); degree of oxygen transported in the circulating blood. Normal 80 to 100 torr.

pH Expression for hydrogen ion concentration or acidity. In blood, alkalemia: values above 7.45; acidemia: values below 7.35; normal 7.4.

Regional anesthesia Loss of sensation in a specific body part or region produced by blocking conductivity of sensory nerves supplying that area. The anesthetic drug is injected around a specific nerve or group of nerves to interrupt pain impulses. The patient remains conscious, with or without intravenous sedation. Regional anesthetic techniques include nerve, intrathecal, peridural, and epidural blocks.

Sedative Pharmacologic agent (drug) that suppresses nervous excitement, allays anxiety, and produces a calming effect. Benzodiazepines, barbiturates, and opioids (narcotics) are the most commonly used drugs for conscious sedation.

Spinal anesthesia Loss of sensation below the level of the diaphragm produced by intrathecal injection of an anesthetic drug into the subarachnoid space without loss of consciousness.

Tachycardia Excessively rapid rate of heart action, heartbeat. The pulse rate is higher than 100 beats/min.

Tachypnea Abnormally rapid rate of breathing.

Topical anesthesia Depression of sensation in superficial peripheral nerves by application of an anesthetic agent directly to the mucous membrane, skin, or cornea.

The Art and Science of Anesthesia

Anesthesiology is the branch of medicine and nursing that is concerned with the administration of medication or anesthetic agents to relieve pain and support physiologic functions during a surgical procedure. It is a specialty that requires knowledge of biochemistry, clinical pharmacology, cardiology, and respiratory physiology. The American Society of Anesthesiologists (ASA), founded in 1905 and incorporated in 1936, has defined anesthesiology as the practice of medicine dealing with the management of procedures for rendering a patient insensible to pain during surgical procedures and with the support of life functions under the stress of anesthetic and surgical manipulations.

The purpose of this chapter is to acquaint the surgical team with several processes associated with the delivery and maintenance of **anesthesia** and how the team works together to provide a safe surgical procedure for the patient. All perioperative team members should be readily available to assist the anesthesia provider as needed. Continuing education is advised for the entire team.

Choice of Anesthesia

Selection of anesthesia is made by the anesthesia provider in consultation with the surgeon and the patient. The primary consideration with any anesthetic is that it should be associated with low morbidity and mortality. Choosing the safest agent and technique is a decision predicated on thorough knowledge, sound judgment, and evaluation of each individual situation.

The anesthesia provider uses the lowest concentration of anesthetic agents compatible with patient **analgesia**, relaxation, and facilitation of the surgical procedure. An ideal anesthetic agent or technique suitable for all patients does not exist, but the one selected should include the following characteristics:

- Provide maximum safety for the patient
- Provide optimal operating conditions for the surgeon
- Provide patient comfort
- Have a low index of toxicity
- Provide potent, predictable analgesia extending into the postoperative period
- Produce adequate muscle relaxation
- Provide **amnesia**
- Have a rapid onset and easy reversibility
- Produce minimum side effects

The patient's ability to tolerate stress and adverse effects of anesthesia and the surgical procedure depends on respiration; circulation; and function of the liver, kidneys, endocrine system, and central nervous system (CNS). The following factors are important:

- Age, size, and weight of the patient
- Physical, mental, and emotional status of the patient
- Presence of complicating systemic disease or concurrent drug therapy
- Presence of infection at the site of the surgical procedure
- Previous anesthesia experience
- Anticipated procedure
- Position required for the procedure
- Type and expected length of the procedure
- Local or systemic toxicity of the agent
- Expertise of the anesthesia provider
- Preference of the surgeon and patient

Anesthesia State

Both the central and the autonomic nervous systems play essential roles in clinical anesthesia. The CNS exerts powerful control throughout the body. The effect of anesthetic drugs is one of progressive depression of the CNS, beginning with the higher centers of the cerebral cortex and ending with the vital centers in the medulla. The cerebral cortex is not inactive during deep anesthesia. Afferent impulses continue to flow into the cortex along primary pathways and excite cells in appropriate sensory areas. Also, the cerebral cortex is integrated with the reticular system.

The brain represents approximately 2% of body weight but receives about 15% of cardiac output. Various factors cause alterations in cerebral blood flow and are of considerable importance in anesthesia. These factors are oxygen, carbon dioxide, temperature, arterial blood pressure, drugs, the age of the patient, anesthetic techniques, and neurogenic factors.

The autonomic nervous system is equally important because of its role in the physiology of the cardiovascular system, the anesthesia provider's ability to block certain autonomic pathways with

local analgesic agents, specific blocking effects of certain drugs, and the sympathomimetic and parasympathomimetic effects of many anesthetic agents.

The anesthesia state involves control of motor, sensory, mental, and reflex functions. The anesthesia provider constantly assesses the patient's response to stimuli to evaluate specific anesthetic requirements. Specific drugs are used to achieve the desired results: amnesia, analgesia, and muscle relaxation. The ASA and American Association of Nurse Anesthetists (AANA) have established guidelines and standards for safely administering and monitoring anesthesia care. The ASA also developed the taxonomy for classifying patients by physical status from Class I, the lowest risk, to Class VI, the highest risk (Box 24.1). More information about the ASA classification system can be found at www.asahq.org

Knowledge of Anesthetics

Anesthesia involves the administration of potentially lethal drugs and gases. Interactions of these with human physiology can be profound. Using discerning observation, astute deduction, and meticulous attention to the minutiae, the anesthesia provider delivers skilled **induction**, careful maintenance of anesthesia, and prophylaxis to avoid postoperative complications.

Being responsible for vital functions of the patient, the anesthesia provider must know physical and chemical properties of all gases and liquids used in anesthesia. These properties determine how agents are supplied, their stability, systems used for their administration, and their uptake and distribution in the body. Important factors are diffusion, solubility in body fluids, and relationships of pressure, volume, and temperature. The synthesized general anesthetic agents are nonflammable, in contrast with the older agents.

Perioperative and postanesthesia care unit (PACU) nurses need to be cognizant of the pharmacologic characteristics of the most commonly used anesthetics and techniques. Anesthesia and surgical trauma produce multiple systemic effects, which are continually monitored throughout the perioperative care period. The type and level of anesthesia will vary according to the type of surgery being performed. These types are described as follows:

1. *Minimal or light sedation (anxiolysis):* A drug-induced state during which patients respond normally to verbal command. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.
2. ***Moderate sedation****/analgesia (formerly known as conscious sedation):* A drug-induced depression of consciousness during which patients can respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate.
3. *Deep sedation/analgesia:* A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance to maintain a patent airway, and spontaneous ventilation may be inadequate.
4. *Full anesthesia:* General anesthesia and regional anesthesia. General anesthesia is a drug-induced loss of consciousness during which patients cannot be roused, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance to maintain a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

• BOX 24.1 ASA Classifications

- Class I theoretically includes relatively healthy patients with localized pathologic processes. An emergency surgical procedure, designated E, signifies additional risk. For example, a hernia that becomes incarcerated changes the patient's status to Class I-E.
- Class II includes patients with mild systemic disease (e.g., diabetes mellitus controlled by oral hypoglycemic agents or diet).
- Class III includes patients with severe systemic disease that limits activity but is not totally incapacitating (e.g., chronic obstructive pulmonary disease or severe hypertension).
- Class IV includes patients with an incapacitating disease that is a constant threat to life (e.g., cardiovascular or renal disease).
- Class V includes moribund patients who are not expected to survive 24 hours with or without the surgical procedure. They are operated on in an attempt to save their lives; the surgical procedure is a resuscitative measure, as in a massive pulmonary embolus. The patient may or may not survive the surgical procedure.
- Class VI includes patients who have been declared brain dead but whose organs will be removed for donor purposes. Mechanical ventilation and life support systems are maintained until the organs are procured.

Types of Anesthesia

Anesthesia may be produced in the following ways:

- *General anesthesia:* Pain is controlled by general insensibility. Basic elements include loss of consciousness, analgesia, interference with undesirable reflexes, and muscle relaxation.
- *Balanced anesthesia:* The properties of general anesthesia (i.e., hypnosis, analgesia, and muscle relaxation) are produced, in varying degrees, by a combination of agents. Each agent has a specific purpose. This often is referred to as *neuroleptanesthesia.*
- *Local or regional block anesthesia:* Pain is controlled without loss of consciousness. The sensory nerves in one area or region of the body are anesthetized. This is sometimes called **conduction anesthesia**. Acupuncture is sometimes used.
- *Spinal or* ***epidural anesthesia****:* Sensation of pain is blocked at a level below the diaphragm without loss of consciousness. The agent is injected in the spinal canal.

General Anesthesia

Anesthesia is produced as the CNS is affected. Association pathways are broken in the cerebral cortex to produce more or less complete lack of sensory perception and motor discharge. Unconsciousness is produced when blood circulating to the brain contains an adequate amount of the anesthetic agent. General anesthesia results in an unconscious, immobile, quiet patient who does not recall the surgical procedure.

Most anesthetic agents are potentially lethal. The anesthesia provider must constantly observe the body's reflex responses to stimuli and other guides to determine the degree of CNS, respiratory, and circulatory depression during induction and the surgical procedure. No one clinical sign can be used as a reliable indication of anesthesia depth. Continuous watching and appraisal of all

TABLE 24.1 Depth of General Anesthesia

From	To	Patient's Responses	Patient Care Considerations
Induction of general anesthesia by IV or inhalant gas	Begins to lose consciousness; will have recall Bispectral state 100	Drowsy, dizzy, amnesic	Close OR doors. Keep room quiet. Stand by to assist. Initiate cricoid pressure if requested.
Loss of consciousness: excitement phase	Relaxation, light hypnosis; low probability of recall Bispectral state 70-50	May be excited, with irregular breathing and movements of extremities; susceptible to external stimuli (e.g., noise, touch)	Restrain patient. Remain at patient's side, quietly, but ready to assist anesthesia provider as needed.
Surgical anesthesia stage of relaxation	Loss of reflexes: depression of vital functions Bispectral state 40: maintenance range	Regular respiration; contracted pupils; reflexes disappear; muscles relax; auditory sensation lost	Position patient and prepare skin only when anesthesia provider indicates this stage is reached and under control.
Danger stage: vital functions too depressed	Respiratory failure; possible cardiac arrest Bispectral state 0	Not breathing; little or no pulse or heartbeat	Prepare for cardiopulmonary resuscitation.

IV, Intravenous; *OR*, operating room.

clinical signs, in addition to other available objective measurements, are necessary. In this way the anesthesia provider judges the level of anesthesia, referred to as light, moderate, or deep, and provides the patient with optimal care (Table 24.1).

The three methods of administering general anesthetic are inhalation, intravenous (IV) injection, and rectal instillation. The latter method is not commonly used, except occasionally in pediatrics, because retention and absorption in the colon are unpredictable. Control of each method varies.

Induction of General Anesthesia

Induction involves putting the patient safely into a state of unconsciousness. Fig. 24.1 depicts the levels of unconsciousness associated with general anesthesia. A patent airway and adequate ventilation must be ensured. If one is not already running, an IV infusion is started. The anesthesia provider should wear gloves for venipuncture. A nasogastric tube may be inserted to decompress the gastrointestinal tract and evacuate stomach contents.

Preoxygenation

The anesthesia provider may have the patient breathe pure (100%) oxygen by facemask for a few minutes. This provides a margin of safety in the event of airway obstruction or **apnea** during induction, with resultant **hypoxia**.

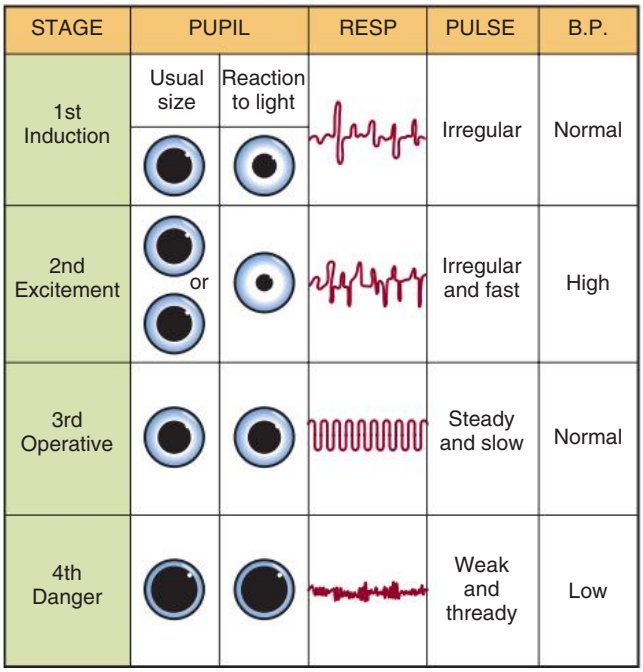
Loss of Consciousness

Unconsciousness is induced by IV administration of a drug or by inhalation of an agent mixed with oxygen. Because the technique is rapid and simple, an IV drug usually is preferred by anesthesia providers and often is requested by patients.

Intubation

A patent airway must be established to provide adequate oxygenation and control breathing of the unconscious patient. The patient's tongue and secretions can obstruct respiration in the absence of protective reflexes.

The anesthesia provider evaluates the airway for the risk for difficult **intubation** using the Mallampati classification chart

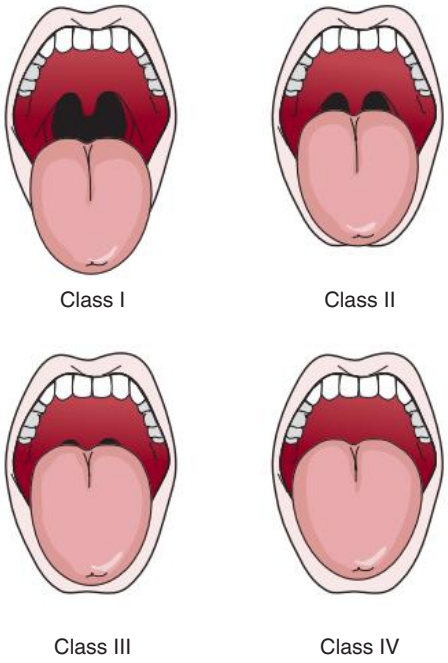


• **Fig. 24.1** Levels of unconsciousness associated with general anesthesia.

(Fig. 24.2). Other measurements include thyromental distance (the distance between the chin and thyroid cartilage), neck flexion/extension range, and the ability to prognath (protrude the mandible). An oropharyngeal airway, nasopharyngeal airway, laryngeal mask, **endotracheal** tube, or endobronchial tube (for lung procedures) may be inserted.

Physiologic indicators of a difficult airway include the following:

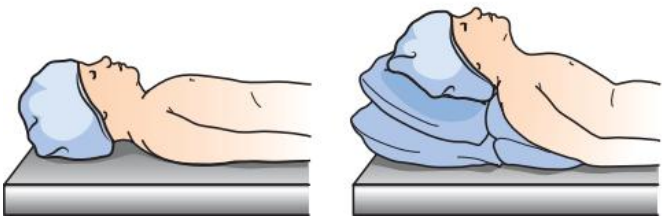
- Inability to open the mouth less than 4 cm. Patients with previous jaw surgery may have jaw wires in place. Wire cutters should be immediately available in the event of a return to surgery.



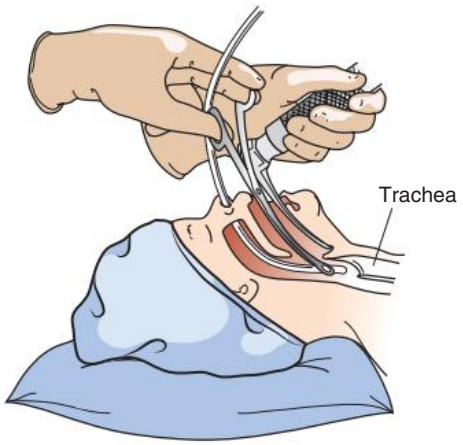
• **Fig. 24.2** Mallampati classification for difficult intubation.

- Immobility of the cervical spine. Patients with vertebral disease or injury may not have full range of motion necessary for intubation.
- Chin or jaw deformities. Patients with small jaws or chin may have a difficult airway. Edentulous patients commonly have some bone loss that alters facial contours.
- Dentition can be an issue if the patient has loose teeth or periodontal disease. A tooth can be aspirated during the airway maintenance process. Children between the ages of 6 and 8 commonly have loose baby teeth.
- Short neck or morbid obesity (Fig. 24.3).
- Pathology of the head and neck such as tumors or deformity. An enlarged tongue can be an obstruction to a full view of the glottis.
- Previous tracheostomy scar, which can cause a stricture.
- Trauma.

Intubation is insertion of an endotracheal tube between vocal cords, usually with an oral tube by direct laryngoscopy. A nasotracheal tube may be inserted by blind intubation or with a direct approach using Magill forceps to guide the tube through the pharynx (Fig. 24.4). Epistaxis can be a complication of nasal airway use. This method is contraindicated in anticoagulated patients. Tubes may be made of metal, plastic, silicone, or rubber. Most styles for adult sizes have a built-in cuff that is inflated with



• **Fig. 24.3** Short neck or morbid obesity. **A,** Supine position. **B,** Sniffing position.



• **Fig. 24.4** Nasotracheal intubation with a Magill forceps.

a measured amount of air, water, or saline after insertion, to completely occlude the trachea.

The anesthesia provider is informed if a laser will be used in the mouth or throat so that a laser-resistant endotracheal tube can be inserted. The endotracheal tube must be securely fixed in place to prevent irritation of the trachea and maintain ventilation. The anesthesia provider should wear a mask and protective eyewear to prevent secretions splashing in the eyes during intubation. An oropharyngeal suction tip and tubing should be kept close at hand.

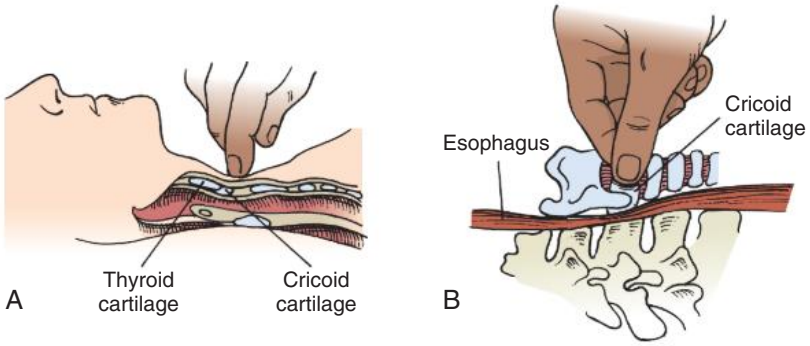
Neuromuscular blocking agents are given before intubation to relax the jaw and larynx. Pediatric patients and patients susceptible to malignant hyperthermia may experience jaw tightness, which is referred to as masseter muscle rigidity (MMR) or trismus. Intubation during induction and **extubation** during **emergence** from anesthesia are precarious times for the patient. The patient may cough, jerk, or experience **laryngospasm** from tracheal stimulation. Cardiac **dysrhythmias** may occur. Hypoxia is a potential complication. Hypoxia commonly precedes dysrhythmia.

Aspiration is also a hazard, particularly in a patient with a full stomach or with increased intraabdominal or intracranial pressure. Any patient who arrives in the operating room (OR) unconscious or who is a victim of trauma should be treated as though he or she has a full stomach.[1] Pregnant and obese patients should also be considered in this category because of increased intraabdominal pressure in the supine position and possible decreased gastric motility.

Cricoid Pressure

The circulating nurse may be asked to apply pressure to the cricoid cartilage to occlude the esophagus and immobilize the trachea. Referred to as *Sellick's maneuver,* this action prevents regurgitation and aspiration of stomach contents. The cricoid cartilage forms a complete ring around the inferior wall of the larynx below the thyroid cartilage prominence. Exerting pressure with one or two fingers to compress the cricoid cartilage against the body of the sixth cervical vertebra obstructs the esophagus (Fig. 24.5).

Compression must begin with the patient awake before induction drugs are injected. It must continue until the endotracheal tube cuff is inflated and the anesthesia provider states that it is safe to release pressure. This is the narrowest portion of the pediatric airway. If the patient is younger than 8 years, an uncuffed tube is used to prevent damage to the airway.[1]



• **Fig. 24.5** Cricoid pressure. **A,** Index finger displaces cricoid cartilage posteriorly, thus obstructing esophagus. **B,** Two-finger technique obstructs esophagus between body of sixth cervical vertebra and cricoid cartilage.

Awake Intubation

Based on preoperative physical assessment, the anesthesia provider may determine that intubation must be performed before the induction of general anesthesia (i.e., "awake intubation"). Acromegaly, an anterior larynx, an enlarged tongue, a limited oral cavity, jaw fixation, a short neck, and limited cervical range of motion are the most common indications for awake intubation. These conditions may inhibit visualization of the vocal cords by direct laryngoscopy and thus increase the potential risk for airway obstruction in the absence of protective reflexes, such as after the induction of anesthesia.

Awake intubation can be performed with a fiberoptic or rigid laryngoscope for direct visualization of vocal cords after the administration of IV sedation and application of a topical spray anesthetic to the posterior pharynx. The anesthesia provider may inject a local anesthetic around the laryngeal nerve to suppress the patient's gag and cough reflex. Usually two anesthesia providers work together during awake intubation.

After the patient is sedated and the topical anesthetic agent is applied, one anesthesia provider inserts the endotracheal or nasotracheal tube as the second anesthesia provider gives a rapid-acting barbiturate to induce general anesthesia.

Key Points during Induction

Induction of general anesthesia is a crucial period requiring maximum attention from the OR team. The following key points are critical to the patient's welfare:

1. The circulating nurse should remain at the patient's side during induction to provide physical protection and emotional support, assist the anesthesia provider as needed, and closely observe the monitors.
2. Although induction is quiet and uneventful for most patients, untoward occurrences are possible. Excitement, coughing, breath holding, retching, vomiting, irregular respiratory patterns, or laryngospasm can lead to hypoxia. Secretions in air passages from irritation by the anesthetic can cause obstruction and dysrhythmias. Induction is gentle and not so rapid as to cause physiologic insult. To prevent these events, the patient must not be stimulated. (Avoid venting steam from the sterilizer in the adjacent substerile room, clattering instruments, or opening paper wrappers. Do not move or begin prepping the patient until the anesthesia provider says it is safe to do so.)
3. Precautions to be taken during induction include continuous electrocardiogram (ECG) monitoring, use of a precordial chest stethoscope, and having resuscitative equipment, including a defibrillator, readily available.
4. Induction is individualized. For example, an obese or pregnant patient may be induced with the head raised slightly to avoid pressure of the abdominal viscera against the diaphragm. The patient is placed flat, however, if the blood pressure begins to drop. The enlarged pregnant uterus can cause pressure on the vena cava, decreasing venous return. One quick method of relieving pressure is to physically push the uterus toward the patient's left side. Another method for displacing the pregnant uterus is to elevate the patient's right hip by tilting the OR bed toward the left or placing a wedge under the right hip.
5. Small children need gentle handling. The circulating nurse can help the anesthesia provider make the induction period less frightening by staying close to the child. Sometimes a drop of artificial flavoring (e.g., orange, peppermint) put inside the facemask facilitates the child's acceptance of it. Parents are often allowed in for induction according to the institution's policy. After induction, the parent is escorted back to the waiting area by transport personnel.
6. The speed of induction depends on the potency of the agent, administration technique, partial pressure administered, and rate at which the anesthetic is taken up by blood and tissues.

Maintenance of General Anesthesia

The anesthesia provider attempts to maintain the lightest level of anesthesia in the brain compatible with operating conditions. The following are five objectives of general anesthesia:

1. *Oxygenation:* Tissues, especially the brain, must be continuously perfused with oxygenated blood. The color of the blood, amount and kind of bleeding, and pulse oximetry are indicators of the adequacy of oxygenation. Controls on the anesthesia machine and monitors of vital functions keep the anesthesia provider aware of the patient's condition.
2. *Unconsciousness:* The patient remains asleep and unaware of the environment during the surgical procedure.
3. *Analgesia:* The patient must be free of pain during the surgical procedure.
4. *Muscle relaxation:* Muscle relaxation must be constantly assessed to provide necessary amounts of drugs that cause skeletal muscles to relax. Less tissue manipulation is required when muscles are relaxed.
5. *Control of autonomic reflexes:* Anesthetic agents affect cardiovascular and respiratory systems. Tissue manipulations and

systemic reactions to them may be altered by drugs that control the autonomic nervous system.

Anesthesia Machine

General anesthesia is maintained by inhalation of gases and IV injection of drugs. An anesthesia machine is always used to deliver oxygen-anesthetic mixtures to the patient through a breathing system.

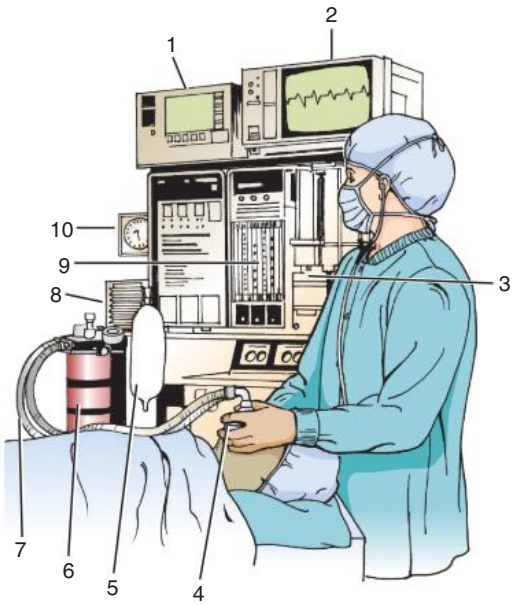
The anesthesia machine includes sources of oxygen and gases with flowmeters for measuring and controlling their delivery; devices to volatilize and deliver liquid anesthetics; a gas-driven mechanical ventilator; devices for monitoring the ECG, blood pressure, inspired oxygen, and end-tidal carbon dioxide; and alarm systems to signal apnea or disconnection of the breathing circuit.

Breathing tubes of corrugated rubber or plastic carry gases from the machine to the facemask and breathing system. The reservoir (breathing) bag compensates for variations in respiratory demand and permits assisted or controlled ventilation by manual or mechanical compression of the bag. Sterile disposable sets containing tubing, a mask, a Y-connector, and a reservoir bag are commercially available in conductive and nonconductive materials.

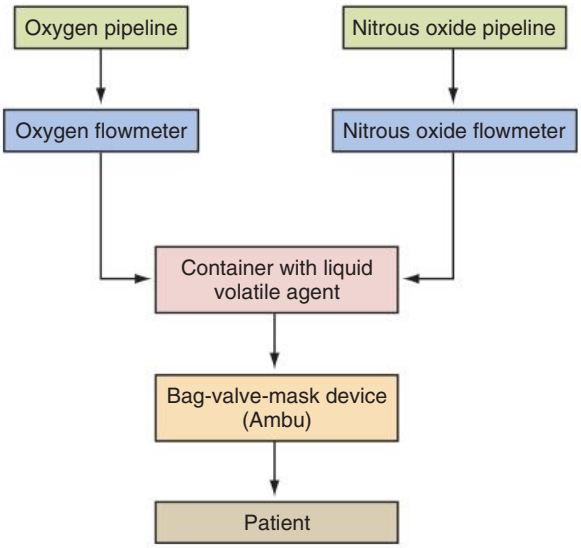
Machine design includes fail-safe alarm systems to prevent delivery of a hypoxic gas mixture and to reduce the possibility of human error or mechanical failure. Reference to a daily machine performance checklist by the anesthesia provider before induction should be routine, as recommended by the U.S. Food and Drug Administration (FDA) in 1986. Studies have shown that many complications associated with the administration of anesthetic could have been avoided if the equipment had been checked before use.

All anesthesia machines have the following features (Fig. 24.6):

1. Sources of oxygen and compressed gases (Fig. 24.7). These may come from piped-in systems, but mounted oxygen tanks are necessary in the event of failure of systems.



• **Fig. 24.6** Anesthesia machine for maintenance of general anesthesia. *1,* Anesthetic and respiratory gas monitor; *2,* physiologic monitor (channels include electrocardiograph [ECG], blood pressure, temperature, heart rate, and pulse oximeter); *3,* flow-through vaporizers; *4,* facemask; *5,* reservoir "breathing" bag; *6,* carbon dioxide absorber canister; *7,* patient breathing circuit; *8,* ventilator; *9,* flowmeters for gases; *10,* sphygmomanometer for manual blood pressure.

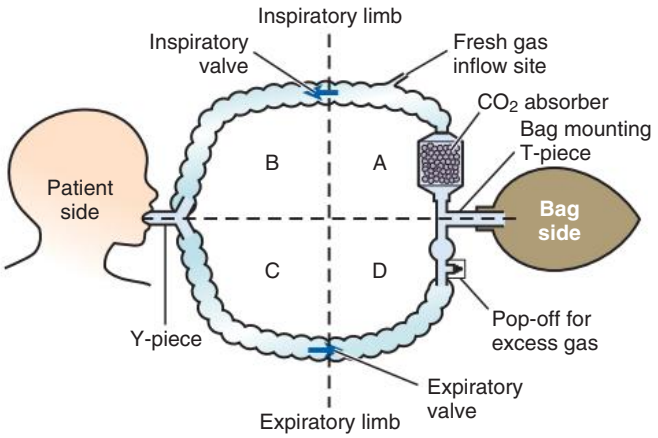


• **Fig. 24.7** Minimum number of components needed for an anesthesia gas machine.

2. Means for measuring (flowmeters) and controlling (reservoir bag) delivery of gases.
3. Means to volatilize liquid (vaporizer) and deliver (breathing tubes) anesthetic vapor or gas.
4. Device for disposal of carbon dioxide (carbon dioxide absorption canister).
5. Safety devices:
   a. Oxygen analyzers
   b. Oxygen pressure interlock system or equivalent to automatically shut off the flow of gases in the absence of oxygen pressure
   c. End-tidal carbon dioxide monitors
   d. Pressure and disconnect alarms to notify the anesthesia provider if the flow of oxygen and gases becomes disproportional
   e. Gas scavenger system to collect exhaled gases

Waste Gases. The elimination of waste gas, vented through an exhaust valve into a waste gas scavenger system, controls pollution of the room air. Most waste anesthetic gas removal hoses are purple and are seen exiting the gas machine at the back of the machine. Nitrous oxide (N_2O) and halogenated agents can escape into room air if they are not directed through the scavenger system. Substantial amounts may be an occupational health hazard to OR team members. Prolonged exposure to high concentrations of waste gases (1000 ppm) can cause reproductive abnormalities. Halogenated waste gases should be lower than 2 ppm and N_2O waste gas should be lower than 25 ppm according to safety regulations set by the National Institute for Occupational Safety and Health (NIOSH) and Centers for Disease Control and Prevention (CDC). Additional information can be found at www.cdc.gov.

Valves on the machine and tubing connections should be checked daily and must be secure for the system to work properly. Room air should be monitored. This may be done by an infrared spectrophotometer, for example, to monitor the escape of gases from the patient's exhalations and from the anesthetic delivery system. Patients continue to exhale retained gases when they arrive in the PACU. Passive dosimeters may be used to monitor air in team members' personal breathing spaces.



• **Fig. 24.8** Complete anesthesia breathing circuit.

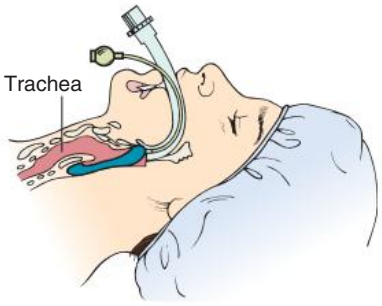
Inhalation Systems. The method for administration of inhalation anesthetics through the anesthesia machine can be classified as semiclosed, closed, semiopen, or open (Fig. 24.8):

- *Semiclosed system:* The most widely used system, a semiclosed system permits exhaled gases to pass into the atmosphere so that they will not mix with fresh gases and be rebreathed. A chemical absorber for carbon dioxide is placed in the breathing circuit. This reduces carbon dioxide accumulation in blood. Induction is slower but with less loss of heat and water vapor than with open methods.
- *Closed system:* A closed system allows complete rebreathing of expired gases. Exhaled carbon dioxide is absorbed by soda lime or a mixture of barium and calcium hydroxide (Baralyme) in the absorber on the machine. The body's metabolic demand for oxygen is met by adding oxygen to the inspired mixture of gases or vapors. This system provides maximal conservation of heat and moisture. It reduces the amount and therefore the cost of agents and reduces environmental contamination.
- *Semiopen system:* With the semiopen system some exhaled gas can pass into surrounding air but some returns to the inspiratory part of the circuit for rebreathing. The degree of rebreathing is determined by the volume of flow of fresh gas. Expired carbon dioxide is not chemically absorbed.
- *Open system:* In an open system, valves direct expired gases into the lower portion of the canister, where they are removed by vacuum. The patient inhales only the anesthetic mixture delivered by the anesthesia machine. The composition of the inspired mixture can be accurately determined. However, anesthetic gases are not confined to the breathing system. High flows of gases are necessary, because resistance to breathing varies. Water vapor and heat are lost. Inspired gases should be humidified for respiratory mucosa to function properly, especially for children and during long surgical procedures.

Administration Techniques. Inhalation gases and vapors can be delivered from an anesthesia machine via a facemask, laryngeal mask, or endotracheal tube. Respirations must be assisted or controlled.

Mask Inhalation. Anesthetic gas or vapor of a volatile liquid is inhaled through a facemask attached to the anesthesia machine by breathing tubes. The mask must fit the face tightly to minimize escape of gases into room air. Significant leakage occurs around an ill-fitting mask, particularly in the area above the nose. Several sizes should be available.

Laryngeal Mask. An airway can be maintained by inserting a laryngeal mask airway (LMA) into the larynx. This flexible tube has an inflatable silicone ring and cuff. When the cuff is inflated, the mask fills the space around and behind the larynx to form a seal between the tube and the trachea. All types do not protect against regurgitation and aspiration. OxyMask and ProSeal have a passage for gastric tube placement which provides better protection against regurgitation. Adult and pediatric styles are available and can be useful when intubation and mask ventilation are complex.



• **Fig. 24.9** Laryngeal mask airway.

Reusable and disposable styles are commercially available (Fig. 24.9). The mask is selected for use by size of the patient, as follows:

- Size 1: 0 to 6.5 kg
- Size 2: 6.5 to 20 kg
- Size 2.5: 20 to 30 kg
- Size 3: 30 to 70 kg
- Size 4: 70 to 80 kg
- Size 5: 80 kg or greater

Endotracheal Administration. Anesthetic vapor or gas is inhaled directly into the trachea through a nasal or oral tube inserted between the vocal cords by direct laryngoscopy. The tube is securely fixed in place to minimize tissue trauma. The patient is given oxygen before and after suctioning of a tracheal tube. Advantages of endotracheal administration are the following:

- It ensures a patent airway and control of respiration. Secretions are easily removed from the trachea by suctioning. Positive pressure can be given immediately by pressing the reservoir bag on the machine without danger of dilating the stomach.
- It protects the lungs from aspiration of blood, vomitus of gastric contents, or foreign material.
- It preserves the airway regardless of the patient's position during the surgical procedure.
- It interferes minimally with the surgical field during head and neck procedures.
- It helps minimize the escape of vapors or gases into the room atmosphere.

Intubation and extubation can cause tracheal stimulation. The patient may cough, jerk, or develop spasms of the larynx (laryngospasm). Other potential complications of endotracheal administration include the following:

- *Trauma to the teeth, pharynx, vocal cords, or trachea:* Postoperatively the patient may experience sore throat, hoarseness, laryngitis, and/or tracheitis. Laryngeal edema is more common in children than in adults. Ulceration of the tracheal mucosa or vocal cords may cause granuloma.
- *Cardiac dysrhythmias:* Cardiac dysrhythmias may occur in light anesthesia or be caused by suctioning through the endotracheal tube.
- *Hypoxia and hypoxemia:* Hypoxia is a common complication during intubation and extubation. Endotracheal tube suctioning can cause hypoxemia.

- *Accidental esophageal or endobronchial intubation:* The latter results in ventilation of only one lung.
- *Aspiration of gastrointestinal contents:* This is a hazard in a patient with a full stomach or a patient who has increased intraabdominal or intracranial pressure. It can also occur in a patient with intestinal obstruction who is extubated before protective reflexes return.

Controlled Respiration. Respirations may be assisted or controlled. Assistance, to improve ventilation, may easily be given by manual pressure on the reservoir (breathing) bag of the anesthesia machine. Assisted respiration implies that the patient's own respiratory effort initiates the cycle. Controlled respiration may be defined as the completely controlled rate and volume of respirations. The latter is best accomplished by means of a mechanical device that automatically and rhythmically inflates the lungs with intermittent positive pressure, requiring no effort by the patient. Gas moves in and out of the lungs.

The combination of a volume preset ventilator with an assist mechanism maintains the integrity of the respiratory center. Controlled respiration is initiated after the anesthesia provider has produced apnea by hyperventilation or administration of respiratory depressant drugs or a neuromuscular blocker.

Controlled ventilation is used in all types of surgical procedures, especially in lengthy ones. The anesthesia provider's artificial control of respiration or the patient's respiratory efforts influence the minute-to-minute level of anesthesia. Advantages of controlled respiration are the following:

- It provides for optimal ventilation.
- It allows for selective lung deflation for thoracic procedures.
- It provides access to deep regions of the thorax and upper abdomen.
- It permits deliberate production of apnea to facilitate surgical manipulation below the diaphragm, ligation of deep vessels, or obtaining radiographic films.

The patient is taken off the respirator gradually near the end of the surgical procedure, and spontaneous respiration resumes. Assisted ventilation may be continued postoperatively after lengthy procedures until reflexes and spontaneous respirations return.

Inhalation Anesthetic Agents

Inhalation is a controllable method of administration because uptake and elimination of anesthetic agents are accomplished mainly by pulmonary ventilation and selective organ metabolism. The anesthetic vapor of a volatile liquid or an anesthetic gas is inhaled and carried into the bloodstream by passing across the alveolar membrane into the general circulation and on to the tissues.

Ventilation and pulmonary circulation are two critical factors involved in the process. Each can be affected by components of the anesthetic experience, such as a change in body position, preanesthetic medication, alteration in body temperature, or respiratory gas tensions.

In inhalation anesthesia, the aim is to establish balance between the content of the anesthetic vapor or gas inhaled and that of body tissues. The blood and lungs function as the transport system. Anesthesia is produced by the development of an anesthetizing concentration of anesthetic in the brain. The depth of anesthesia is related to concentration and biotransformation (Table 24.1).

Pulmonary blood-gas exchange is important to tissue perfusion. Defective gas exchange can cause hypoxemia and respiratory failure. It also interferes with delivery of the anesthetic. Potent inhalation agents, such as myocardial depressants, affect oxygenation. Most of them induce a dose-related hypoventilation. The deeper the anesthesia, the more depressed ventilation becomes. Surgical stimulation partially corrects depression, but respiration must be controlled to keep oxygen and carbon dioxide exchange constant to prevent hypoventilation and cardiac depression.

Although the respiratory system is employed for distribution of the anesthetic, it also must carry on its normal function of ventilation (i.e., meeting tissue demands for adequate oxygenation and elimination of carbon dioxide and helping maintain normal acid-base balance). The amount of anesthetic vapor inspired is influenced by the volume and rate of respirations. Gas or vapor concentration and the rate of delivery are also significant.

Pulmonary circulation is the vehicle for oxygen and anesthetic transport to the general circulation. The large absorptive surface of the lungs and their extensive microcirculation provide a large gas-exchanging surface. In optimal gas exchange, all alveoli share inspired gas and cardiac output equally (ventilation-perfusion match). Because respiratory and anesthetic gases interact with pulmonary circulation, alveolar anesthetic concentrations are rapidly reflected in circulating blood.

Alveolar concentration results from a balance between two forces: ventilation that delivers the anesthetic to the alveoli and uptake that removes the anesthetic from the alveoli. Certain factors influence uptake of the anesthetic and thus induction and recovery. Uptake has two phases:

1. *Transfer of anesthetic from alveoli to blood:* The rate of transfer is determined by the solubility of the agent in the blood, the rate of pulmonary blood flow (related to cardiac output), and the partial pressure of the anesthetic in arterial and mixed venous blood.
2. *Transfer of anesthetic from blood to tissues:* Factors influencing uptake by individual tissues are similar to those for uptake by blood. They are the solubility of the gas in tissues, the tissue volume relative to the blood flow (flow rate), and the partial pressure of the anesthetic in arterial blood and tissues. Tissues differ; thus uptake of the anesthetic differs. Highly perfused tissues (heart) equilibrate more rapidly with arterial tension than does poorly perfused tissue (fat), which has a slow rise to equilibrium and retains anesthetic longer.

Elimination of the anesthetic is affected by the same factors that affected uptake. As an anesthetic is eliminated, its partial pressure in arterial blood drops first, followed by that in tissues.

The most important factors influencing safe administration of any anesthetic are the knowledge and skill of the anesthesia provider. A perfect agent has not been found, and no agent is entirely safe. Commonly used agents are listed in Table 24.2. Advantages and disadvantages are relative.

Synthesis of potent, nonflammable, halogenated, volatile liquids has replaced cyclopropane and ether, which are highly flammable agents. All inhalation agents are administered with oxygen. Volatile liquids are vaporized for inhalation by oxygen, which acts as a carrier, flowing over or bubbling through liquid in the vaporizer on the anesthesia machine. The oxygen picks up 0.25% to 5% concentration of the halogenated agent as adjusted by the anesthesia provider. Known sensitivity to halogenated agents or a history significant for the risk for malignant hyperthermia is a contraindication for their use.

Nitrous Oxide (N_2O)

Generally used as a nonvolatile adjunct to an IV drug, N_2O can be inhaled for a comfortable, rapid induction. It has a pleasant,

TABLE 24.2 Most Commonly Used General Anesthetic Agents

Generic Name	Trade Name	Administration	Characteristics	Uses
			INHALATION AGENTS	
Nitrous oxide	None	Inhalation	Inorganic nonvolatile gas; slight potency; pleasant, fruitlike odor; nonirritating; nonflammable but supports combustion; poor muscle relaxation	Rapid induction and recovery; short procedures when muscle relaxation unimportant; adjunct to potent agents. Should be mixed with 30% oxygen to prevent hypoxia.
Halothane	Fluothane	Inhalation	Halogenated volatile liquid; potent; pleasant odor; nonirritating; cardiovascular and respiratory depressant; incomplete muscle relaxation; potentially toxic to liver	Rapid induction; wide spectrum for maintenance; depth of anesthesia easily altered; rapid reversal Rarely used
Enflurane	Ethrane	Inhalation	Halogenated ether; potent; some muscle relaxation; respiratory depressant	Rapid induction and recovery; wide spectrum for maintenance Rarely used
Desflurane	Suprane	Inhalation	Halogenated liquid with low solubility, desflurane has faster uptake by inhalation and elimination	Not used for induction with children. Can be used for maintenance in adults and children.
Sevoflurane	Ultane	Inhalation	Volatile liquid form, nonflammable and nonexplosive; noted for its rapid induction and rapid emergence qualities	Used for adults and children Rapid elimination
Isoflurane	Forane	Inhalation	Halogenated methyl ether; potent; muscle relaxant; profound respiratory depressant; metabolized in liver	Rapid induction and recovery with minimal after-effects; wide spectrum for maintenance
			INTRAVENOUS AGENTS	
Thiopental sodium	Pentothal sodium	Intravenous	Barbiturate; potent; short acting with cumulative effect; rapid uptake by circulatory system; no muscle relaxation; respiratory depressant	Rapid induction and recovery; short procedures when muscle relaxation not needed; basal anesthetic
Methohexital	Brevital	Intravenous	Barbiturate; potent; circulatory and respiratory depressant	Rapid induction; brief anesthesia
Propofol	Diprivan	Intravenous	Alkyl phenol; potent short-acting sedative-hypnotic; cardiovascular depressant	Rapid induction and recovery; short procedures alone; prolonged anesthesia in combination with inhalation agents or opioids
Ketamine	Ketaject, Ketalar	Intravenous, intramuscular	Dissociative drug; profound amnesia and analgesia; may cause psychologic problems during emergence	Rapid induction; short procedures when muscle relaxation not needed; children and young adults
Fentanyl	Sublimaze	Intravenous	Opioid; potent narcotic; metabolizes slowly; respiratory depressant	High-dose narcotic anesthesia in combination with oxygen
Sufentanil	Sufenta	Intravenous	Opioid; potent narcotic, respiratory depressant	Premedication; high-dose narcotic anesthesia in combination with oxygen
Fentanyl and droperidol	Innovar	Intravenous	Combination narcotic and tranquilizer; potent; long acting	Neuroleptanalgesia
Diazepam	Valium	Intravenous, intramuscular	Benzodiazepine; tranquilizer; produces amnesia, sedation, and muscle relaxation	Premedication; awake intubation; induction
Midazolam	Versed	Intravenous, intramuscular	Benzodiazepine; sedative; short-acting amnesic; central nervous system and respiratory depressant	Premedication; conscious sedation; induction in children

fruitlike odor and is administered by facemask. Relaxation is poor. Excitement and laryngospasm may occur. It is the only true gas in use for anesthesia. The other inhalants used are liquid volatile drugs administered through a vaporizer.

Because it lacks potency, N_2O is rarely used alone but rather as an adjunct to barbiturates, **narcotics**, **opioids**, and other IV drugs. In combination, the concentration of potent drug is reduced, thereby lessening circulatory and respiratory depression. Because exposure can be an occupational hazard for personnel, measures are taken to minimize levels of N_2O in room air.

Advantages. When N_2O is used in combination with other forms of inhalants and IV drugs, excessive depth of anesthesia is

avoided. N_2O is rapidly cleared from the circulation. The incidence of nausea and vomiting is minimal. The gas has a rapid uptake and elimination and few after-effects except headache, vertigo, and drowsiness. It causes minimal physiologic change, and adverse effects can be quickly reversed. It is an excellent analgesic for procedures not producing severe pain. It does not cause myocardial depression.

Disadvantages. N_2O can cause bowel distention and increased volume in other air pockets. The use of N_2O can cause displacement of tympanoplasty grafts or increased intracranial pressure. It is a potent cerebral vasodilator. It should not be used in pregnant patients because of teratogenic effects.

It should not be used during laparoscopy. N_2O is combustible. There is no muscle relaxation. There is possible excitement or laryngospasm. Hypoxia is a hazard. There is a depressant effect on myocardial contractility.

Halothane (Fluothane)

A rarely used halogenated hydrocarbon, halothane reduces myocardial oxygen consumption more than it depresses cardiac function. Halothane was previously used in a wide spectrum of all types of surgical procedures for adults and children except routine obstetrics, when uterine relaxation is not desired. It is a profound uterine relaxant.

Because its metabolites have a possible effect as a hepatotoxin, some anesthesia providers avoid repeated administration within an arbitrary time (e.g., 3 months) in adults. Recent jaundice and known or suspected liver disease (past or present) are usually contraindications to its use. It is a trigger and contraindicated in patients who are susceptible to malignant hyperthermia. Malignant hyperthermia is covered in depth in Chapter 31.

Advantages. Halothane is nonflammable, potent, versatile, chemically stable, and rapid, and it has a smooth induction.

Disadvantages. Halothane is potentially toxic to the liver and has a profound effect on body temperature control; it may cause **hypothermia**. Complete elimination of halothane takes some time.

Enflurane (Ethrane)

A nonflammable, stable, halogenated ether, enflurane is similar in potency and versatility to halothane. It is not in common use today. Enflurane was used in a wide spectrum of procedures.

Advantages. Enflurane has a rapid induction and recovery with minimal after-effects. Pharyngeal and laryngeal reflexes are obtunded easily, salivation is not stimulated, and bronchomotor tone is not affected. The cardiac rate and rhythm remain relatively stable, although caution is advised when it is used with epinephrine. Muscle relaxation is produced, but small supplementary doses of muscle relaxants may be required; nondepolarizing relaxants are potentiated by enflurane.

Disadvantages. Enflurane has a pungent odor. Respiration and blood pressure are progressively depressed with deepening anesthesia. Although biotransformation (metabolism) of enflurane is less than what occurs with other halogenated agents, small amounts of fluoride ion are released. Severe renal disease is a contraindication to use. At deeper levels, an electroencephalographic (EEG) pattern resembling seizures may occur. The agent is absorbed by rubber.

Isoflurane (Forane)

Isoflurane comes closer to ideal than other inhalation agents and is most commonly used. Isoflurane is a nonflammable, fluorinated, halogenated methyl ether similar to halothane and enflurane, yet different. It is a more potent muscle relaxant, but unlike the others, it protects the heart against catecholamine-induced dysrhythmias. Heart rhythm is remarkably stable, with a slightly elevated rate. The blood pressure drops with induction but returns to normal with intraoperative stimulation. A dose-related lowering of the blood pressure occurs, but cardiac output is unaltered, mainly as a result of increased heart rate. Isoflurane potentiates all commonly used muscle relaxants, the most profound effect occurring with the nondepolarizing type.

Isoflurane is used for induction and maintenance in a wide spectrum of procedures except routine obstetrics. Isoflurane produces uterine relaxation. Safety to the mother and fetus has not been established. Because the drug is metabolized in the liver, it may be given to patients with minimal renal disease.

Advantages. There is less cardiac depression; there is increased cardiac output with a wide margin of cardiovascular safety. Isoflurane does not sensitize the myocardium to the effects of epinephrine. There are no CNS excitatory effects. There is rapid induction and, especially, rapid emergence with minimal after-effects (less postoperative nausea and confusion).

Isoflurane is innocuous to organs; it has low organ toxicity because of its low blood solubility and minimal susceptibility to biodegradation and metabolism. It provides superb muscle relaxation. Pharyngeal and laryngeal reflexes are easily obtunded. Isoflurane depresses bronchoconstriction; it may be used in patients with asthma and patients with chronic obstructive pulmonary disease.

Disadvantages. Isoflurane is expensive. It is a profound respiratory depressant and reduces respiratory minute volume. Respirations must be closely monitored and supported. Assisted or controlled ventilation is used to prevent respiratory acidosis. In the absence of intraoperative stimulation, the blood pressure may drop as a result of peripheral vasodilation. Cerebral vascular resistance decreases, cerebral blood flow increases, and intracranial pressure rises but is reversible with hyperventilation. Secretions are weakly stimulated. It also causes coronary vasodilation.

Desflurane (Suprane)

A nonflammable, volatile liquid with low solubility, desflurane has faster uptake by inhalation and elimination than do halothane and isoflurane. Desflurane is used in induction and maintenance of anesthesia in adults. It may be used for maintenance in infants and children, but it is not used for induction because of its potential for causing coughing and laryngospasm. Because it has a high vapor pressure, desflurane is delivered only through a vaporizer specifically designed for this agent. Desflurane vaporizers require electrical power to heat the liquid. It works well for ambulatory surgery patients because of the rapid emergence at the end of the case.

Advantages. There is rapid emergence and recovery from anesthesia. Desflurane resists biotransformation (metabolism) and degradation; it produces few urinary metabolites. The dosage of nondepolarizing muscle relaxants to maintain neuromuscular blockade may be reduced. It can be the inhalant of choice for bariatric procedures.

Disadvantages. Desflurane has a pungent odor that may be irritating during induction. Increasing alveolar concentration may lower the blood pressure, which may be corrected by reducing the inspired concentration. Hemodynamic effects, including an elevated heart rate, preclude use of desflurane by itself in a patient with cardiovascular disease; it may be combined with IV opioids or benzodiazepines.

Sevoflurane (Ultane)

Sevoflurane is a volatile liquid used for inhalation anesthesia. It is nonflammable and nonexplosive. Noted for its rapid induction and rapid emergence qualities, it is commonly used for induction and maintenance of general anesthesia.

Advantages. Sevoflurane is used as an inhalant anesthetic for adults and pediatric patients. It is rapidly eliminated by the lungs. It causes less cerebral vasodilation and can be the inhalant of choice for neurosurgery when the patient has increased intracranial pressure.

Disadvantages. Sevoflurane may cause glycosuria and proteinuria when used for long procedures at low flow rates.

Intravenous Anesthetic Agents

IV anesthesia became popular with the introduction in the 1930s of ultrashort-acting barbiturates. A drug that produces hypnosis, sedation, amnesia, and/or analgesia is injected directly into the circulation, usually via a peripheral vein in the arm. Diluted by blood in the heart and the lungs, the drug passes in high concentration to the brain, heart, liver, and kidneys—the organs of highest blood flow. Concentration in the brain is rapid. With recirculation, redistribution occurs in the body, decreasing cerebral concentration.

Dissipation of effects depends on redistribution and biotransformation. Because removal of a drug from the circulation is impossible, safety in use is related to metabolism. It is advisable for the anesthesia provider to give a small test dose at induction.

Oxygen is always given during IV and inhalation anesthesia. A barbiturate, dissociative agent, or narcotic may be given (see Table 24.2). Each has advantages, disadvantages, and contraindications. They may be supplemented with other drugs.

Thiopental (Pentothal)

Thiopental sodium is a **sedative-hypnotic** used as an IV induction agent and a supplement to regional anesthesia. This drug can be used as a safe adjunct for intubation in head injuries. Cerebral perfusion pressure is maintained while decreasing elevated intracranial pressure. Thiopental is also used as a cerebral protectant in barbiturate **narcosis**.

Repeated doses are cumulative because of high lipid solubility. Systemic vascular resistance is decreased, causing lowered arterial pressure and lower cardiac output. It decreases uterine blood flow in pregnant patients.

Advantages. Its onset of action is within 30 seconds and short-acting duration is 5 to 30 minutes depending on body mass. It can be used as an anticonvulsant.

Disadvantages. Thiopental is contraindicated in status asthmaticus, chronic renal disease, or hepatic disease. Lower doses are required in the elderly and high-risk surgical patients. Thiopental should not be used in patients who are sensitive to the drug.

Propofol (Diprivan)

An ultrashort-acting alkyl phenol, propofol is a sedative-hypnotic that produces anesthesia. It is used for rapid induction and maintenance of anesthesia for short procedures. It can be used in combination with inhalation agents or opioids for prolonged anesthesia. Propofol is supplied in a sterile, milky soybean, egg lecithin, oil-in-water emulsion. Studies have shown that it is safe to use in egg-sensitive patients, because it is not based in egg albumin, which is the primary cause of egg allergy.

In low doses it produces sedation (i.e., drowsiness, decreased responsiveness). Continued IV administration leads to hypnosis and unconsciousness. Propofol is twice as potent as thiopental sodium.

Propofol is used for general anesthesia for ambulatory surgery patients and for maintenance of moderate sedation during local and regional anesthesia. It is acceptable for patients who are allergic to barbiturates or who have porphyria.

Advantages. Propofol is rapidly distributed, metabolized, and eliminated. Emergence is very rapid, with few postoperative side effects. Can be used for postoperative nausea and vomiting (PONV). It is useful when timed wake-sleep neurologic procedures are performed.

Disadvantages. Propofol produces dose-related cardiorespiratory depression. Cardiovascular depressant action will decrease the blood pressure. Its hypotensive effect is potentiated by narcotics. The solution supports rapid growth of microorganisms if the infusion pump or syringes become contaminated. The vial should be discarded 6 hours after opening.

Propofol is used with caution in geriatric, debilitated, and hypovolemic patients. It is not recommended for pediatrics, obstetrics, and some neurosurgical procedures. Patients with egg albumin or soybean sensitivities may experience an allergic or sensitivity reaction.

Ketamine (Ketalar, Ketaject)

General anesthesia may be produced by a phencyclidine derivative to produce a state referred to as *dissociative anesthesia.* The drug acts by selectively interrupting associative pathways of the brain before producing sensory blockage. This permits a surgical procedure on a patient who appears to be awake (i.e., eyes are open, may move) but who is anesthetized (i.e., unaware, amnesic).

Ketamine may be given IV or intramuscularly (IM) to yield profound analgesia. Ketamine is available in a nasal spray (esketamine) for the treatment of depression in adults. It is swiftly metabolized. Individual response varies, depending on the dose, route of administration, and age. Because of a dose-response relationship, careful patient selection and dose selection are important. Ketamine is used alone or with nitrous oxide. **Anticholinergics** may be given to decrease hypersalivation.

Ketamine is used mainly in children between the ages of 2 and 10 years and in adults younger than 30 years for short procedures not requiring skeletal muscle relaxation, for plastic and eye procedures when combined with local agents, for diagnostic procedures, as an induction agent before other general agents are used, and to supplement nitrous oxide when adequate respiratory exchange is maintained.[3] For longer procedures, repeated doses are given that may prolong recovery time. If relaxation is needed, muscle relaxants and controlled ventilation are indicated.

Advantages. Ketamine has a rapid induction. Respirations are not depressed unless the drug is administered too rapidly or in too large a dose. A mild stimulant action on the cardiovascular system may elevate the blood pressure. The effects of ketamine are potentiated by narcotics and barbiturates.

Low-dose ketamine (1 mg/kg) has been used as an induction agent for obstetric procedures because of rapid onset, intense analgesia and amnesia, and minimal fetal effects. With its cardiovascular-stimulating properties, it is useful in hypovolemic and hypotensive patients, allowing the use of high oxygen concentration, both in obstetric and trauma procedures.

Disadvantages. Psychological manifestations (e.g., delirium, vivid imagery, hallucinations, unpleasant dreams) may occur during emergence. These can be reduced by giving preanesthetic diazepam and allowing the patient to lie quietly and undisturbed

during recovery except for essential procedures. Reactions are more common in adults than children. IV thiopental sodium or diazepam may be given to treat emergence delirium.

Ketamine is contraindicated in procedures involving tracheobronchial stimulation, because pharyngeal and laryngeal reflexes are usually active. If the drug is used alone, mechanical stimulation of the pharynx should be avoided. Other contraindications include pregnancy, hypertension, increased intracranial pressure, intraocular procedures, and previous cerebrovascular accident, because this agent increases cerebrospinal fluid (CSF) and intraocular pressure.

Adjunctive Drugs Used in Anesthesia

Many drugs are used to supplement nitrous oxide, halogenated inhalation agents, and IV drugs to maintain amnesia and analgesia, control hypertension, attenuate the extent of postoperative respiratory depression, or maintain or control other effects of general anesthesia. These drugs must be carefully controlled to avoid adverse drug interactions. For example, morphine sulfate and nitrous oxide have a synergistic action with thiopental sodium (i.e., when they are given together, each potentiates the action of the other). Therefore they are given concomitantly with caution because of their combined respiratory depressant effect.

Some drugs are given preoperatively, during induction, and/or intraoperatively. Adjunctive drugs are used primarily for analgesia and amnesia or to counteract side effects of anesthesia. Some are particularly useful for ambulatory surgery patients, because they are short acting.

Narcotics

Historically, natural opiates and synthetic opioids have been given to produce analgesia and sedation preoperatively and postoperatively. In addition, they are used intraoperatively as supplemental agents and/or in combination with oxygen for complete anesthesia for short procedures and in patients with little cardiovascular reserve. Cardiovascular depression must be avoided in these patients. Halogenated agents are contraindicated in patients with liver and renal disease and malignant hyperthermia risk.

The most popular narcotics for general anesthesia are the opioids fentanyl (Sublimaze), sufentanil (Sufenta), alfentanil (Alfenta), and meperidine (Demerol) and the opiate morphine sulfate. Although they are analgesics, to reliably achieve anesthesia, markedly larger doses of narcotics are needed (e.g., 10 to 30 times as much morphine [3 to 8 or more mg/kg body weight]). High doses of fentanyl range from 50 to 100 mg/kg body weight.

The drugs may be given in bolus doses or continuously via IV infusion in combination with inhalant anesthesia. Surprisingly, side effects seem to occur less frequently as the potency of narcotics increases. Some drugs work as agonists to each other. An agonist is a drug or a combination of drugs given to augment each other. In some circumstances, lower doses of each can be given to achieve the desired effect. They reduce adverse physiologic responses to the stress of the surgical procedure, such as increased work of the heart, potential dysrhythmias, sodium and water retention, and increased blood glucose levels. Narcotics produce a dose-related respiratory depression. The respiratory effects of narcotics are as follows:

- Reduction of responsiveness of the CNS respiratory centers to carbon dioxide (less stimulation)
- Impairment of respiratory reflexes and alteration of rhythm (prolonged inspiration, delayed expiration)
- Reduction in the respiratory rate before reduction in the tidal volume
- Production of bronchoconstriction (morphine, meperidine) or rigidity of the chest wall (fentanyl)
- Impairment of ciliary motion

Factors that influence narcotic respiratory actions include age, pain, sleep, urinary output, other drugs, intestinal resorption, and disease.

The neurophysical state obtained by use of large doses of narcotics is not the same as "the general anesthesia state" resulting from use of volatile inhalation agents such as halothane. Narcotics are more selective in action. Narcotics do not produce muscle relaxation. Conversely, they cause an increase in muscle tone. Neuromuscular blocking agents can block or treat this action or rigidity.

After high-dose narcotic anesthesia, patients are awake and pain free, with adequate although not good ventilation. These patients need careful monitoring by a well-trained PACU staff because narcotization after large doses of narcotics can occur rapidly in an apparently awake and responsive patient. The patient can hypoventilate, become hypoxic, and stop breathing when intraoperative stimuli cease. The vital signs, pupils, and skin color must be monitored.

Clinical signs of narcotic toxicity are pinpoint pupils, depressed respiration, and reduced consciousness. A narcotic antagonist is given to reverse narcotic-induced hypoventilation. Antagonists are used to block cellular receptor sites that bind to a drug. The potential for delayed toxicity after IM injection of narcotics, as opposed to IV administration, exists because absorption from muscle mass may be irregular.

Narcotic Reversal (Narcotic Antagonist). A narcotic antagonist neutralizes or impedes the action of another drug (i.e., reverses its effects). For example, narcotics produce a dose-related respiratory depression that can be reversed by opiate antagonists. These drugs are given IV, IM, subcutaneously (SQ), and nasally.

Naloxone (Narcan). A specific narcotic antagonist, naloxone reverses respiratory depression caused by narcotics. It has no respiratory or circulatory action of its own in the presence or absence of a narcotic or other agonist-antagonist. Complications can include hypertension and **tachycardia** if naloxone is combined with opioids.

Naloxone has a shorter duration of action than the narcotic being reversed. Respiratory depression can occur. Initial dose is 0.4 to 2 mg diluted in 10 mL normal saline titrated IV in 1-mL increments every 2 to 3 minutes as needed until adequate reversal is attained. Narcan can be administered SQ, IM, and by nasal spray. The nasal spray is 4 mg and can be repeated every 2 to 3 minutes.

Flumazenil (Romazicon). Flumazenil is a benzodiazepine antagonist used for complete or partial reversal after general anesthesia or conscious sedation. The duration of action is shorter than the action of the drugs being reversed, and resedation can occur. The initial dose is 0.2 mg IV over 15 seconds. This may be repeated in 1-minute intervals up to a total dose of 1 mg. If resedation occurs, the dose may be repeated but is not to exceed 3 mg in 1 hour.

Muscle Relaxants

Skeletal muscle relaxant drugs, referred to as *neuromuscular blockers,* facilitate muscle relaxation for smoother endotracheal intubation and working conditions during the surgical procedure. Their use has eliminated the need for deep inhalation anesthesia to produce relaxation. Administered IV in small amounts at intervals, they interfere with the passage of impulses from motor nerves to skeletal muscles. They act primarily at autonomic

receptor sites, the neuromuscular junction, and prejunctional and postjunctional acetylcholine-binding sites, causing paralysis of variable durations. They also can affect transmission of impulses at preganglionic and postganglionic endings in the autonomic nervous system.

Neuromuscular blockers paralyze all skeletal muscles, including the diaphragm and accessory muscles of respiration. Therefore the chief danger in their use is that they decrease pulmonary ventilation, causing respiratory depression. They also may cause circulatory disturbance. Special attention to anesthesia depth, ventilation, and electrolyte balance is required.

The anesthesia provider must constantly verify the degree of paralysis present by noting the amount of relaxation of the abdominal wall or the limpness of extremities or by using a nerve stimulator connected to the patient through needle electrodes. The use of neuromuscular blockers requires surgeon–anesthesia provider teamwork and communication. Use of these drugs always presents the hazard of overdosage, a danger alleviated by the anesthesia provider's familiarity with the surgeon's technique and the requirements of the particular surgical procedure; thus the anesthesia provider can regulate the dosage of anesthetic and relaxant necessary to produce the conditions required at the appropriate time. For example, a major use of neuromuscular blockers is in intraabdominal procedures.

At different times during the surgical procedure, blockade may be more or less essential. Although tightness of tissues and inadequate exposure may be a result of factors other than relaxation, it is helpful to the anesthesia provider to be told before pertinent action, such as closure of the peritoneum, is taken. Inadequate muscle relaxation makes closure difficult. Controlled respiration during upper abdominal manipulation can prevent descent of the diaphragm into the surgical field.

Neuromuscular blockers are classified as nondepolarizing or depolarizing. Although theoretically they are antagonistic, combinations are used. They may widen the scope of less potent anesthetics, such as nitrous oxide, or lessen the overall amount of anesthetic needed. Depolarizing and nondepolarizing drugs behave differently; depolarizers stimulate, whereas nondepolarizers inhibit autonomic receptors. Duration of action should be balanced against duration of effect on ventilation.

Nondepolarizing Neuromuscular Blockers. Nondepolarizing neuromuscular blockers act on enzymes to prevent muscle contraction. They produce tetanic electrical impulses that gradually fade, but they do not cause muscular **fasciculation** on IV injection. Their effects are decreased by anticholinesterase drugs, acetylcholine, epinephrine, and depolarizing neuromuscular blockers. Action is potentiated by halogenated inhalation agents and some aminoglycoside antibiotics.

Interactions with other drugs can result in delayed recovery. For example, antibiotics may act synergistically to produce prolonged paralysis, such as occurs when the peritoneal cavity is irrigated with an antibiotic solution or antibiotic is injected IV. Box 24.2 lists some antibiotics that can potentiate neuromuscular blockers.

Synergism also occurs with local and inhalation anesthetic agents. They are useful for patients on mechanical ventilators. Nondepolarizing blockers may be referred to as *competitive antagonists.* A peripheral nerve stimulator is useful for assessing neuromuscular transmission as a guide to the dosage, degree, and nature of the blockade, and evidence of muscle-response recovery during and after the use of nondepolarizing agents. The anesthesia provider can choose from several drugs.

• BOX 24.2 Antibiotics That Can Potentiate Neuromuscular Blocking Agents

Aminoglycosides
- Streptomycin
- Gentamicin
- Tobramycin
- Kanamycin
- Amikacin
- Netilmicin

Beta-Lactams
- Penicillin G
- Penicillin V
- Piperacillin

Miscellaneous Antibiotics
- Polymyxin A
- Polymyxin B
- Colistin
- Lincomycin
- Clindamycin
- Tetracycline

Short-Acting Neuromuscular Blocking Agents

- *Mivacurium (Mivacron):* Blockade lasts 15 to 20 minutes. It has minimal cardiovascular effect but can cause skin flushing.

Intermediate-Acting Neuromuscular Blocking Agents

- *Atracurium (Tracrium):* With a duration of action of about 30 minutes, atracurium metabolizes more quickly than the other blockers, which may be an advantage in patients with liver or renal disease. Repeated doses are not cumulative. Atracurium causes histamine release, vasodilation, and hypotension.
- *Cisatracurium (Nimbex):* Cisatracurium can cause bradycardia, hypotension, and skin flushing.
- *Vecuronium (Norcuron):* Similar to pancuronium, vecuronium has a shorter duration of action and is more potent. It does not noticeably increase the heart rate or blood pressure unless it is combined with opioids.
- *Rocuronium (Zemuron):* With a rapid onset of action, rocuronium facilitates intubation. The duration of action is about 30 minutes, with minimal overall effect on cardiovascular stability. Can be reversed with neostigmine. Tachycardia is possible. Rocuronium interacts with some antibiotics, including gentamicin, neomycin, and polymyxin B. Must be refrigerated.
- *Other:* Sugammadex (Bridion) is a selective neuromuscular reversal agent specifically for rocuronium, pancuronium, and vecuronium. It is a synthetic cyclodextrin that works by encapsulating the muscle relaxant to reverse paralytic effects.

Long-Acting Neuromuscular Blocking Agents

- *Tubocurarine (Curare):* Obtained from plants, tubocurarine was used centuries ago by South American Indians for poison arrows. The poison caused death by suffocation from respiratory paralysis. The effects of tubocurarine on the neuromuscular junction were first described in 1856.

  Blocking transmission of nerve impulses to muscle fibers results in paralysis, predominantly of voluntary muscles. Tubocurarine releases histamine. Autonomic blockade can cause vasodilation, hypotension, and histamine release. Tubocurarine is used as pretreatment if succinylcholine is used, to decrease the possibility of fasciculation.
- *Gallamine (Flaxedil):* Similar in action and duration to d-tubocurarine, gallamine does not cause hypotension or bronchospasm. It may increase arterial pressure and cause tachycardia. It is contraindicated in patients with iodide and sulfide allergies.
- *Metocurine (Metubine):* Metocurine iodide produces less hypotension and releases less histamine than d-tubocurarine. It is contraindicated in patients with known iodine allergy.
- *Pancuronium (Pavulon):* Pancuronium is similar in action to d-tubocurarine but about five times more potent. It has a

vagolytic action that may raise the blood pressure, pulse rate, and heart rate. It can cause dysrhythmia if used with digoxin.
- *Pipecuronium (Arduan):* Pipecuronium can cause decreased arterial pressure with moderate histamine release.

Depolarizing Neuromuscular Blockers. Depolarizing neuromuscular blockers have the opposite effect of the nondepolarizing drugs. They stimulate autonomic receptors. For example, they cause muscular fasciculation (i.e., involuntary muscle contractions). These contractions, the result of **depolarization** of the nerve-muscle end plate, are seen after injection. They are followed by fatigue. Drugs may be given IM, but IV use is more common.
- *Succinylcholine (Anectine, Quelicin, Sucostrin):* An ultrashort-acting synthetic drug with an onset of action in seconds, succinylcholine produces paralysis for up to 20 minutes. It is used primarily for endotracheal intubation. A dilute solution may be used to provide continuing muscle relaxation.

Repeated IV administration may effect changes in the heart rate and rhythm (i.e., bradycardia and ventricular dysrhythmias) until the drug is metabolized by enzymes. Muscle pain may occur after use unless fasciculation is prevented by a small preliminary dose of a nondepolarizing agent. Succinylcholine is contraindicated in patients with a known or suspected history of malignant hyperthermia. It can cause increased intracranial and intraocular pressures.
- *Decamethonium (Syncurine):* A very potent synthetic with a rapid onset and short duration of action, decamethonium is not cumulative and has little effect on vital systems. It is used for deep relaxation of a short duration, such as for endoscopy, treatment of laryngeal spasm, abdominal closure, and endotracheal intubation. It is excreted through the kidneys. Prolonged blockade may result if decamethonium is given to a patient in renal failure.

Muscle Relaxant Reversal Agents (Cholinergics)
- *Neostigmine (Prostigmin):* Neostigmine inhibits the destruction of acetylcholine released from parasympathetic nerves. It is used to reverse nondepolarizing neuromuscular blocking agents. Use with care in patients with bronchial asthma, bradycardia, seizure disorders, coronary artery disease, and hyperthyroidism. Monitor vital signs, particularly respirations, carefully, and have atropine close at hand. Neostigmine is not for use in patients with peritonitis or bowel or urinary obstruction.
- *Edrophonium (Tensilon):* Edrophonium works as a curare antagonist to reverse the nondepolarizing neuromuscular blocking action. It has a rapid onset, but short duration. It is contraindicated in bowel or urinary tract obstruction. Monitor vital signs, and have atropine immediately available.

Monitoring the Depth of General Anesthesia

The anesthesia provider monitors the level of anesthesia, balancing doses of medications, throughout the surgical procedure. The bispectral index (BIS) is a compact system for monitoring the effects of anesthesia on the brain. The BIS monitor allows the anesthesia provider to accurately track the patient's level of consciousness by using an electrode applied to the patient's forehead that sends EEG-like signals to a small monitor. The digital readout is a single number ranging from 100 (wide awake) to 0 (absence of brain activity).

The device can be used as a stand-alone unit or be integrated into other monitoring devices. The result of its use is decreased amounts of anesthetic administration and a faster postoperative return to alertness. The BIS monitor is not a substitute for clinical judgment and does not detect cerebral ischemia or blood pressure.

Emergence from General Anesthesia

The anesthesia provider attempts to have the patient as nearly awake as possible at the end of a surgical procedure. Pharyngeal and laryngeal reflexes must be recovered to prevent aspiration and respiratory obstruction. The degree of residual neuromuscular blockade must be determined and treated if necessary for respiratory adequacy. The action of nondepolarizing muscle relaxants may be reversed with antagonists, such as long-acting neostigmine (Prostigmin) or pyridostigmine (Regonol), or short-acting edrophonium (Tensilon, Enlon). These anticholinesterase drugs are accompanied or preceded by atropine to minimize side effects, such as excessive secretions and bradycardia.

Extubation is delayed until spontaneous respiration is ensured. The endotracheal tube is carefully removed when this maneuver is deemed safe. A patent airway and adequate manual or mechanical ventilation are maintained until full recovery. In the absence of a means of respiratory control, such as when a maxillofacial procedure endangers the airway, the endotracheal tube may be left in place.

Vomiting and restlessness may accompany emergence. Slight cyanosis, stertorous respiration, rigidity, and shivering are not uncommon as a result of a temporary disturbance of body temperature–regulating mechanisms, thus altering circulation to the skin and muscles. Administering oxygen and pain medication and applying warm blankets help relieve these after-effects. The anesthesia provider should flush the patient's lungs with oxygen to minimize exhalation of gases in the PACU.

Balanced Anesthesia

Balanced anesthesia has become a widely used technique to achieve physiologic homeostasis, analgesia, amnesia, and muscle relaxation. A combination of agents is used with many possible variations, depending on the condition of the patient and requirements of the procedure. The technique is especially useful for preventing CNS depression in older and high-risk patients.

Induction

Induction can be accomplished with a thiobarbiturate derivative (thiopental [Pentothal], methohexital [Brevital]), diazepam (Valium), midazolam (Versed), or other induction agent. Oxygen is administered in physiologic quantities. Neuromuscular blockers permit control of ventilation while providing muscle relaxation during intubation.

Maintenance

Different combinations of narcotics and neuroleptic drugs (tranquilizers) are administered IV, whether they are used alone or in combination with inhalation agents. Neuroleptics reduce motor activity and anxiety; produce a detached, apathetic state; and potentiate hypnotic and analgesic narcotic effects. The dosage can be regulated to produce the desired state.

Emergence

Residual effects of narcotics or muscle relaxants may require reversal by antagonists during and/or at the conclusion of the surgical procedure. Other precautions are taken as for any patient emerging from general anesthesia.

Controlled Homeostasis

Functions controlled by homeostatic mechanisms include body temperature, heartbeat, blood pressure, electrolyte balance, and

respiration. These parameters may be altered by anesthetic and other pharmacologic agents and by physiologic stresses during surgical manipulations. In the hands of a skilled anesthesia provider, adjunctive methods of control may be used concurrently with the administration of general anesthesia, but only when the expected outcomes will outweigh the inherent risks.

Induced Hypothermia

Hypothermia is an artificial, deliberate lowering of body temperature below the normal limits (Box 24.3). It reduces the metabolic rate and oxygen needs of the tissues in conditions causing hypoxia or during a decrease or interruption of circulation. Bleeding is also decreased, and less anesthetic is needed. The patient can therefore better tolerate the surgical procedure.

Hypothermia may be used as follows:

- For direct-vision intracardiac repair of complex congenital defects in infants and in other cardiac procedures (most common usage)
- After cardiac resuscitation, to decrease oxygen requirements of vital tissues and limit further damage to the brain after **anoxia**
- In treatment of hyperpyrexia and some other nonsurgical conditions, such as hypertensive crisis
- To increase tolerance in septic shock
- In neurosurgery, to decrease cerebral blood flow, CSF volume, and venous and intracranial pressures
- To aid in transplantation of organs

Attaining Hypothermia. To achieve hypothermia, heat must be lost more rapidly than it is produced. The following methods may be used:

- *Surface-induced hypothermia:* External cooling of infants and small children weighing less than 20 lbs (10 kg) may be attained by immersion in ice water, packing the body in ice, or alcohol sponging. A hypothermia/hyperthermia machine with a cooling blanket or mattress is used for adults and larger children.
- *Internal cooling:* A decreased or interruption of blood flow can be achieved by placing sterile iced saline slush packs around a specific internal organ or irrigation of cold fluids within a body cavity, such as intraperitoneal lavage. The cold cardioplegia technique combines cold from saline slush with drugs injected into coronary arteries for myocardial protection during heart surgery. Drugs may be used to lower metabolism and increase resistance to shivering during cooling.
- *Systemic hypothermia:* The bloodstream is cooled by diverting blood through heat-exchanging devices of extracorporeal circulation and returning it to the body by a continuous flowing circuit (e.g., core cooling by cardiopulmonary bypass or IV administration of cold fluids). Systemic hypothermia is used in adults and larger children to 78.8° F (26° C). Oxygen consumption and metabolism of different organs vary, making uniform hypothermia impossible.

• BOX 24.3 Hypothermia

- Normal core temperature: 98.2° F to 99.9° F (36.8° C to 37.7° C)
- Systemic hypothermia may be:
  - Light: 98.6° F to 89.6° F (37° C to 32° C)
  - Moderate: 89.6° F to 78.8° F (32° C to 26° C)
  - Deep: 78.8° F to 68° F (26° C to 20° C)
  - Profound: 68° F (20° C) or below
  - Sensorium fades at: 91° F to 93° F (32.8° C to 33.9° C)

The temperature is not deliberately lowered below about 84.5° F (29° C) unless arrest of the heart is desired by means of deep hypothermia (below 78.8° F [26° C]). This is accompanied by perfusion of the rest of the body with the extracorporeal circulation method, permitting an open, motionless dry field while the blood flow is interrupted. A noncontracting heart requires very little oxygen.

The patient is progressively rewarmed at the close of the surgical procedure until the temperature is 95° F (35° C) or until consciousness returns. Sometimes a degree of hypothermia is maintained for a day or two postoperatively to allow the patient to adapt more readily. Oxygen therapy and intubation, if advised, are part of postoperative care.

Complications in the Use of Hypothermia. Hypothermia carries many inherent risks. Primarily it affects the myocardium, decreasing its resistance to ventricular fibrillation and predisposing the patient to cardiac arrest. This is more likely to happen with deep hypothermia or during manipulation of the heart itself. Other dangers are heart block, effects on the vascular system, atrial fibrillation, embolism, microcirculation stasis, undesired downward drift of temperature, tissue damage, metabolic acidosis, and numerous effects on other organs and systems.

Time is required for cooling and rewarming. Shivering and vasoconstriction, normal defenses of the body against cooling, can be problems during the use of hypothermia. This muscle activity greatly increases oxygen needs. Shivering can be overcome by the administration of a muscle relaxant drug, IV injection of chlorpromazine, or an analgesic such as meperidine.

Rewarming can be accomplished by circulating warmed blood by means of extracorporeal circulation or by using a heating mattress with circulating fluid and warm blankets. If external heat is applied, care should be taken not to burn the patient. Rewarming carries potential problems such as reactive bleeding or circulatory collapse. If the patient is rewarmed too rapidly, vasodilation causes the blood pressure to drop. Organ ischemia can occur from severe shivering. These superficial and systemic events impair perfusion (oxygenation) of tissues. "Rewarming shock" may be prevented by slow warming, adequate oxygenation, and prevention of massive sudden vasodilation or vasoconstriction associated with shivering.

Induced Hypotension

Induced, deliberate hypotension is the controlled lowering of arterial blood pressure during anesthesia as an adjunct to the surgical procedure. Hypotensive anesthesia is used to shorten the operating time, reduce blood loss and the need for transfusion, and facilitate dissection and visibility, especially of tumor margins in radical procedures. Visible vessels are ligated, even in the absence of active bleeding.

Adequate oxygenation of blood and tissue perfusion in vital organs (heart, liver, kidneys, lungs) and in the cerebrum must be maintained to prevent damage. The degree and duration of hypotension must be carefully controlled so the state can be rapidly terminated at any time.

Naturally, controlled hypotension is not indicated as a routine procedure. It is used only when the expected gain for a particular patient requiring a specific surgical procedure outweighs the risks. Hypotension may be specifically induced for the following:

- Surgical procedures in which excessive blood loss is anticipated, such as spinal surgery, to decrease gross hemorrhage or venous oozing.
- Surgical procedures on the head, face, neck, and upper thorax, especially radical dissection, in which the position of the

patient allows blood to pool in dependent areas and reduces venous return to the heart and cardiac output.
- Neurosurgical procedures when control of intracranial vessel hemorrhage may be difficult. It reduces leakage, makes an aneurysm less turgid and prone to rupture, decreases blood loss in the case of rupture, and facilitates placement of ligating clips.
- Surgical procedures in which blood transfusions should be avoided, such as when compatible blood is unavailable or transfusion is against the patient's religious belief.
- Surgical procedures on the spine or posterior torso. Blood loss is decreased in the prone position.
- Total hip replacement.

Attaining Hypotension. Several techniques will produce hypotension. The blood pressure may be lowered chemically by direct arterial or venous dilators or by ganglionic blocking drugs. Perfusion pressure drops in proportion to a decrease in vascular flow resistance, but adequate tissue blood flow exists.

Fine adjustment of the desired level of hypotension can be achieved by mechanical maneuvers—namely, alterations in body position or changes in airway pressure, control of the heart rate or blood volume, or addition of other vasoactive drugs in conjunction with hypotensive drugs. Properly used, these maneuvers can reduce the total dose of potentially toxic drugs needed for maintenance of hypotension.

Methods to produce hypotension include:
1. Deep general anesthesia with halothane or isoflurane, followed by a vasodilator, produces the desired minute-to-minute effect. With increased concentration, halogenated agents produce hypotension as a result of myocardial and peripheral vascular depression.
2. Sodium nitroprusside is a potent, fast-acting vasodilator that reduces virtually all resistance in vascular smooth muscle (resistance vessels). It also reduces preload and afterload of the heart and pulmonary vascular resistance. To achieve safe arterial pressure control, administration is via a calibrated drug pump. The acid-base status and blood cyanide level are determined frequently to guard against metabolic acidosis and nitroprusside-induced cyanide and thiocyanate toxicity.
3. Nitroglycerin, primarily a vasodilator, directly dilates capacitance vessels. It reduces preload and improves myocardial perfusion during diastole—a protection against potential ischemia. Nitroglycerin for IV infusion (Nitrostat), after dilution in 5% dextrose or physiologic saline, dilates both venous and arterial beds. Arterial pressures are reduced. Nitroglycerin migrates into plastic. To avoid its absorption into plastic parenteral solution containers, dilution and storage are done in glass parenteral solution bottles. A special nonabsorbing infusion set prevents loss of nitroglycerin.
4. Trimethaphan (Arfonad) blocks sympathetic ganglia, which results in relaxation of resistance and capacitance vessels and reduces arterial pressure.
5. Fentanyl may be used as a basal anesthetic for hypotension. The blood pressure can be maintained at the desired level by the addition of a small amount of a volatile agent. Fentanyl lowers arterial pressure; volatile agents reduce cardiac output.
6. Other drugs such as verapamil, nifedipine, phentolamine, tetrodotoxin, or adenosine triphosphate may be used.

Safe lower limits of arterial pressure may vary. Mean systolic value is 50 mm Hg and values range between 65 and 70 mm Hg, with lower values for short periods only.

Precautions in the Use of Hypotension. Potential complications of hypotensive anesthesia include cerebral or coronary ischemia or thrombosis, reactionary hemorrhage, anuria in acute renal failure, delayed awakening, and dermal ischemic lesions. Primary contraindications are vascular compromise to any vital organ system or the brain. Precautions include the following:
- Careful selection of the patient
- Preoperative cardiac, renal, and hepatic evaluation of the patient to avoid circulatory insufficiency in vital organs
- Selection of an appropriate but not arbitrary level of blood pressure
- Administration and evaluation by expert anesthesia providers
- Use for only a short time and lowering of blood pressure only enough to obtain the desired result
- Maintenance of blood volume at an optimal level by continuous infusion
- Controlled ventilation with adequate oxygenation via an endotracheal tube, because hypotension increases susceptibility to hypoxia
- Extensive monitoring: ECG, core temperature, esophageal stethoscopy, urinary output, central venous pressure and arterial catheters, and electrophysiologic brain monitoring or EEG via BIS monitoring

Normovolemic Hemodilution Technique

Intraoperative normovolemic hemodilution has been used in cardiac surgery for several decades but more recently as an adjunct technique in major surgery when large blood loss is anticipated. It is especially useful in infants and children and in patients who, for religious or personal reasons, do not accept administration of blood products.

At the beginning of the surgical procedure, whole blood is withdrawn from the patient to a hematocrit of 14% to 15% and replaced with three times the volume of a balanced electrolyte solution to maintain intravascular volume. This diluted blood is transparent, giving the surgeon a clearer, almost bloodless field. This may decrease operating time. The patient is maintained under controlled hypotension with halothane anesthetic and a supplemental narcotic. The body temperature may be lowered to 89.6° F (32° C) or below for moderate hypothermia to help protect vital organs against hypoxia and hypotension.

After significant blood loss has ceased, the patient's own blood is reinfused. Diuresis is stimulated to remove electrolyte solution. Normovolemic hemodilution can make a difficult surgical procedure easier and in some patients makes an otherwise impossible resection possible.

Care of the Anesthetized Patient

Anesthetic agents and drugs vary in potency. Therefore they differ in the amount of analgesia, amnesia, or muscle relaxation produced. Each patient's ability to detoxify anesthetic agents and to tolerate physiologic stress differs. Impairment of pulmonary function accompanies general anesthesia to some degree. General anesthesia is usually more complicated than local or regional anesthesia.

Considerations

The anesthesia provider keeps the surgeon informed of significant physiologic changes detected by monitoring vital functions. The following should be considered:
1. A deficit in pulmonary and/or cardiac functions is detrimental to the patient's physiologic status. Abnormalities of pulmonary

ventilation and diffusion influence the course of anesthesia and diminish tolerance to stress or the insults from the anesthetic and the procedure.
   a. Respiratory patterns vary from breath holding and apnea to deep breathing and **tachypnea**.
   b. Drug action affecting respiratory stimulation or depression is related to changes in oxygen tension ($\mathbf{Pao_2}$) or arterial carbon dioxide tension ($\mathbf{Paco_2}$).
   c. Hypoxia, anemia, and decreased cardiac output may produce inadequate tissue oxygenation. Subnormal cardiac reserve or oxygen-transporting ability, combined with anemia or hypoxia in an arteriosclerotic patient, for example, can be lethal.
2. Circulation is affected both centrally and peripherally. Individual agents are associated with characteristic hemodynamic patterns. Generally, the agents are circulatory depressants that reduce arterial pressure, myocardial contractility, and cardiac output.
3. The liver is affected by general agents (e.g., the rate of visceral blood flow). Alterations in liver function tests may follow anesthesia. Halogenated hydrocarbons have been associated with hepatotoxicity. The liver metabolizes many anesthetic agents and other medications.
4. Kidney function is affected by disturbances in systemic circulation, because kidneys normally receive 20% to 25% of the cardiac output. A reduced renal plasma flow and glomerular filtration rate depress renal functions related to hemodynamics and to water and electrolyte excretion.

   Oliguria, with reduced sodium and potassium excretion, accompanies induction. Postoperative fluid retention may result from a reduction in urine volume from anesthesia, intraoperative trauma, and the use of narcotics. In the absence of renal disease, changes in renal function are usually transitory and reversible. Endocrine effects on renal function during anesthesia are important. Many drugs and agents are excreted by the kidneys.
5. Biotransformation of agents varies with metabolites excreted by the kidneys. Urinary excretion of IV agents may be slow and unpredictable. Studies indicate that nitrous oxide may be exhaled as long as 56 hours after anesthesia, and metabolites of halothane have been recovered from patients' urine as long as 20 days after anesthesia.
6. Agents may cause nausea, emesis, or systemic complications.

General anesthesia may be contraindicated for the following:

- Elective procedures on patients who are medically at high risk or severely debilitated.
- Elective procedures during the first 5 months of pregnancy. Some anesthesia providers avoid general anesthesia because of unknown teratogenic effects of inhalation anesthetics.
- Emergency surgical procedures on patients who have recently ingested food or fluids. Gastric suction and awake intubation are indicated if the surgical procedure cannot be delayed.

Intraoperative Awareness

Although seemingly anesthetized, the patient may be aware of conversations, noises, and even pain. Is it possible to imagine anything more terrifying than to feel intraoperative maneuvers but be unable to communicate this discomfort? Intraoperative awareness varies, depending on the type of procedure and depth of anesthesia. Monitoring techniques, such as BIS monitoring, may decrease the incidence of intraoperative awareness.

The common use of narcotics and muscle relaxants as adjuncts has consequently decreased the amount of anesthetic used to induce and maintain unconsciousness. This is particularly true in balanced anesthesia. As a result, studies have shown evidence of intraoperative awareness (i.e., recall), consciously or unconsciously, of events and sounds during a state of anesthesia. Even though the patient may not consciously recall or remember the experience, unconsciously it may affect behavior and attitudes postoperatively. Subconscious memory may cause anger, generalized irritability, anxiety, repetitive nightmares, preoccupation with death, or physiologic complications.

Patient awareness of pain is rare in the hands of skilled anesthesia providers. However, hearing is the last sensation to surrender to anesthesia. Therefore perioperative caregivers should be constantly aware of the patient's vulnerability to auditory stimuli, including conversations and room noise. Even potent amnesic drugs may not totally block recall of stimuli, especially disturbing stimuli.

Safety Factors

Team members, especially the anesthesia provider and the circulating nurse, must be constantly aware of potential trauma to the patient, because he or she is unable to produce a normal response to painful or injurious stimuli. The circulating nurse assists the anesthesia provider during the extubation of the patient at the conclusion of the surgical procedure. Although safety factors are stressed throughout the text, important factors in the care of the anesthetized patient are reiterated here for emphasis:

1. The patient's position is changed slowly and gently to allow circulation to readjust (i.e., to compensate for physiologic changes caused by motion or position).
2. Proper positioning and padding are important to avoid pressure points, stretching of nerves, or interference with circulation to an extremity.
3. The patient's chest must be free for adequate respiratory excursion during the surgical procedure. The airway must be patent. Leaning on the patient during the procedure can cause permanent injury.
4. The lungs must be adequately ventilated intraoperatively and postoperatively by either voluntary or mechanical means. Anesthetic agents are basically depressants that affect the vasomotor and respiratory centers, predisposing the patient to postoperative respiratory complications.
5. The anesthesia provider assesses the patient and assists in transferring the patient to a stretcher or bed, safeguarding the head and neck, when it is safe to move the patient. The anesthesia provider calls the count and initiates the move from operating bed to transport cart. The transfer is made carefully and gently to avoid strain on ligaments or muscles of the patient and the caregivers. The relaxed, unconscious patient is adequately supported.
6. The anesthesia provider gives the PACU nurse a verbal report, including specific problems in regard to this patient, and completes records before the transfer of responsibility. The circulating nurse gives a report of preoperative baselines and intraoperative care to the PACU nurse. The PACU hand-over exchange report is described in detail in Chapter 30.

Care of General Anesthesia Equipment

The anesthesia equipment is a potential vector in the spread of infection. The anesthesia provider may become the victim of an acquired infection from contact with a patient's body fluids or blood. Studies have found that nearly 20% of anesthesia providers have had hepatitis B infections. The AANA provides guidelines for infection prevention. (More information can be found at www.aana.com)

Standard Precautions

The need for anesthesia staff to strictly adhere to standard precautions while caring for patients and equipment should be emphasized. Gloves should be worn to prevent skin contact with the patient's blood and body fluids, such as when starting the IV infusion, when intubating and/or extubating, or when suctioning the patient. Soiled gloves should not be worn to open cabinets or press buttons on the monitor.

Protective eyewear should be worn. Hands should be washed when removing gloves and the mask should be changed between patient contacts. Needles must be handled carefully without recapping to avoid accidental needlesticks. All anesthesia equipment that has come in contact with mucous membranes, blood, or body fluids is cleaned, disinfected, or sterilized after use to render it safe for handling and for subsequent patient use. Disposable items are discarded in the appropriate receptacles.

Hazards of Equipment

Anesthesia techniques encompass the use of drugs for parenteral administration and gases and volatile liquids for inhalation administration by means of anesthesia machines. These machines and their component parts (reservoir bags, canisters, connecting pieces, ventilators) accumulate large numbers of microorganisms during use. Consequently, the parts that come in contact with the patient's skin or respiratory tract are sources of cross-contamination.

Inhalation, exhalation, and the forcible expulsion of secretions create moist conditions favorable to the survival and growth of a multitude of organisms (streptococci, staphylococci, coliform bacteria, fungi, yeasts). Therefore the anesthesia circuit can become a veritable reservoir for microorganisms and a pathway for transmission of disease. When the apparatus is used on a patient with a known respiratory disease, such as tuberculosis, the risk increases.

All used accessories must be terminally cleaned and either undergo high-level disinfection or sterilization before reuse because clinical respiratory cross-infection has been traced to contaminated apparatus. Valves of the breathing circuit become contaminated from essentially healthy patients at an average rate of 35 organisms per minute. *Pseudomonas aeruginosa* has been cultured from carbon dioxide absorption devices. Many microorganisms accumulate in valves and air passages and in soda lime canisters. Although the alkalinity of soda lime inhibits many organisms, it is neither a dependable germicide nor an effective mechanical filter nor is it meant to be one. Respiratory therapy equipment, mechanical ventilators, resuscitators, and suction machines and bottles present the same problems.

Resistant strains of organisms, as well as opportunists, have caused health care–associated infections. Patient-to-patient infection must be eliminated. The following are points to remember:

- The patient's respiratory tract is a portal of entry for pathogenic organisms and a source of delivering pathogens into the environment.
- The respiratory tract loses some of its inherent defense mechanisms during anesthesia.
- Aseptic precautions are necessary to prevent needless exposure of air passages to foreign, potentially pathogenic organisms from equipment and hands of anesthesia personnel.
- Anesthesia machines and equipment, unless properly treated, increase the danger of airborne contamination and contact transmission of pathogenic microorganisms capable of causing postoperative wound infections and systemic infections.

In the presence of tuberculosis or a virulent respiratory infection, the anesthesia provider should wear a gown and strictly adhere to standard precautions. Some contacts require donning a mask with high-efficiency particulate air (HEPA) filters. The patient should wear a mask during transportation and until induction of anesthesia.

Disposable Equipment

Disposable equipment warrants use for reasons of safety, efficiency, and convenience. Presterilized, disposable airways, endotracheal tubes, tracheotomy tubes, breathing circuits, masks and canisters (with soda lime sealed in the plastic), and spinal trays reduce the hazard of cross-infection. They are especially recommended for the compromised host and the bacteriologically contaminated patient. Single-use components of the anesthesia system are discarded after use. Needles are disposed of in puncture-resistant containers. Needleless syringes that attach into infusion sets should be used when possible to reduce the risk for needlesticks.

Care of Reusable Equipment

All parts of patient-exposed, reusable equipment must be thoroughly cleaned after every use to prevent pulmonary complications. Thorough cleaning to remove organic debris and drying must precede any high-level disinfection or sterilization process. All items that can be sterilized should be sterilized. Manufacturers strive to make the machines that cannot be sterilized more amenable to adequate terminal cleaning and freedom from microorganisms. The following points also should be considered:

1. The anesthesia machine should be disinfected immediately whenever it is soiled by blood and secretions.
2. The surfaces of anesthesia machines, carts, or cabinets should be disinfected after each patient use. The specific work area used for airways, endotracheal tubes, and other items should also be cleaned. The top of a cart or tray should be draped with a disposable impervious material that is changed between patients. All equipment for maintenance of the airway should be set up on and returned to this drape.

   Disposable items should be discarded in suitable containers after use. Reusable equipment must be set aside after use for terminal cleaning and testing, thereby diminishing the risk for contaminating clean equipment needed for subsequent patients. A biohazard disposal container should be placed by the anesthesia machine.
3. Monitoring equipment, including ECG and other electrodes and blood pressure cuffs, should be cleaned with a detergent-disinfectant when contaminated and preferably after each use.
4. All equipment that comes in contact with mucous membranes of the patient and the inside of the breathing circuit must be terminally cleaned and sterilized, preferably, or undergo high-level disinfection:
   a. Endotracheal tubes, stylets, airways, laryngoscope blades, facemasks, and suction equipment should be sterile for each patient. Suction catheters and tubing should be sterile, single-use disposable items.
   b. Disposable breathing circuits are preferred to reusable equipment because of the complexities of cleaning and maintaining cleanliness. The interior of reusable breathing circuits remains sterile if they stand unused in their normal position on the machine, but contamination rapidly occurs when the circuits are used on patients. The parts of the

circuit nearest the patient are the most heavily contaminated. Therefore reusable corrugated hoses, breathing tubes, and reservoir bags are sterilized or undergo high-level disinfection between each patient use.

c. Items located farther away, such as circle systems and ventilators, are cleaned and sterilized according to a regular schedule—at least once or twice a month.

5. For cleaning, an automated process is available for decontamination. Machines wash equipment in mild detergent and hot water, and rinse and dry it. Some machines incorporate a chemical disinfection cycle. If automatic equipment is not used, anesthesia and respiratory therapy equipment must be disconnected and manually cleaned before sterilization. Prompt immersion in a detergent-disinfectant solution prevents crusting of secretions. Tubing takes a long time to dry. Commercial dryers are available.
6. Sterilization methods:
   a. Steam is the preferred method for all heat-stable materials.
   b. Ethylene oxide is used for materials that are deteriorated by heat, such as rubber, plastics, mechanical ventilators, and electronic equipment. Thorough aeration, according to the manufacturer's recommendations, is necessary before use to remove all residual gas from the material sterilized. Otherwise, facial burns, laryngotracheal inflammation, and obstruction or bilateral vocal cord paralysis may be caused by use of the equipment.
   c. Buffered glutaraldehyde solution does not impair conductivity of antistatic rubber. Although its use is the least convenient method, it is preferred if ethylene oxide is not available for heat-sensitive items.

      The manufacturer's recommendations should be followed for a 100% kill of *Mycobacterium tuberculosis* by immersion methods. When glutaraldehyde is used, the items must be thoroughly rinsed with sterile water because tap water contains microorganisms.
7. Sterile packaged equipment should be stored in a closed, clean, and dry area. Anesthesia and respiratory therapy equipment should be kept sterile until used.
8. Policies and procedures regarding processing of equipment should be written, available, and reviewed annually.

Checking Anesthesia Equipment

Inhalation systems are tested biologically at regular intervals and checked daily for proper functioning. Preventive maintenance is essential to avoid mechanical failures, which could be fatal. Goals for quality control are to ensure that equipment is available and that it performs reliably when needed. The anesthesia machine and its components should be checked and serviced only by qualified personnel.

Local and Regional Anesthesia

Local and regional anesthetic techniques are used to decrease intraoperative stimuli, thereby diminishing stress response to surgical trauma. Injected at or near the nerves of the surgical site, the anesthetic drug temporarily interrupts sensory nerve impulses during manipulation of sensitive tissues.

When a local anesthetic drug is used, the patient usually remains conscious. Local infiltration anesthesia is particularly advantageous for procedures performed in ambulatory surgery settings from which the patient is discharged to home soon after completion of the procedure. Oral, IM, or IV sedation may be given to relieve anxiety and produce amnesia. IV sedation is commonly used and is referred to as *moderate sedation.*

Anesthetic may be administered locally during general anesthesia for postoperative pain control. When injected before the incision is made, the patient's nervous system is preempted from sensory stimulation associated with the initial trauma of incision. Some surgeons elect to inject **local anesthesia** drugs before the skin is closed for additional delay of sensory stimulation associated with postoperative pain.

Regional blocks are useful for more extensive procedures. **Regional anesthesia** may be used, with or without moderate sedation, when general anesthesia is contraindicated or undesired.[2] **Nerve blocks**, intrathecal blocks, peridural blocks, and epidural blocks are examples of regional anesthesia techniques. These techniques block conduction of pain impulses from a specific area or region. The anesthetic drug is injected around a specific nerve or group of nerves to prevent pain of the surgical procedure.

Local anesthetics and regional blocks, with or without supplementary sedation, are administered as the anesthetic of choice for many diagnostic and therapeutic surgical procedures.

Preparation of the Patient

Preparation of the patient who will receive a local or regional anesthetic depends on the extent of the procedure to be performed and on the anticipated technique of administration.[3] Although it is anticipated that the patient will remain conscious, it is sometimes desirable or necessary to supplement the local or regional anesthesia with moderate sedation. Careful preoperative assessment, history taking, and a clear explanation of what to expect are part of the preparatory process.

Preoperative assessment of the patient who is scheduled for a procedure provides baseline data and identifies risk factors.[4] Data that should be documented include the following:

- Baseline vital signs, blood pressure, laboratory values, and results of ECG monitoring and any other tests that were performed.
- Weight, height, and age; dosage of some drugs is calculated on the basis of body weight in kilograms (milligrams per kilograms of body weight). Some drugs are contraindicated for age extremes (i.e., pediatric or geriatric patients).
- Current medical problem(s) and history of medical events, including a history of substance abuse.
- Current medications or drug therapy, such as insulin for diabetes or hypertensive drugs.
- Allergy or hypersensitivity reactions to previous anesthetics or other drugs.
- Mental status, including emotional state and level of consciousness.
- Communication ability; a patient with hearing impairment or language barrier may be unable to understand verbal instructions during the procedure or respond appropriately.

Preoperative orders regarding the time when the patient should cease taking anything by mouth vary with the circumstances; 6 to 8 hours before the surgical procedure is the usual minimum for adults and children older than 1 year. If possible, the adult patient is instructed to remain on nothing-by-mouth (nil per os [NPO]) status after midnight. Some patients are permitted a few sips of water to take oral medications, such as hypoglycemics or antihypertensives. Other individualized plans for NPO time is considered based on the time of the surgical procedure, patient status, nutritional and medication needs.

Children younger than 1 year should be NPO for at least 2 hours if they have been on clear fluid. Breastfeeding infants should be NPO for 4 hours. Formula-fed babies should be NPO for 6 hours.

Many ambulatory surgical patients scheduled for same-day procedures have no premedication and are permitted to walk to the OR. Some facilities require the use of a cart or wheelchair for transport. The patient should be transported via cart if sedated.

Intraoperative Patient Care

The patient must be able to respond cooperatively and maintain respiration unassisted. The patient needs careful observation throughout the surgical procedure and for a period afterward for signs and symptoms of delayed reaction or complications. The care the patient will need depends on the type and length of the procedure, the amount of sedation given, and the type and amount of local anesthetic used. Psychologic support and reassurance are given before and during the surgical procedure. The patient should be told what to expect and what is expected of him or her. The patient should be monitored by qualified personnel and observed for adverse effects of the medication or the procedure.

Local Anesthesia

The surgeon injects the anesthetic drug or applies it topically. The anesthesia provider is not in attendance for this method. Supplemental agents should be available for analgesia or anesthesia, if necessary, or for adverse reactions (Table 24.3). Resuscitative equipment, suction, and oxygen must be at hand before administration of any anesthetic. Qualified personnel should be immediately available to assist in the event of an emergency.

Administration of Local Anesthesia

In the absence of an anesthesia provider, a qualified registered nurse (RN) is responsible for monitoring the patient's physiologic status and safety during local anesthesia. This should be the only activity assigned to this perioperative nurse for the duration of the procedure. Circulating duties should not be done simultaneously.

The perioperative nurse who assumes the responsibility for patient monitoring should have the knowledge, skill, and ability to use and interpret data from monitoring equipment. The nurse also should be able to recognize signs and symptoms of abnormal reactions to local anesthetic drugs and provide interventions to prevent further complications.

The patient who is under local anesthesia requires observation of physiologic changes in pulse, blood pressure, oxygenation, and respiration. Baseline data obtained during preoperative assessment are compared with intraoperative and postoperative findings. The vital signs, including blood pressure, pulse, and respirations, are continuously monitored. Monitoring devices may include an electrocardiograph and pulse oximeter. Monitoring equipment is used to assess the patient's physiologic status in combination with direct observation.

Data from monitoring and direct observation are documented at frequent intervals, (preferably every 5 minutes) and with any significant event, such as the injection of medication or the removal of a specimen. The patient is monitored for reaction to drugs and for behavioral and physiologic changes. It is important for the perioperative nurse to be aware of the maximum dosages of local anesthetics in milligrams per kilogram of body weight.

The total amount of anesthetic and supplementary drugs administered is also recorded in the patient's record. AORN (The Association of periOperative Registered Nurses) has established recommended practices for the care of patients receiving local anesthesia. Policies and procedures should be in place to delineate patient care, monitoring activities, and documentation during the use of local anesthetics.

Moderate Sedation

During procedures performed with the patient under local anesthesia, mild sedation may be given by IV infusion. Moderate sedation refers to a mild to moderate depressed level of consciousness

TABLE 24.3 Comparison of Toxicity and Allergy Caused by Local Anesthetic Drugs

Toxic Reaction	Allergic Reaction[a]
Symptoms vary depending on the drug	Immediate localized reaction followed by generalized body reaction
Subjective	
Dizziness, somnolence, paresthesia, nausea, visual/speech problems	Sense of uneasiness, pruritus, agitation, paresthesia
Objective	
Decreased breathing rate and depth, muscle twitches, tremors, slurred speech, seizures, vomiting, unconsciousness, coma	Erythema, urticaria, wheals
Vasovagal	
Dysrhythmias, bradycardia, vasodilation, hypotension, myocardial depression, cardiac arrest	Coughing, wheezing, bronchospasm, hypotension, hypovolemia, vasodilation, cardiovascular collapse, cardiac arrest
Treatment	
Supportive airway management; need intravenous (IV) line; Trendelenburg's position; muscular contractions are treated with diazepam (Valium)	Especially with amino ester type: airway management, IV fluids, epinephrine, diphenhydramine, and steroids as needed

[a]Not common with amino amide.

that allows the patient to maintain a patent airway independently and respond appropriately to verbal instructions or physical stimulation. A benzodiazepine, such as midazolam (Versed) or diazepam (Valium), is most commonly given either alone or in combination with a narcotic and atropine or scopolamine. Benzodiazepines provide amnesia with sedation, but they also may cause respiratory depression and fluctuations in blood pressure and heart rate and rhythm.

All team members need to understand the objectives and desired effects of moderate sedation. If the primary objective is to allay the patient's anxiety and fear, the therapeutic effects of the drugs given should produce relaxation and some degree of amnesia. Because consciousness is maintained, the patient has intact protective reflexes to respond to physical stimuli. The patient also can be easily aroused with verbal commands as necessary. In this state, vital signs may fluctuate to a minimal extent. Documentation in the patient's record should reflect evidence of continuous assessment and identification of any untoward or significant reactions during administration of local anesthesia with moderate sedation.

The Perioperative Nurse's Role During Local Anesthesia and Moderate Sedation

The patient under moderate sedation should be monitored continuously for cardiac status, blood pressure, pulse, respiration, and oxygen saturation. Monitoring devices may include, but are not limited to, an ECG and pulse oximeter. In the absence of an anesthesia provider, a qualified RN should be assigned to monitor the patient's physiologic state. This nurse should not be assigned to simultaneously circulate and should be competent in the use and interpretation of monitoring devices.

An anesthesia provider should be in attendance to monitor those patients whose physiologic status is unstable. Policies and procedures should be in place that address the RN's competency in patient monitoring and the nurse's role during the use of moderate sedation.

Monitored Anesthesia Care

When an anesthesia provider's presence is necessary, the surgical procedure is scheduled as monitored anesthesia care (MAC), attended local, or anesthesia standby. Terminology may vary at different institutions. Patients with particular medical problems or age-extreme patients (pediatric or geriatric) may require supervision by anesthesia personnel.

Patients receiving a local anesthetic because they are too ill to undergo general anesthesia should have an anesthesia provider in attendance. The type and length of procedure also may be factors that influence the surgeon's request for an anesthesia provider to be available to give and monitor moderate sedation. The anesthesia provider may initiate and maintain a regional nerve block, such as an axillary brachial plexus block for hand surgery. Moderate sedation and regional blocks with MAC have gained popularity for ambulatory surgery.

Monitoring the Patient Receiving a Local Anesthetic

The extent of monitoring, determined in consultation with physicians in the department of surgery and anesthesiology where applicable, depends on the seriousness of the procedure, sedation required, and/or patient's condition. The perioperative nurse assigned to monitor the patient receiving a local anesthetic, with or without moderate sedation, continuously attends the patient. This nurse does not have other responsibilities during the surgical procedure. *AORN Guidelines for Perioperative Practice* provides guidance for the perioperative nurse in monitoring the patient receiving a local anesthetic and the patient receiving moderate sedation. The guidelines may be summarized briefly as follows:

1. The patient is monitored for reaction to drugs and for behavioral and physiologic changes. The circulating nurse should recognize and report to the physician significant changes in the patient's status and be prepared to initiate appropriate interventions.
2. The nurse attending the patient should have basic knowledge of the function and use of monitoring equipment, ability to interpret information, and working knowledge of resuscitation equipment. The nurse should have appropriate training and knowledge in pharmacology and the application of the drugs used in the patient's care.
3. Accurate reflection of perioperative care should be documented on the patient's record.
4. Institutional policies and procedures in regard to patient care, including monitoring, should be written, reviewed annually, and readily available. This information should be included in orientation and inservice programs. It should include policies regarding permissible drug administration and emergency interventions by the nurse.

In addition to preoperative assessment and postoperative evaluation for a continuum of care, intraoperative activities include determining and documenting the patient's baseline physiologic status before administration of sedatives, analgesics, and anesthetic drugs and monitoring the patient throughout the procedure. Parameters include but are not limited to the following[5]:

- Blood pressure
- Heart rate and rhythm
- Respiratory rate
- Oxygen saturation by pulse oximetry
- Body temperature
- Skin condition and color
- Mental status and level of consciousness

Baseline vital signs are taken when the patient arrives in the OR. These are compared with admission vital signs. Vital signs are taken continually before injection of a drug and at 5 to 15-minute intervals after injection. Changes in the patient's condition are reported to the surgeon immediately. If an adverse reaction occurs, emergency measures should be instituted on request as per policy. These may include maintaining a patent airway, starting oxygen therapy when clinically indicated, and administering IV therapy per the physician's order.

Considerations in the Selection of Local Anesthetics

A local anesthetic depresses superficial peripheral nerves and blocks conduction of pain impulses from their site of origin. Regional nerve blocks interrupt conduction of pain impulses from a specific area or region. These techniques may be employed, with or without moderate sedation, when general anesthesia is contraindicated. As with any anesthetic agent, local anesthetics offer advantages in some circumstances but have disadvantages and are contraindicated in others.

Advantages

- Use of local anesthetic agents can minimize the recovery period. The patient can ambulate, eat, void, and resume normal activity.
- Use of local anesthetic requires minimal equipment and is economical.
- Loss of consciousness does not occur unless anesthesia is supplemented with additional drugs.

- Local anesthesia avoids the undesirable effects of general anesthesia.
- Local anesthesia is suitable for patients who recently ingested food or fluids (e.g., before an emergency procedure).
- Local anesthesia is useful for ambulatory patients having minor procedures.
- Local anesthesia is ideal for procedures in which it is desirable to have the patient awake and cooperative.

Disadvantages

- Local anesthesia is not practical for all types of procedures. For example, too much drug would be needed for some major surgical procedures; the duration of anesthesia is insufficient for others.
- There are individual variations in response to local anesthetic drugs.
- Rapid absorption of the drug into the bloodstream can cause severe, potentially fatal reactions.
- Apprehension may be increased by the patient's ability to see and hear. Some patients prefer to be unconscious and unaware.
- Local anesthesia is generally contraindicated in patients with the following:
  - Allergic sensitivity to the local anesthetic drug.
  - Local infection or malignancy at the site of injection, which may be carried to and spread in adjacent tissues by injection. A bacteriologically safe injection site should be selected.
  - Septicemia. In a proximal nerve block, a needle may open new lymph channels that drain through a region, thereby causing new foci and local abscess formation from the perforation of small vessels and escape of bacteria.
  - Extreme nervousness, apprehension, excitability, or inability to cooperate because of mental state or age.

Spinal and Epidural Anesthesia

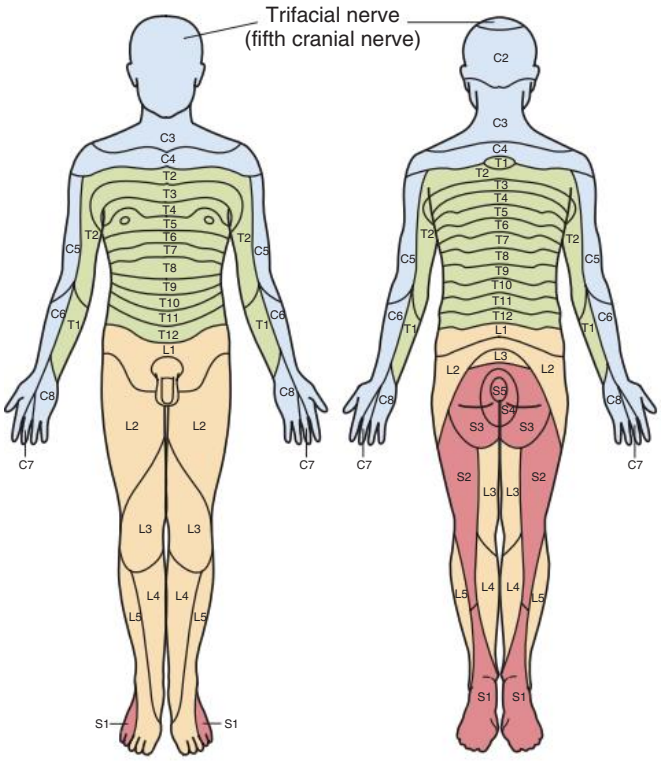
Intraspinal injection of an anesthetic drug is a technique of regional anesthesia performed by a person who has been properly trained and has acquired the necessary skill. Regional anesthesia is delivered to select areas, referred to as *dermatomes,* to affect motor and sensory nerves as desired (Fig. 24.10). The patient's dermatome levels can be tested by touch and by asking the patient to move his or her extremities. Dermatome level T12 is near the iliac crest, T10 is near the umbilicus, and T6 is near the xyphoid.

Assessment of the patient's level of consciousness, pulse, respirations, and blood pressure is essential for early detection of hypotension associated with high **spinal anesthesia**. If regional anesthesia extends above the level of T4, a full sympathetic block may follow, causing cardiorespiratory arrest. Ventilatory support equipment and naloxone should be immediately available.

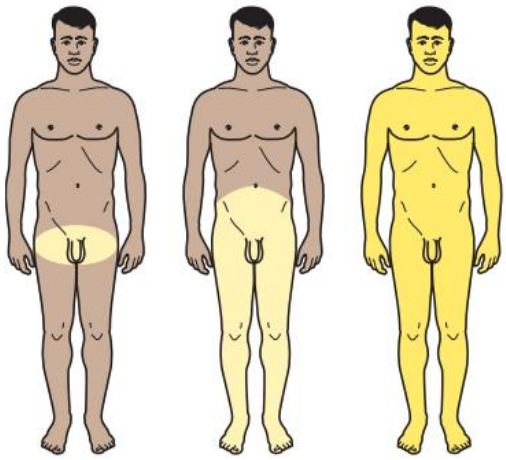
Choices in Regional Drugs

The choice of drug depends on factors such as the duration, intensity, and level of anesthesia desired; the anticipated surgical position of the patient; and the surgical procedure (Fig. 24.11). Patient factors include the anesthetic history, physical condition, and preference of the patient and surgeon. The duration of action depends on physiologic and metabolic factors. The addition of a vasoconstrictor, usually epinephrine 1:200,000, prolongs the duration.

Diffusion of the drug into the CSF is affected by solubility, molecular weight, and volume. Glucose may be added to make the drug heavier than CSF (hyperbaric). Anesthesia diminishes as



• **Fig. 24.10** Dermatomes of the body.



• **Fig. 24.11** Levels of spinal and epidural anesthesia.

the drug is absorbed into the systemic circulation. The most commonly used anesthetic drugs for spinal and epidural anesthesia are listed in Table 24.4.[6]

The anesthesia provider determines the placement site of the injection needle according to the bony landmarks of the spine (Fig. 24.12). The spinal and epidural drugs are injected using specially designed needles with angles and lumens that are specific to the type of anesthesia being delivered (Fig. 24.13).

Spinal Anesthesia

Spinal anesthesia, also referred to as an *intrathecal block,* causes desensitization of spinal ganglia and motor roots. The agent is injected into the CSF in the subarachnoid space of the meninges

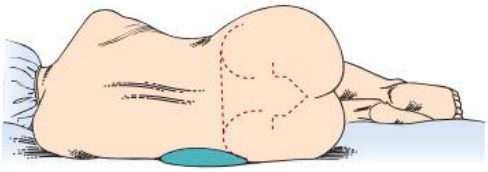
TABLE 24.4 Local and Regional Anesthetic Agents

Generic Name	Trade Name(s)	Uses	Concentration	Duration of Effect (Hours)	Maximum Dosage
Amino Amides					
Bupivacaine	Marcaine Sensorcaine	Local infiltration[a] Regional block[a] Surgical epidural	0.25%-0.75%	2-3	400 mg
Dibucaine	Nupercaine Percaine Cinchocaine	Local infiltration Peripheral nerves	0.05%-0.1%	3-3½	30 mg
Etidocaine		Peripheral nerves Epidural	0.5%-1%	2-3	500 mg
Lidocaine	Xylocaine Lignocaine	Topical Infiltration[a] Peripheral nerves[a] Nerve block[a] Spinal Epidural	2%-4% 0.5% 1%-2%	½ to 2	200 mg or 4 mg/kg; 500 mg or 7 mg/kg when mixed with vasoconstrictor
Mepivacaine	Carbocaine	Infiltration Peripheral nerves Epidural	0.5%-1% 1%-2%	½ to 2	400 mg
Prilocaine	Citanest	Infiltration Peripheral nerves Regional block Epidural	1%-2% 2%-3%	½ to 2½	600 mg
Ropivacaine	Naropin	Infiltration Field block Nerve block Epidural Postoperative pain management Not used for Bier block	0.2% 0.5% 0.75% 1%	2½ for surgical analgesia; 6-10 for surgical nerve block	200 mg for analgesia; 300 mg for nerve block
Amino Esters					
Chloroprocaine	Nesacaine	Infiltration[a] Peripheral nerves[a] Nerve block[a] Epidural Topical	0.5% 2% 2% 2%-3% 4%-10%	¼ to ½ ½	1000 mg 200 mg or 4 mg/kg body weight
Cocaine		Topical anesthesia and vasoconstrictor in ENT surgery	4%	2	1 mg/kg
Procaine	Novocain	Infiltration Peripheral nerves Spinal	0.5% 1%-2%	¼ to ½	1000 mg or 14 mg/kg body weight
Tetracaine	Cetacaine Pontocaine	Topical Spinal	2% 1%	2-4	20 mg

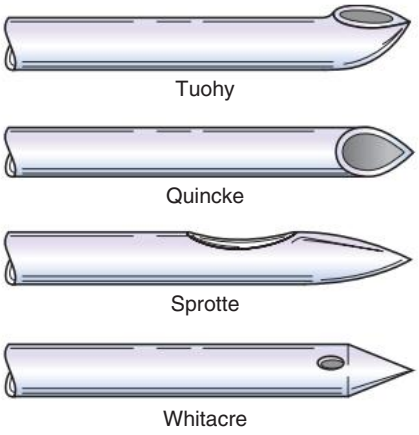
[a]Epinephrine may be used.
ENT, Ear, nose, and throat.

(the three-layered covering of the spinal cord) using a lumbar interspace in the vertebral column (Fig. 24.14). The subarachnoid space is located between the pia mater (the innermost membranous layer covering the spinal cord) and the arachnoid (the thin, vascular, weblike layer immediately beneath the dura mater, which is the outermost sheath covering the spinal cord). Spinal ganglia, motor nerve roots, and blood vessels pass through the meninges. The drug diffuses into the CSF around ganglia and nerves before it is absorbed into the bloodstream. Absorption into nerve fibers is rapid.

Spinal anesthesia is often used for abdominal (mainly lower) or pelvic procedures requiring relaxation, inguinal or lower extremity



• **Fig. 24.12** Landmarks used for epidural or spinal anesthesia.



• **Fig. 24.13** Physical characteristics of four different spinal and epidural needles (not to scale).

procedures, surgical obstetrics (cesarean section without effect on the fetus), and urologic procedures. It is preferred for patients with alcoholism, substance abusers, or obese or muscular patients (who would need large doses of general anesthetic and muscle relaxant), and for emergency surgical procedures on patients who have eaten recently. It is also used in the presence of hepatic, renal, or metabolic disease, because it causes minimal upset of body chemistry.

The level of anesthesia attained depends on various factors, such as the patient's position during and immediately after injection; CSF pressure; site and rate of injection; volume, dosage, and specific gravity (baricity) of the solution; inclusion of a vasoconstrictor, such as epinephrine; spinal curvature; interspace chosen; uterine contractions with labor; and coughing or straining, which can inadvertently raise the level. Spread of the anesthetic is controlled mainly by solution baricity and patient position.

The period immediately after injection is decisive; the anesthetic is becoming "fixed" (i.e., absorbed by the tissues and unable to travel). Further control of the anesthetic level is attained by tilting the operating bed at that time. The direction of tilting depends on whether the drug is hyperbaric (specific gravity greater than that of spinal fluid) or hypobaric (lighter than spinal fluid). Isobaric anesthetics (same weight as spinal fluid) are made hyperbaric by the addition of 5% or 10% dextrose to the anesthetic before injection.

Immediately after the anesthetic is injected, the anesthesia provider carefully tests the level of anesthesia by pinprick, touch, or nerve stimulation, tilting the bed as necessary to achieve the desired level for the surgical procedure. After anesthetic fixation and with the anesthesia provider's permission, the patient is placed in surgical position. The patient is asked to relax and let the team turn him or her. Straining or holding the breath can alter the position of the dural sac and precipitate hypotension or an inadvertent rise in the level of anesthesia. The incision is not made until it is certain that anesthesia is adequate. Supplementation of spinal anesthesia is necessary if anesthesia or muscular relaxation is insufficient or the patient is unduly apprehensive. Sometimes the patient is given moderate sedation but can still be roused.

Choice of Agent

The drug used depends on various factors such as the duration, intensity, and level of anesthesia desired, the anticipated surgical position of the patient, and the surgical procedure.

Duration of Agent

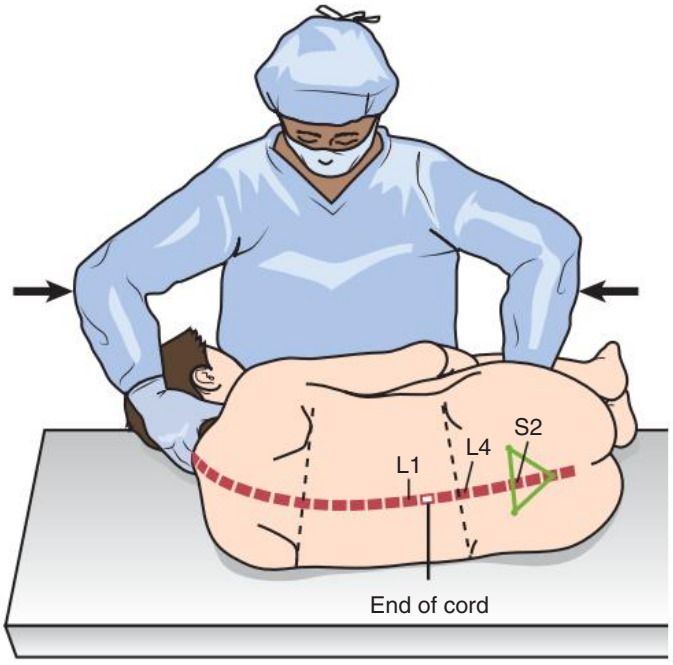
The variable duration of anesthesia depends on physiologic and metabolic factors. It is prolonged by the addition of a vasoconstrictor. Anesthesia diminishes as the agent is absorbed into the systemic circulation.

Spinal Anesthesia Procedure

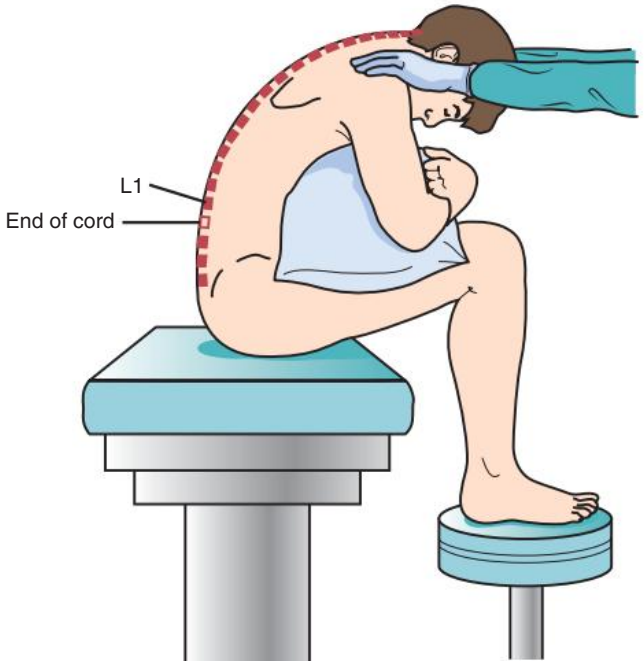
For injection, the patient is placed in the position desired by the anesthesia provider, depending on patient condition, solution baricity, and level of anesthesia to be produced:

- *Lateral position:* The patient lies on the side with the back at the edge of the OR bed. The knees are flexed onto the abdomen, and the head is flexed to the chest. The hips and shoulders are vertical to the OR bed to prevent rotation of the spine (Fig. 24.15).
- *Sitting position:* The patient sits on the side of the OR bed with the feet resting on a stool. The spine is flexed, with the chin lowered to the sternum; the arms are crossed and supported on a pillow on an adjustable table or Mayo stand (Fig. 24.16).

The circulating nurse or an anesthesia technician supports and reassures the patient in an aligned position and assists the anesthesia provider as possible. Attention to asepsis is extremely important. The anesthesia provider dons sterile gloves before handling sterile items. Sterile disposable spinal trays eliminate the need for



• **Fig. 24.15** Spinal block—lateral position.



• **Fig. 24.16** Spinal block—sitting position.

cleaning and sterilizing of reusable equipment. They also avoid the hazards of sterilizing ampules. The dates on the drugs supplied by the manufacturer should be checked.

A spinal tray usually contains the following:

- Fenestrated drape.
- Ampules of local anesthetic, spinal anesthetic, vasoconstrictor drug, and 10% dextrose.
- Gauze squares, forceps, and antiseptic solution. Some kits include disposable skin prep sponges on plastic applicator sticks.
- Needles: 25-gauge hypodermic needle for infiltration of local anesthetic into the skin; 22-gauge × 2-inch (5-cm) needle for IM injection; blunt 18-gauge needles for mixing drugs; and 22 or 26-gauge × 3½-inch (9-cm) spinal needle with stylets for **intrathecal injection**.
- Syringes: 5-mL syringes for spinal anesthetic; 10-mL syringes for hypobaric solutions; and 2-mL syringes for superficial anesthesia.

The puncture site is cleansed with an antiseptic solution and draped with a fenestrated drape. Advise the patient that the prep solution will feel cold and wet. Before the skin is penetrated, the patient should be told that the skin will be numbed with local anesthetic and the spinal needle will be inserted. This prevents the startle effect of the needlestick in the patient. The blood pressure is checked before, during, and after spinal anesthesia because hypotension is common.

Advantages. The patient is conscious if desired. The procedure can be performed with moderate sedation as necessary. Throat reflexes are maintained; breathing is quiet without airway problems because the respiratory system is not irritated. The bowel is contracted. Muscle relaxation and anesthesia are excellent if the procedure is properly executed.

Disadvantages. Spinal anesthesia produces a circulatory depressant effect: hypotension and stasis of blood as a result of interference with venous return from motor paralysis and arteriolar dilation in the lower extremities. A change in body position may be followed by a sudden drop in blood pressure; after fixation of the anesthetic, a slight elevation of the feet and legs may increase venous return to the heart. The agent cannot be removed after injection. Nausea and emesis may accompany cerebral ischemia, traction on viscera and peritoneum, or premedication. There is possible sensitivity to the agent and danger of trauma or infection. The patient has all senses present, such as hearing, sight, and smell, and is able to speak.

Transient or permanent neurologic sequelae from cord trauma, irritation by the agent, lack of asepsis, and loss of spinal fluid with decreased intracranial pressure syndrome are potential complications. Examples include spinal headache; auditory and ocular disturbances, such as tinnitus and diplopia; arachnoiditis; meningitis; transverse myelitis; cauda equina syndrome (failure to regain use of the legs or control of urinary and bowel functions); temporary paresthesias, such as numbness and tingling; cranial nerve palsies; and urinary retention. Late complications include nerve root lesions, spinal cord lesions, and ruptured nucleus pulposus.

True spinal headache caused by a persistent CSF leak through the needle hole in the dura usually responds to supine bed rest, copious oral or IV fluids, and systemic analgesia. Refractory postspinal headache may be treated by an epidural blood patch: 5 to 10 mL of the patient's own blood is administered at the puncture site. This usually affords prompt relief.

If a high level of anesthesia is reached, extreme caution is essential to prevent respiratory paralysis ("total spinal"), which is an emergency situation requiring mechanical ventilation until the level of anesthesia has receded. Respiratory arrest, although rare, is thought to be a result of medullary hypoperfusion caused by a sympathetic block. Apnea also can be produced by respiratory center ischemia resulting from precipitous hypotension.

The anesthesia machine, oxygen, and IV line must be in readiness before injection. Constant vigilance of respiration and circulation is critical. The blood pressure and heart rate are monitored and maintained at normal levels.

Epidural Anesthesia

The terms *epidural, peridural,* and *extradural* are used synonymously. The epidural space lies between the dura mater, the

outermost sheath covering the spinal cord, and the walls of the vertebral column. It contains a network of blood vessels, lymphatics, fat, loose connective tissue, and spinal nerve roots. Injection is made into this space surrounding the dura mater (see Fig. 24.14). The drug diffuses slowly through the dura mater into CSF. Anesthesia is prolonged while the drug is absorbed from CSF into the bloodstream.

The spread of anesthetic and duration of action are influenced by the concentration and volume of solution injected (total drug mass) and the rate of injection. The anesthetic diffuses toward the head (cephalad) and toward the coccyx (caudad). In contrast to spinal anesthesia, patient position, baricity, and gravity have little influence on anesthetic distribution. The high incidence of systemic reactions is attributed to absorption of the agent from the highly vascular peridural area and the relatively large mass of anesthetic injected. Epinephrine 1:200,000 is usually added to retard absorption.

Approaches used for epidural anesthesia and analgesia include thoracic, lumbar, and caudal approaches. Skin and ligaments are infiltrated with a local anesthetic agent before the epidural catheter is placed.

The management and sequelae of epidural anesthesia are similar to those of spinal anesthesia. An epidural approach may be used for lower extremity, abdominal, urologic, anorectal, vaginal, or perineal procedures. It is used commonly for postoperative pain management and in obstetrics during labor and delivery or during and after cesarean section.

A qualified RN attends the patient constantly once the block is initiated for analgesia. Vital signs should be monitored at regular intervals, and any deviation of level of consciousness, pulse, respirations, or blood pressure should be reported immediately to the anesthesiologist. Use of an apnea monitor may be indicated. In an obstetric patient, the fetal heart rate should be electronically monitored continuously because the patient is insensitive to uterine contractions.

Epidural narcotic analgesia may provide sustained postoperative relief or control of pain in patients with intractable or prolonged pain. This may be administered by a percutaneous indwelling epidural catheter, an implanted epidural catheter with infusion port or reservoir and pump, or an implantable infusion device. A patient may come to the OR for placement of an epidural catheter or pump device for ongoing pain management.

An epidural catheter for administration of a narcotic for prolonged postoperative pain relief, usually for 2 or 3 days, may be inserted before induction of general anesthesia, for postoperative use. Morphine, fentanyl, sufentanil, and buprenorphine are the drugs most commonly used for prolonged pain relief. Although probability of respiratory depression is less when the epidural route is used compared with spinal narcotics, use of an apnea monitor is advisable.

Side effects include nausea and vomiting, urinary retention, and pruritus. Epidural narcotics block pain at the level of opiate receptors in the dorsal horn of the spinal cord, not in the brain, so the patient is mentally alert and able to ambulate.

Thoracic and Lumbar Approaches

The thoracic and lumbar approaches are peridural blocks. Equipment is similar to that for a spinal block with the addition of a 19-gauge × 3½-inch (9-cm), thin-walled needle with a stylet with a rigid shaft and a short, beveled tip to minimize the danger of inadvertent dural puncture. Insertion of a catheter allows repeated injections for continuous intraoperative and postoperative epidural anesthesia, requiring additional needles, stopcocks, and a plastic catheter in the setup.

Caudal Approach

The caudal approach is an epidural sacral block. Epidural injection is through the caudal canal, desensitizing nerves emerging from the dural sac. The patient position for injection is prone with the hips flexed, sacrum horizontal, and heels turned outward to expose the injection site. The sacral area is prepared and draped, with care taken to protect the genitalia from irritating solution. The left lateral position is used in the pregnant patient. The spread of agents in epidural anesthesia is enhanced in pregnancy, atherosclerosis, and advanced age.

The tray includes the addition of a 20 to 24-gauge × 1½-inch (4-cm) spinal needle with a stylet. Commercial sets are available.

Advantages. Compared with spinal anesthesia, epidural anesthesia has a decreased incidence of hypotension, headache, and potential for neurologic complications, although a higher failure rate is reported.

Disadvantages. There is less controllable height of anesthesia; it is a more difficult technique; there is a greater area of potential infection from anaerobic organisms with the caudal approach; it is unpredictable; it is time consuming (i.e., a longer time is required for complete anesthesia); a larger amount of agent is injected; and continuous technique may slow the first stage of labor.

Intravascular injection, accidental dural puncture and total spinal anesthesia, blood vessel puncture and hematoma, profound hypotension, backache, and transient or permanent paralysis (paraplegia) are possible complications. The patient may suffer hypoxia, respiratory arrest, and/or cardiac arrest.

Techniques of Administration of Local or Regional Anesthesia

Topical Application

The anesthetic is applied directly to a mucous membrane, a serous surface, or an open wound. A topical agent is often applied to the respiratory passages to eliminate laryngeal reflexes and cough, for insertion of airways before induction or during light general anesthesia, or for therapeutic and diagnostic procedures such as laryngoscopy or bronchoscopy. It is also used in the urethral meatus for cystoscopy.

Mucous membranes readily absorb topical agents because of their vascularity. The onset of anesthesia occurs within minutes. The blood level of a topical agent may equal the same level obtained by IV injection. The duration of anesthesia is 20 to 30 minutes. If a spray or atomizer is used, it should contain a visible reservoir so the quantity of drug administered is clearly observed, because droplets vary in size, causing variations in dosages.

Preanesthetic anticholinergics are important before topical application within the respiratory tract. Saliva can dilute the topical anesthetic and prevent adequate duration of contact with mucous membranes. In addition, a dry throat is necessary to prevent aspiration until the anesthetic effect has disappeared and throat reflexes have returned. Adverse reactions to topical anesthetic agents are uncommon when dosage is carefully controlled. Sudden cardiovascular collapse can occur, more commonly after **topical anesthesia** of the respiratory tract.

Topical local anesthetic ointment may be used on the skin surface before establishing IV access. The ointment should be applied and allowed to remain in contact with the skin for several minutes to an hour for optimal effect. A transparent cover dressing may be

placed over the application point to prevent accidental smearing of the medication. Care is taken to prevent contact with the eyes and other mucous membranes.

Cryoanesthesia

Cryoanesthesia involves blocking local nerve conduction of painful impulses by means of marked surface cooling (i.e., freezing) of a localized area. It is used in such brief procedures as the removal of warts or noninvasive papular surface lesions. Cryotherapy units are commercially available.

Simple Local Infiltration

The agent is injected intracutaneously and subcutaneously into tissues at and around the incisional site to block peripheral sensory nerve stimuli at their origin. It is used before suturing superficial lacerations or excising minor lesions.

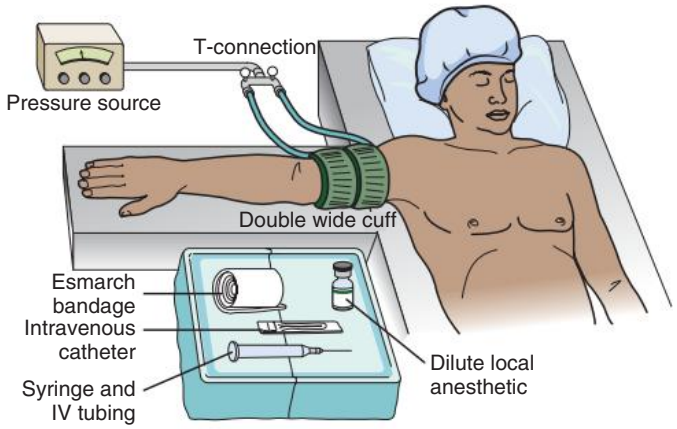
Regional Injection

The agent is injected into or around a specific nerve or group of nerves to depress the entire sensory nervous system of a limited, localized area of the body. The injection is at a distance from the surgical site. A wider, deeper area is anesthetized than with simple infiltration. There are several types of regional blocks.

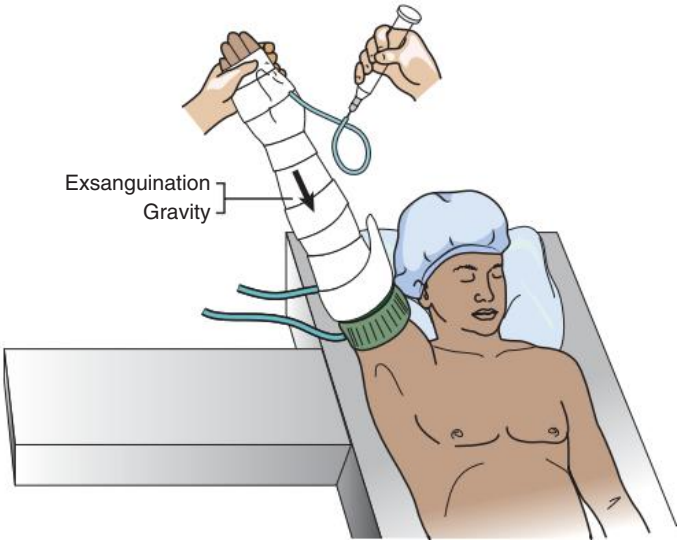
Nerve Block. A selected nerve is anesthetized at a given point. Nerve blocks are performed to interrupt sensory, motor, and/or sympathetic transmission. Blocks may be used preoperatively, intraoperatively, and postoperatively to prevent pain of the procedure; diagnostically to ascertain the cause of pain; or therapeutically to relieve chronic pain. Blocks are useful in various circulatory and neurosurgical syndromes, such as reflex sympathetic dystrophy (RSD). For prolonged pain relief (e.g., during a long procedure or to treat chronic pain associated with disease or trauma), a continuous infusion or incremental injections through a catheter may sustain regional anesthesia. Some examples of blocks are as follows:

1. Surgical blocks
   a. Paravertebral block of the cervical plexus for procedures in the area between the jaw and the clavicle
   b. Intercostal block for relatively superficial intraabdominal procedures, such as drain placement
   c. Brachial plexus or axillary block for arm procedures
   d. Median, radial, or ulnar nerve block for the elbow or wrist
   e. Hand and digital block for fingers (an additive vasoconstrictor, such as epinephrine, is not added to the local agent because necrosis can result from inadequate circulation to the digit)
   f. Blocks in other specific areas, such as a penile block for circumcision in adults
2. Diagnostic or therapeutic blocks
   a. Sympathetic nerve ganglion block to produce desired vasodilation by paralysis of the sympathetic nerve supply to the constricting smooth muscle in the artery wall
   b. Stellate ganglion block to increase circulation in peripheral vascular disease in the head, neck, arm, or hand
   c. Paravertebral lumbar block to increase circulation in the lower extremities
   d. Celiac block for relief of abdominal pain of pancreatic origin

Bier Block. A Bier block is a regional IV injection of a local anesthetic to an extremity below the level of a double-cuffed tourniquet. A Bier block is used for upper extremity procedures and for those that last an hour or less.



• **Fig. 24.17** Bier block equipment with double tourniquet in place.



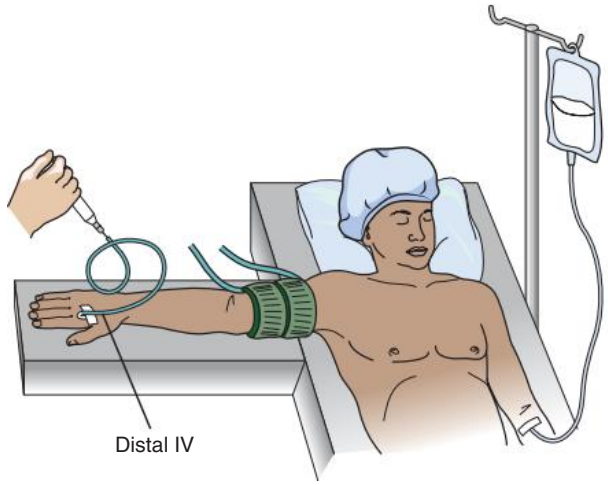
• **Fig. 24.18** Bier block: Exsanguination of limb by elevation and elastic wrap before inflating the proximal cuff and injecting anesthetic.

- A double tourniquet cuff is applied, but not inflated. An IV catheter is inserted in the dorsum of the hand (Fig. 24.17).
- A plastic drape is wrapped around the cuff to seal it off from prep solutions.
- The arm is elevated, prepped, and wrapped with a sterile Esmarch or ACE from the hand to the tourniquet cuff (distal to proximal) to exsanguinate the limb (Fig. 24.18).
- The proximal cuff is inflated and the wrap is removed. The Esmarch wrap should be rerolled and set aside on the sterile field.
- Local anesthetic is injected into the IV catheter (Fig. 24.19).
- When the anesthetic takes effect over the limb, the lower (distal) cuff of the tourniquet is inflated.
- The upper (proximal) cuff is released.

The patient feels less discomfort related to the tourniquet, because the lower cuff is over an anesthetized region.

On release of the tourniquet at the conclusion of the surgical procedure, entry of a bolus of the remaining drug and metabolic waste (lactic acid from ischemia) into systemic circulation may cause cardiovascular or CNS symptoms of toxicity, such as blindness.

Field Block. The surgical site is blocked off with a wall of anesthetic drug. A series of injections into proximal and surrounding



• **Fig. 24.19** Bier block: Anesthetic is injected and distal cuff inflated. Wrap is removed and proximal cuff deflated.

tissues will provide a wide area of anesthesia, as in an abdominal wall block for herniorrhaphy.

Complications of Blocks. Each type of block carries unique complication potential. Examples of complications include the following:

- *Intercostal blocks:* Pneumothorax, atelectasis, total spinal anesthesia, air embolism, transverse myelitis
- *Brachial plexus blocks:* Pneumothorax, hemothorax, recurrent laryngeal nerve paralysis, phrenic paralysis, subarachnoid injection, Horner syndrome (axillary approach may be preferred to interscalene approach)
- *Stellate ganglion blocks:* Pneumothorax
- *Celiac blocks:* Large vessel perforation, pancreatic injury, total spinal anesthesia

Actions of Local and Regional Anesthetics

Local and regional anesthetics interfere with the initiation and transmission of nerve impulses by interacting with the membranous sheath that covers nerve fibers. By physical and biochemical mechanisms, drugs retard and stop the propagation of nerve impulses, eventually blocking conduction.

Drug Pharmacodynamics

The duration of action depends not only on pharmacologic properties of drugs but also on the volume and concentration of the solution and its systemic interactions. Drugs vary in potency, penetration, rapidity of hydrolysis or destruction, and toxicity.

Conduction Velocity. Nerve fibers vary in their susceptibility to drugs. The larger the fiber, the greater the concentration required. The least amount and lowest concentration to achieve the desired effect should be administered. Conduction of a peripheral stimulus is blocked at its origin by topical application or local infiltration of the drug. Transmission of stimuli along afferent nerves from the surgical site is blocked in regional anesthesia. Conductive pathways in and around the spinal cord are blocked for spinal and epidural anesthesia.

Blocking Quality. Drugs of high potency, minimal systemic activity, and prompt metabolism and those that lack local irritation are most effective. Blocking qualities include the following:

- Latency time between administration and maximum effect
- Duration of action
- Regression time between beginning and end of pain perception

Sensory nerves are blocked initially. Motor nerves also are affected, with resultant paralysis of both voluntary and involuntary muscles. Some degree of vasodilation occurs with all local and regional use of anesthetic drugs except cocaine.

Absorption Rate and Additives. Local blood flow, vasodilation, and vascularity of tissues can markedly influence local anesthetic action and systemic absorption of drugs. Fibrous tissue and fat in some injection sites act as diffusion barriers and nonspecific binding sites. Additives to slow uptake include the following:

- *Epinephrine (Adrenalin):* A catecholamine, epinephrine is a potent stimulant. When combined with an anesthetic drug, it causes vasoconstriction to slow circulatory uptake and absorption, thus prolonging anesthesia. It is used to counteract cardiovascular depressant effects of large doses of local anesthetic. It also decreases bleeding, which is a desired effect in many surgical procedures. A concentration of epinephrine that is 1:1000 (1000 mg/1000 mL × 1 mg/mL) to 1:200,000 (0.005 mg/mL) may be optimal for absorptive and hemostatic purposes.

  Epinephrine is premixed in commercially prepared solutions. If it is added to an anesthetic drug, it is best to do so with a calibrated syringe to avoid overdosage. epinephrine can produce an acute adrenergic response: nervousness, pallor, diaphoresis, tremor, palpitation, tachycardia, and hypertension. The patient receiving epinephrine should be well oxygenated.
- *Sodium bicarbonate:* A small amount of carbonation can be added to local anesthetic agents. The carbonation lowers the **pH** of the solution, causing it to cross the cell membrane more readily. Alkalization results in decreased pain on injection. One potential problem with the addition of bicarbonate is that it may precipitate in the local anesthetic solution.
- *Dextran:* Anesthetic solutions with a pH higher than 8 can be mixed with dextran for prolongation of the localized anesthetic effect.

Toxicity. Allergic reactions to anesthetic drugs can occur but are rare. Toxic reactions occur when the concentration of drug in the blood affects the CNS. Slurred speech, numbness of the tongue, blurred vision, and tinnitus are symptoms of toxicity that can progress to drowsiness and confusion.

The maximum recommended dosage for each drug should not be exceeded. Severe toxic reaction can quickly lead to cardiovascular collapse. In topical anesthesia, extremely rapid systemic absorption from the mucous membranes explains the relatively high frequency of toxic reactions. In local or regional anesthesia, inadvertent intravascular injection and use of fairly large quantities in highly vascular areas will contribute to local anesthetic toxicity.

Pharmacologic Agent Overview

Many local or regional anesthetic drugs are in use. All are direct myocardial depressants, but the CNS effects precede this depression. Detoxification occurs in the liver. They differ in structure and therefore in action. These drugs are hydrochloride salts of weak bases in solution. They are categorized by chemical structure as amino amides and amino esters (see Table 24.4).

Amino Amides. Amino amides are metabolized in the liver by enzymes and are excreted by the kidneys. Patients with hepatic disease may become toxic with normal dosages because of ineffective metabolism. The amides include the following:

- *Ropivacaine (Naropin):* One of the newest local anesthetics on the market, ropivacaine is used for field blocks, nerve blocks, epidurals, and postoperative pain control epidural applications. Four strengths are available: 0.2% (2 mg/mL), 0.5%

(5 mg/mL), 0.75% (7.5 mg/mL), and 1% (10 mg/mL). Epidural administration may result in hypotension and bradycardia. The maximum dose for children is 3 mg/kg.

- *Lidocaine (Xylocaine):* Probably the most widely used agent, this potent anesthetic slowly hydrolyzes in circulating plasma. It undergoes hepatic degradation. The dosage should be reduced if hepatic function or blood flow is impaired. Its major advantages are a rapid onset of anesthesia and lack of local irritant effect. Allergic reactions are rare.

  Used extensively for surgical procedures and dentistry, it has moderate potency and a moderate duration of action. For adult infiltration: 0.5%; for peripheral nerves: 1% to 2% with vasoconstrictor additive; maximum dose is 500 mg, or 7 mg/kg body weight. It is a good topical anesthetic, although it is not as effective as cocaine. For topical use in the respiratory tract: 2% to 4%; maximum dose is 200 mg without vasoconstrictor additive. It is commonly used topically before awake intubation. The maximum dose for pediatric patients is 5 mg/kg.

  Clinical indications of lidocaine toxicity usually are related to the CNS, such as complaints of circumoral and tongue numbness. Excessive doses can produce myocardial and circulatory depression. Toxic IV dose is 250 mg.
- *Mepivacaine (Carbocaine):* Similar to lidocaine, mepivacaine takes effect rapidly but produces a 20% longer duration of anesthesia. It has moderate potency and a moderate duration of action. It is commonly employed for infiltration and nerve block. It produces minimal tissue irritation and few adverse reactions. Epinephrine may not be added to it because of its duration of action. For infiltration: 0.5% to 1%; for peripheral nerves: 1% to 2%; maximum dose is 400 mg.
- *Bupivacaine (Marcaine, Sensorcaine):* Four times more potent than lidocaine, bupivacaine has high potency of long duration. The onset of anesthesia is slow, but the duration is two to three times longer than that of lidocaine or mepivacaine, with toxicity approximate to that of tetracaine.

  Cumulation occurs with repeated injection. The drug affords prolonged pain relief after caudal block for rectal procedures. It is contraindicated for obstetric paracervical block and epidural anesthesia and for a Bier block. For local infiltration or a regional block, with or without epinephrine: 0.25% to 0.50%; maximum dose is 175 mg per dose without epinephrine or 225 mg with epinephrine 1:200,000 to a total dose of 400 mg. Pediatric maximum dose is 3 mg/kg.
- *Prilocaine (Citanest):* With prilocaine the onset of anesthesia is slower than with lidocaine, but the duration of action is longer. It is particularly useful for patients with diabetes or cardiovascular disease. It is used without epinephrine. For infiltration: 1% or 2%; for regional blocks and peripheral nerves: 2% or 3%; maximum dose is 600 mg. Pediatric maximum dose is 7 mg/kg.
- *Etidocaine (Duranest):* The onset of anesthesia is slower than that of lidocaine, but the block is of greater potency and toxicity, with a longer duration of action. For peripheral nerves: 0.5% to 1%; maximum dose is 500 mg.
- *Dibucaine (Nupercaine, Percaine, Cinchocaine):* Dibucaine is a very potent drug with a high rate of systemic toxicity. The onset is slow, and the duration of action is long. For infiltration and peripheral nerves: 0.05% to 0.1%; maximum dose is 30 mg.

Amino Esters. Amino esters are hydrolyzed in plasma by pseudocholinesterase enzymes produced by the liver. Para-aminobenzoic acid (PABA), a factor in the vitamin B complex, is a product of this metabolism. Some patients are allergic to PABA. The esters include the following:

- *Cocaine:* The first known local anesthetic, introduced in 1884, cocaine is a crystalline powder with a bitter taste in solution. It is the most toxic of the local drugs and, in contrast to all but lidocaine, is a vasoconstrictor and a CNS stimulant. Cocaine reduces bleeding and shrinks congested mucous membranes. It causes temporary paralysis of sensory nerve fibers, produces exhilaration, lessens hunger and fatigue, and stimulates pulse and respiratory rates.

  Administration is by topical application only, because of its high toxicity; the solution rapidly penetrates mucous membranes and spreads into highly vascular tissue. Absorption is self-limiting because of vasoconstrictive properties associated with the drug. epinephrine should not be added. When applied to the throat, cocaine abolishes throat reflexes. The patient is awake and can cooperate, but its limited use and possible addiction are disadvantages.

  Cocaine is used topically in 4% concentration for anesthesia of the upper respiratory tract (nose, pharynx, tracheobronchial tree) in 1 to 2-mL amounts on a cottonoid (pattie). Untoward reactions may occur rapidly in response to even a very small amount of the drug.

  Maximum dose is 200 mg, or 1.5 mg/kg body weight. Cocaine is metabolized by the liver and excreted by the kidneys. It should be used with caution in patients with impaired liver or kidney function. It is contraindicated in pregnancy because it decreases uterine blood flow.
- *Procaine (Novocain):* Procaine is similar to cocaine but less toxic. Concentrations used: 0.5% for infiltration; 1% to 2% for peripheral nerves. It is injected SQ, IM, or intrathecally. It has low potency, is of short duration, and is ineffective topically. Its advantages include minimal toxicity, easy sterilization, low cost, and lack of local irritation. Newer agents are used more frequently. Maximum dose is 1000 mg (1 g), or 14 mg/kg body weight.
- *Chloroprocaine (Nesacaine):* Chloroprocaine is possibly the safest local anesthetic from the standpoint of systemic toxicity because of its fast metabolism. It has moderate potency of short duration. It is rapidly hydrolyzed in the plasma. Its action is fast, but it is not active topically. When used in obstetrics, it does not alter neurobehavioral responses of newborn infants in any detectable way. For infiltration: 0.5%; for peripheral nerves: 2%; maximum dose is 1000 mg (1 g). Maximum pediatric dose is 8 mg/kg.
- *Tetracaine (Cetacaine):* With tetracaine, the onset of analgesia is slow but the duration of its effect is longer than that of many other drugs. It has high potency of long duration. It is also more toxic systemically because of the slow rate of destruction in the body, but low total dosage tends to reduce the chances of reaction. It is not used for local tissue infiltration or nerve block. Tetracaine in 2% solution is used only for topical anesthesia on accessible mucous membranes such as the oropharynx. Maximum adult dose is 20 mg. Tetracaine is used primarily for spinal anesthesia. Maximum pediatric dose is 2 mg/kg.

Complications of Local and Regional Anesthesia

Minor or transient complications of local and regional anesthesia are common. Serious complications, although rare, are usually permanent. Complications may be caused by the mechanical effect of needles or pharmacologic effect of the drug administered.

As with general anesthesia, the prevention of complications requires patient assessment and preparation, knowledge of anatomy and physiology, and attention to detail.

Proper choice of drug and equipment and constant monitoring are as necessary in local and regional anesthesia as in general anesthesia. Complications of local and regional anesthesia may be summarized briefly as local effects, systemic effects, and effects unrelated to the anesthetic drug.

Local Effects

Tissue trauma, hematoma, ischemia, drug sensitivity, and infection can be minimized by the use of proper drugs and equipment, sterile technique, avoidance of local anesthetics with vasoconstrictors in sites with smaller vascular structures (e.g., digits, penis, pinna), and avoidance of repetitive injection that promotes trauma, edema, tissue necrosis, and infection.

Systemic Effects

Systemic effects are primarily cardiovascular, neurologic, or respiratory (e.g., hypotension, seizure, respiratory depression). Drug interactions also are systemic.

After high blood levels, toxicity that affects more than one system may occur. Blood levels depend on the amount of drug used, its physical characteristics, the presence or absence of vasoconstrictors, and the injection site. For example, because of vascularity of surrounding tissue, intercostal blocks produce higher anesthetic blood levels in a shorter time than do axillary or epidural blocks. Absorption and the blood level of drugs are related to their uptake and rate of removal from the circulation. A linear relationship exists between the amount of drug administered via a given route and the resultant peak anesthetic blood level.

Predisposing Factors for Hypersensitivity. True hypersensitivity that produces an allergic response can occur, but it is less frequent than reactions from overdosage of pharmacologic agents. The following may predispose a patient to hypersensitivity:

- *Immunologic sensitization:* Allergies are thought to be more common with the amino esters than with the amide group of compounds. An allergic reaction to the preservative in some solutions, such as methylparaben, also is possible. Some local anesthetics release histamine, which is the basis of an allergic response.

  True allergy, mediated by antigen-antibody reaction, can cause anaphylaxis, urticaria (skin wheals), dermatitis, itching, laryngeal edema, and possibly cardiovascular collapse.
- *Overdosage:* An excessive amount of drug may enter the bloodstream if the injection exceeds maximum dose or is absorbed too rapidly. The IV method is the most dangerous route of injection, because histamine is released into the systemic circulation. The injection site is also pertinent. Hazardous sites involve vascular areas of tracheobronchial mucosa, and tissues of the head, neck, and paravertebral region. The least hazardous areas are subcutaneous tissue of the extremities and trunk (abdominal wall and buttocks).

Precautions. Extraordinary precautions must be taken for a patient with a history of any allergies, hypersensitivities, or reactions to previous anesthetics or other drugs. Atopic individuals, those with a hereditary tendency or multiple allergies, may be more prone to adverse reactions to anesthetics or other drugs. Prediction of allergic reactions is unreliable. If testing for sensitivity to specific drugs is done, it is executed cautiously under well-controlled conditions.

Precautions for preventing adverse drug reactions in all patients include the following:

1. Assessing the patient's preoperative physiologic and psychologic condition to determine potential problems and abnormal stress responses:
   a. Identify all medications the patient has recently received or is currently taking, including any history of substance abuse. If local anesthesia is planned, ask the patient if he or she has ever had local anesthesia at the dentist's office and if there were any adverse effects.
   b. Question the patient about known or suspected previous drug reactions. Any chemically related drug is not given.
   c. Help the patient cope with anxiety and fears by giving preoperative instructions and answering questions.
2. Handling drugs with care. Before administering or placing drugs on the sterile table:
   a. Read the label carefully. Check the expiration date.
   b. Discard the ampule or vial if the label is not completely legible or has been disturbed.
   c. Open, unlabeled, undated, multiple-use vials should be discarded and not used.
   d. Observe the solution for clarity, and discard any suspicious ampule or vial.
3. Administering drugs selected by a physician in appropriate concentrations and dosages for anesthesia and moderate sedation:
   a. Give the minimum effective concentration and smallest volume needed. Adjust the precise amount to the weight of the patient in kilograms as appropriate.
   b. Limit the total amount of drug injected or applied to prescribed safe limits. Sterile single-dose ampules and prefilled syringes are recommended.
   c. Inject slowly to retard absorption and avoid overdosage. Use incremental titration of drug.
   d. Pull back on the syringe plunger frequently while injecting tissues to be sure the solution is not entering a blood vessel inadvertently. Intravascular injection of an anesthetic drug can release histamine into the systemic circulation, causing an anaphylactoid (nonimmunologic) reaction.
   e. Exercise caution with drugs that depress respiratory or cardiovascular functions, such as sedatives, when the upper dose limit of the anesthetic drug is used.
   f. Provide continuous IV access for administering drugs for moderate sedation or adverse reactions. An IV line should be established in case of adverse reaction or inadvertent intravascular injection or bolus of anesthetic. A heparin lock device or infusion of IV fluids may be used to maintain continuous access.
   g. Cease administration of the drug immediately at the sign of any sensitivity.
   h. Record the drug name, dosage, route, time, and effects of all drugs or pharmacologic agents used.
4. Monitoring patient continuously:
   a. Observe the patient, including facial expressions, and note responses to conversation and the patient's state of alertness.
   b. Assess the patient's physical signs and symptoms, such as skin color and temperature. Use assessment knowledge and skill, and avoid total reliance on monitoring equipment.
   c. Monitor the patient's vital signs as appropriate (ECG, blood pressure, pulse, oxygen saturation, and respiration).
   d. Know resuscitation measures and be able to assist or initiate them as necessary, as per institutional policies and

procedures. Basic cardiac life support certification (BCLS) is required of all RNs who monitor patients. Advanced cardiac life support certification (ACLS) is preferred.

Signs and Symptoms of Systemic Reactions. Signs and symptoms of systemic reaction may be CNS stimulation or depression. Conversely, stimulation may be followed by depression and cardiovascular collapse (see Table 24.3). The cardiovascular system seems more resistant than the CNS to toxic effects of local anesthetics. The seizure threshold may differ enormously in individual patients, as may the relationship of the dose to signs and symptoms of CNS effect. For example, lidocaine usually produces drowsiness before a convulsion whereas bupivacaine may cause sudden seizure, disorientation, decreased hearing ability, paresthesias, muscle twitching, or agitation in a wide-awake patient without premonitory signs. **Hypercapnia** or hypoxemia from hypoventilation lowers the seizure threshold.

Toxicity of local anesthetics is manifested primarily by CNS effects resulting from high blood levels. Signs and symptoms of systemic reaction include, but are not limited to, the following:

- *Stimulation:* Talkativeness, restlessness, incoherence, excitation, tachycardia, bounding pulse, flushed face, hyperpyrexia, tremors, hyperactive reflexes, muscular twitching, focal or grand mal convulsions
- *Depression:* Drowsiness; disorientation; decreased hearing ability; stupor; syncope; rapid, thready pulse or bradycardia; apprehension; hypotension; pale or cyanotic, moist skin; coma
- *Other signs and symptoms:* Nausea, vomiting, dizziness, blurred vision, sudden severe headache, precordial pain, extreme pulse rate or blood pressure change, angioneurotic edema (wheeze, laryngeal edema, bronchospasm), rashes, urticaria, severe local tissue reaction

Systemic reactions or undesired effects of moderate sedation used in combination with local anesthetics may include slurred speech, agitation, combativeness, unarousable sleep, hypotension, hypoventilation, airway obstruction, and apnea.

Other signs and symptoms may be related to specific drugs. Benzodiazepines and sedatives used in moderate sedation may cause somnolence, confusion, diminished reflexes, depressed respiratory and cardiovascular function, and coma. Nystagmus (involuntary eye movements), which may be normal with large doses of diazepam (Valium), may be an abnormal reaction with other drugs. Opioids (narcotics) may cause nausea and vomiting, hypotension, and respiratory depression.

Treatment of Adverse Reactions

Treatment of an adverse reaction is aimed at preventing respiratory and cardiac arrest. Treatment must be prompt. ACLS protocol may be needed.

Administration of the agent thought to produce the reaction is stopped immediately at the first indication of reaction. Therapy is generally supportive, the specifics dictated by clinical manifestations. Treatment consists of the following:

1. Maintaining oxygenation of vital organs and tissues with ventilation by manual or mechanical assistance to give 100% oxygen with positive pressure. Tracheal intubation may be indicated.
2. Reversing myocardial depression and peripheral vasodilation before cardiac arrest occurs. The patient is supine with the legs elevated. IV fluid therapy is begun, and a vasoconstrictor drug may be given IV or IM for hypotension or a weak pulse, which are signs of progressive circulatory depression. The choice of vasopressor is suggested by the signs and symptoms, and the drug is used with caution. Drugs that may be used include the following:
   a. Epinephrine (IV) counteracts hypotension, bronchoconstriction, and laryngeal edema. It also stimulates beta- and alpha-adrenergic receptors and inhibits further release of mediators. It increases arteriolar constriction and force of the heartbeat. When appropriate, application of a tourniquet or subcutaneous injection of Epinephrine in an area of drug injection may delay absorption of toxic drug.
   b. Ephedrine and other vasoconstrictors such as phenylephrine (Neo-Synephrine) or mephentermine (Wyamine) cause peripheral vasoconstriction, increased myocardial contraction, and bronchodilation.
   c. Antihistamines block histamine release but generally are not advocated.
   d. Steroids enhance the effect of Epinephrine and inhibit further release of histamine. The effect is not immediate, and use is directed toward late manifestations of allergic response.
   e. Isoproterenol (Isuprel) is used predominantly in asthma and heart attacks; it is a bronchodilator.
   f. An antagonist drug may be given in situations in which the causative agent is identified.
3. Stopping muscle tremors or convulsions if they are present, since they constitute a hazard for further hypoxia, aspiration, or bodily injury. Diazepam in 5-mg doses or a short-acting barbiturate is given IV to inhibit cortical irritation.

For patients in whom the adverse response is caused by hypersensitivity, the previous measures are applicable. However, aminophylline may be administered to help alleviate bronchospasm, hydrocortisone (IV) to combat shock, and sodium or potassium iodide (IV) to reduce mucosal edema.

The perioperative nurse who is monitoring the patient must know resuscitation measures and be able to assist in or initiate them when necessary. An emergency cart with emergency resuscitative drugs and a defibrillator should be immediately available to the room where local or regional anesthetic with or without moderate sedation is administered. The following equipment should be in the room and ready for use:

- Oxygen and positive pressure breathing device (e.g., Ambu bag and mask)
- Oral and nasopharyngeal airways and endotracheal tubes in an assortment of sizes
- Cardiac and oxygen saturation monitoring equipment
- Suction

Unrelated Effects

A nerve deficit, such as pain or neuritis that occurs in the postoperative period, may be related to a preexisting condition such as multiple sclerosis. Alternatively, it may be from a cause unrelated to the anesthetic drug, such as faulty positioning; trauma from retractors; a tourniquet inflated for an inordinately long period, resulting in ischemia or pressure on peripheral nerves; or an improperly applied cast. Less common causes involve bleeding around the nerve or reaction to epinephrine.

Alternatives to Conventional Anesthesia

When local or regional anesthesia may be contraindicated but consciousness is desirable, acupuncture or hypnoanesthesia may offer alternative methods to control pain. An altered state of

awareness of painful stimuli may be advantageous in selected patients.

Hypnosis

Hypnoanesthesia refers to hypnosis used as a method of anesthesia. Hypnosis produces a state of altered consciousness characterized by heightened suggestibility, selective wakefulness, reduced awareness, and restricted attentiveness. Although hypnosis has a long history of misuse, modern application by highly trained medical specialists is appropriate.

Hypnoanesthesia, although seldom used, has been successfully employed in adult and pediatric patients. Motivation and concentration on the part of the patient are important factors. The method may be combined with the use of a small dose of a chemical anesthetic or muscle relaxing drug. Hypnosis should not be used indiscriminately in place of standard treatment and is used as a therapeutic aid in selected patients in the following situations:

- When chemical agents are contraindicated (patient may be kept pain-free, asleep, or awake, without toxic side effects)
- As an adjunct to chemical anesthesia to decrease the amount of anesthesia needed
- When it is desirable to free the patient from certain neurophysical effects of an anesthetic
- When anxiety and fear of anesthesia are so great as to contribute to serious anesthetic risk
- When posthypnotic suggestion may be valuable in the postoperative period
- When it is desirable to raise the pain threshold
- When it is desirable to have the patient respond to questions or commands

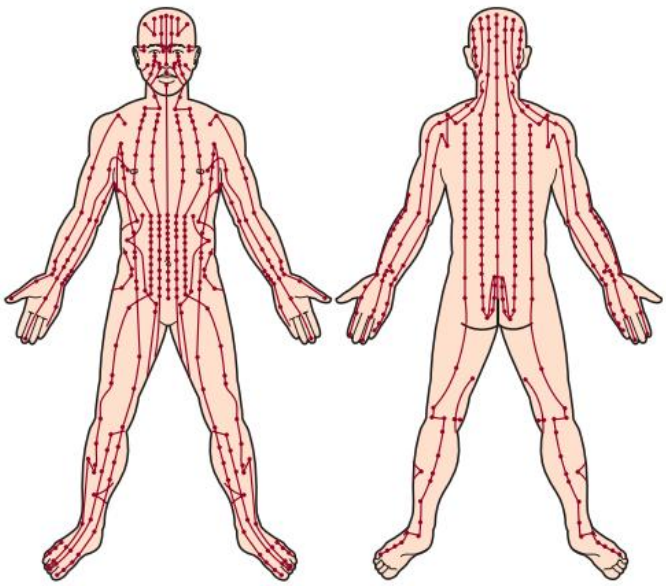
Hypnoanesthesia is advantageous for changing burn dressings and debridement of wounds and for patients with severe respiratory or cardiovascular disease or multiple drug allergies. The anesthesia provider must establish rapport with the patient preoperatively so that the patient will listen to and obey hypnotic commands. Hypnosis is a time-consuming method and is unreliable compared with chemical anesthesia.

Acupuncture

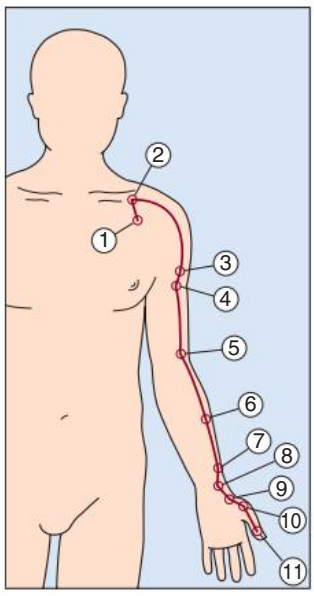
The ancient Chinese art of acupuncture has been practiced for more than 5000 years. Its acceptance by Western medical practitioners is fairly recent. Acupuncture is a technique of providing intense stimulation at meridian points, or planes of energy referred to as *Chi* (Fig. 24.20). This stimulation prompts the brain to release endorphins and other chemicals that can relieve or block pain. Some meridians are associated with prevention of nausea and vomiting postoperatively. An example of Chi points in a meridian line for the lung is depicted in Fig. 24.21.

Stimulation is effected by manually rotating or applying electric current to very-fine-gauge needles inserted into meridian points. When acupuncture is used for anesthesia, a minute electric current is used to speed and enhance analgesia or anesthesia in the desired body region.

The meridian points generally correspond to the area where the somatic nerve supply is located. It is a time-consuming technique. It may be used immediately after premedication is given to reduce postoperative nausea and vomiting after short procedures with the patient under general anesthesia.



• **Fig. 24.20** Meridians for acupuncture.



• **Fig. 24.21** Example of Chi points in meridian line used in acupuncture for treatment of the left lung.

Acupuncture is gaining popularity in surgical and dental procedures and for postoperative or intractable pain. The patient remains conscious. Procedures are limited to use by physicians or qualified certified personnel under their direct supervision in keeping with acceptable standards of medical practice.

25 Coordinated Roles of the Scrub Person and the Circulating Nurse

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Describe the activities of the scrub person.
- Describe the activities of the circulating nurse.
- Discuss the preliminary care of the patient by the circulating nurse.
- Differentiate between counting and being accountable for items used in patient care.

Division of Duties

The circulating nurse and the scrub person should plan their duties so that through coordination of their efforts, the sterile and unsterile parts of the surgical procedure move along simultaneously. From the time the scrub person starts the surgical scrub until the surgical procedure is completed and dressings are applied, an invisible line separates the duties of the scrub person (Box 25.1) and the circulating nurse (Box 25.2), which neither person may cross. In this chapter, the duties of the two positions are listed separately, but a spirit of mutual cooperation is essential to move the schedule of surgical procedures efficiently and serve the best interests of the patient.

As a coordinated, systematic effort, the scrub person and the circulating nurse should complete the preparation of the environment as described in Chapter 12, whether it is for the first case of the day or for a subsequent case performed during the course of the day. Establishing a system for performance of roles helps minimize the risk for human error.[1]

Both caregivers should double-check the needs for the procedure before the patient arrives at the room. Table 25.1 contains a systematic checklist of the case flow and case-related activities for the scrub person. Table 25.2 contains a systematic checklist of the case flow and patient care activities for the circulating nurse.

Setting Up the Room

Both the circulating nurse and the scrub person set up the room and position equipment. One suggested room arrangement is illustrated in Fig. 25.1. The case cart and the room furniture are checked by both people as a team. The duties and activities change when the patient arrives at the room. The circulating nurse begins caring for the patient, and the scrub person continues readying the room. The following activities are performed together before the patient arrives:

1. Place a clean sheet, lift sheet, armboard covers, and safety straps on the operating room (OR) bed. Put a pressure-reducing mattress or gel pads on the OR bed if needed to relieve pressure during a long procedure. A warming or cooling blanket or air conduction system may be needed to heat or cool the patient during a long procedure. Obtain special equipment, such as OR bed attachments, pillows, or padding, needed to position and protect the patient.
2. Obtain appropriate patient monitoring equipment. Sequential compression devices may be indicated.
3. Obtain any specialized equipment that will be needed, such as an electrosurgical unit (ESU), smoke evacuator, sponge counting device (if available), suction apparatus, pneumatic tourniquet, laser, or operating microscope, and check/test each for proper function. Have the appropriate attachments and adjunctive supplies in the room.
4. Gather protective devices such as x-ray–protective gowns and/or lead screens and laser eyewear of the correct optical density as needed. If the C-arm will be used, place gonadal shielding under the bed sheet in the area of the patient's pelvis. The x-ray tube will be positioned under the OR bed and emanate upward.
5. Position the OR bed under the overhead spotlight fixture. Orient the head of the bed for anesthetic access according to the type of procedure to be performed. Patient positioning for

• BOX 25.1 Role of the Scrub Person as Part of the Sterile Team

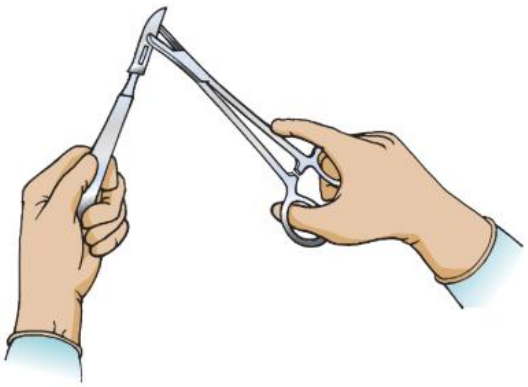
Prepares
- Sterile instruments and supplies
- Works in concert with the circulating nurse to set up the OR
- Surgeon's specific procedural needs
- Procedure specific needs
- Hemostatic techniques
- Suture and closure materials

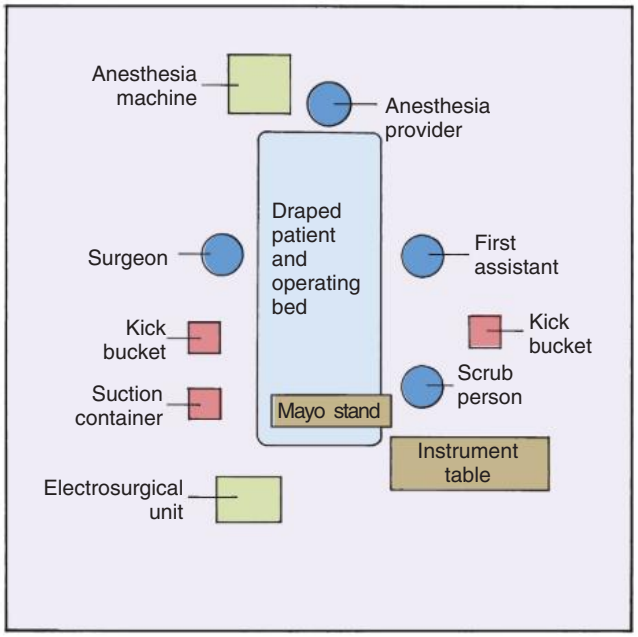
Sterile Technique
- Scrubs, gowns, and gloves using the closed gloving method
- Establishes the sterile field
- Facilitates the surgical procedure
- Anticipates the needs of the sterile team
- Gowns other team members using the open-assisted gowning and gloving technique

Adaptability
- Participates in preincision time out
- Remedies any breach of sterile technique
- Requests and prepares material needed by surgeon
- Keeps the sterile field neat and functional

Accountability
- Establishes baseline counts with circulating nurse
- Informs the circulating nurse of items placed inside patient
- Double-checks items dispensed to the sterile field
- Labels all medication containers and delivery devices
- Reports volume of drug administered to patient for documentation by circulating nurse

Safety
- Manages sharps
- Prevents retained foreign objects in the patient
- Reconciles counts and is accountable for items used in the surgical procedure





• **Fig. 25.1** Arrangement of the operating room showing sterile field, team members, and unsterile equipment.

some procedures requires the anesthesia provider to be located at the patient's side instead of at the head of the bed. Anesthesia personnel should be responsible for moving the anesthesia equipment to the proper position. The hoses and connections should be checked each time the anesthesia machine is moved. The circulating nurse and scrub person are not trained in this checking procedure.

6. Test the overhead spotlights to check focus and intensity, and pre-position as much as possible. Do not leave the light turned on. The light should be positioned in relationship to the location of the surgeon at the OR bed and to that part of the patient's anatomy that will be encountered during the surgical procedure. The circulating nurse should know how to change the light bulb in case a bulb burns out during a procedure. Newer lights have replacement bulbs in place that activate if one bulb burns out.
7. Connect and check the suction between the receptacle canisters and the wall outlet to be certain suction functions at maximum vacuum. Some facilities use inline filters for specialized equipment. The filters are changed between cases. Gloves and personal protective equipment (PPE) are worn to prevent contact with harmful microorganisms when changing these filters.
8. Place a waterproof laundry bag or antistatic plastic bag in the laundry hamper frame for disposal of reusable woven fabric items.
9. Place appropriately marked receptacles in the room for safe disposal of biohazardous items, such as sharps, disposable drapes, or other biologically contaminated materials. Clean trash containers should be available for noncontaminated trash. Many hospitals do not have in-house incinerators and pay per the pound to have biohazard trash hauled away. Mixed clean and biohazard trash disposal is an unnecessary expense.
10. Line each kick bucket and wastebasket with an impervious plastic liner with a cuff turned over the edge.
11. Arrange furniture with those pieces that will be draped to become part of the sterile field at least 18 inches (45 cm) away from walls or cabinets. They should be kept side by side, away from the laundry hamper, trash container, anesthesia equipment, doors, and paths of traffic. Take emergencies into consideration. A clear path for the crash cart should be maintained at all times. If the patient will be positioned prone, a clear pathway for the transport cart will be needed. A transport cart should be immediately available outside the room to reposition the patient supine if an emergency arises.

• BOX 25.2 Role of the Circulating Nurse as Part of the Nonsterile Team

Indirect Patient Care
- Assists with OR preparation
- Opens sterile supplies
- Prepares medication for use in OR
- Maintains patient confidentiality
- Communicates with surgical services personnel
- Pretests equipment
- Plans postoperative care
- Initiates discharge planning

Direct Patient Care
- Patient identification
- Patient assessment
- Identifies correct surgical site
- Transfers patient between cart and bed
- Participates in preoperative time out procedure
- Assists the anesthesia provider
- Provides skin antisepsis
- Provides thermoregulation
- Prevents electrosurgical injury
- Collaborates with patient fluid intake and output
- Monitors vital signs as needed
- Provides dressings and drains

Coordinates
- Plans for each member of the sterile team to enter the sterile field
- Positioning, prepping, and draping
- Connection of surgical machinery
- Laboratory tests
- Multidisciplinary teams
- Diagnostic activities
- Emergency response to patient crisis
- Communication with patient's significant others

Anticipates
- Sequence of the procedure
- Needs of the sterile team
- Breaches of sterile technique
- Hemostatic needs
- Radiation (ionizing and nonionizing) protection for sterile team
- Potential for patient's physiologic changes
- Wound class at conclusion of the procedure
- Patient responses to care
- Significant other's response to patient's condition

Accountability
- Participates in time out
- Validates implants
- Documents patient care
- Specimen care and reporting
- Promotes a culture of safety
- Accountability for instruments, sponges, and sharps
- Patient's advocate
- Evaluates patient outcomes
- Provide hand-over report to perianesthesia nurse

TABLE 25.1 Systematic Activities for the Scrub Person

Baseline Systematic Activity	Systematic Critical Thinking Activity
ROOM SETUP	
• Plan for patient to enter the room without contaminating the setup. • Plan for position of patient, surgeon, and anesthesia provider.	Determine the position of the surgeon and preference for positioning of the scrub person before setting up table.
CASE CART CONTENTS	
• Instrument set(s) • Custom pack • Gowns • Sterile towels • Prep supplies • Additional soft goods	Check cart contents. Inspect package integrity. Check for each item listed on case cart sheet. Record preference changes on case cart sheet for computer update.
ITEMS TO HAVE AVAILABLE	
• Suture • Sponges • Pack of towels • Gloves • Staplers • Dressing	Have extra preferred suture in the room. Extra sponges may be needed.

Continued

TABLE 25.1 Systematic Activities for the Scrub Person—cont'd

Baseline Systematic Activity	Systematic Critical Thinking Activity
TABLE SETUP	
• Open the main custom drape pack. The outer wrapper is the sterile table drape. • Determine which part of the table will be closest to the draped patient and establish this area as the working end of the table. Sharps and sutures should be opened onto this location. • Open remaining items into a position of function. Inspect package integrity. • Do not open items into closed container system. Edges are unsterile. • Don eyewear. • Open gown and gloves for self before performing hand and arm cleansing. • Don gown and gloves using closed glove procedure. Remember to tie in. • Set up the working end of the table according to position of patient. • Plan to pass off cords in one direction. • Sterile marker and labels are placed on the sterile instrument table near the working end. • Place items once. Do not leave trash on the field.	The surgical site on the patient establishes the level of the sterile field. Stack drapes in order of use and place away from main instrument setup area of sterile table. Create towel roll(s) for instrument stringers. Align stringer on the roll with shortest instruments closest to the working end of the table. Instrument ratchets are open on the table and closed on the Mayo stand. Establish baseline: Count instruments, sharps, and sponges with circulating nurse. Plan for exchange of scalpel by no touch technique.
MAYO STAND SETUP	
• Drape the Mayo stand. Cover surface with one unfolded towel to protect from perforation by sharps. A towel roll can be used to organize instruments on the Mayo stand.	Mayo setup: 2 scalpels, 3 scissors (1 curved and 1 straight Mayo and 1 Metzenbaum), 4 curved Crile hemostats, 2 medium pickups, 4 Allis forceps, and 2 small skin retractors (Army Navy). 2 Light handles, suction tubing and suction tip (Yankauer), electrosurgical unit (ESU) pencil and holder, tip cleaner, and sponges.
MEDICATION AND/OR CHEMICALS ON THE STERILE INSTRUMENT TABLE	
• Place medication cups near edge of field. • Validate all medications and solutions with circulating nurse and then apply labels.	Label syringes and administration devices after the solution or medication has been dispensed to the field. Do not label ahead of time because the wrong drug or solution could be poured. Label states name of product and percent.
IRRIGATION AND FLUIDS ON THE STERILE INSTRUMENT TABLE	
• Place basins near edge of sterile field. Label is applied after the solution is poured. • Label all delivery devices.	Normal saline or other solution for irrigation. Sterile water for instrumentation.
PATIENT POSITIONING	
• Stand clear and remain sterile, because positioning is a nonsterile activity.	Note the presence of safety restraints and padding as the second set of eyes. Drapes and blankets can obscure safety straps.
TEAM GOWNING	
• Assist team to gown and glove using the open-assisted or closed-assisted method. • Contaminated gloves are changed using the open method. Circulating nurse will remove contaminated gloves. Scrub person will reglove the individual.	Do not pass any towels or gowns from the sterile field during the procedure. Biologic contamination is present.
PATIENT DRAPING	
• Prep solution must be completely dry. • Patient is draped to establish the level of the sterile surgical field before instrument tables are positioned for use.	Some surgeons use towel clips to secure drapes. Nonperforating styles are preferred. Some surgeons suture or staple specialty drapes in place.
PROCEDURE START AND FLOW	
• Position Mayo stand. • Position sterile instrument table. • Hand off ESU cords, tubing, and cables to circulating nurse. • Apply light handles.	Initiate time out before skin scalpel is provided. • Correct patient • Correct site • Correct procedure

TABLE 25.1 Systematic Activities for the Scrub Person—cont'd

Baseline Systematic Activity	Systematic Critical Thinking Activity
• Two sponges on field adjacent to incision. • Provide scalpel for skin (place skin knife aside on working end immediately after use; disarm and reload as time permits). • Provide ESU for hemostasis (keep in holder when not in use). • Clean the ESU pencil tip. • Keep instrumentation free of debris with moist sponge. • Trade one-for-one sponges and needles. • Open soiled sponges completely before discarding into sponge bucket.	Inform circulating nurse if any uncounted item has been brought into the surgical field. Reconcile all counts by starting at the patient and working toward Mayo stand and then to instrument table. Count sponges and sharps at each cavity within cavity closure. Do closing counts of sponges, sharps, and instruments during surgical site closure. Contain pathology specimen in closed container as possible before passing to gloved circulating nurse.
DRESSINGS AND DRAINS	
• Double-check type of dressing material before circulating nurse dispenses to field. • Dressing is placed over surgical site after incision is cleaned. • Disconnect tubing and cords from field. • Drapes are removed by rolling them off and away from the patient after placement of the surgical site dressing.	Wet sponge followed by dry sponge to clean closed incision. Wound closure strips may be placed over subcuticular closure. Dressing is positioned over cleaned incision before removal of drapes. Skin surrounding the dressing area is cleaned with wet and dry sponges before tape is applied.
PROCEDURE COMPLETION	
• All reusable instruments are opened or disassembled and placed in bins for decontamination in the processing area. Enzyme solution or foam may be applied before transit.	Remove the Bovie tip and place in sharps container. Disarm scalpels. Open all instrument ratchets and box locks and place in mesh tray.
Room Breakdown	**Trash Disposal**
• When patient leaves the room the table can be broken down completely. • Dispose of sharps in sharps container. • Remove light handles. • Case cart is reloaded with used instrument trays and reusable equipment. • Don examination gloves after removing gown and gloves and washing hands. • Transport the case cart to the processing area.	Dispose of biologic trash in biohazard containers. Dispose of clean trash in regular garbage receptacle. Dispose of linens in hampers. Remove contaminated gown first followed by gloves using peel-off glove-to-glove–skin-to-skin method. Wash hands with soap and water after removing gloves. Clean all case-specific equipment with antiseptic and return to storage.

TABLE 25.2 Systematic Activities for the Circulating Nurse

Baseline Systematic Activity for All Cases	Systematic Patient Care
PATIENT ASSESSMENT AND SAFETY	
• Assess for patient identity and correct site information concerning the planned procedure. Note the presence of correct site markings. • Assess physiologic and psychologic status. • Laboratory work • Current medications and herbals • Allergies and sensitivities • Last intake by mouth • Location of family or significant other	Talk to the patient and determine understanding of the procedure. Observe surgeon's initials on surgical site. Follow facility policy concerning hard to mark sites. Check the paperwork/chart/computer for consents, tests, and family contact information. Check for x-rays, digital information, or scans for use during the procedure. Consult with anesthesia provider and surgeon for information exchange.
ROOM SETUP	
• Ensure a clear path for emergency equipment. • Plan for adequate positioning of the anesthesia provider. • Check the OR bed for correct position. • Make sure lights are in working order.	All necessary positioning aids are available. Plan for entrance of patient without impeding the process of setup or contamination. Plan setup for position of instrument table in relation to surgical field.
STANDARD ROOM EQUIPMENT	
• Appropriate OR bed with armboards • Patient transfer device • Sequential compression device • Two IV poles • Patient-warming device	Check equipment (suction and ESU) for proper function. Place equipment in a position of function. Plan for cords and tubing to be passed off in one direction. Avoid having cords and cables as "trip hazards" if lights are lowered for endoscopy or other procedure in which the lighting is changed. Some facilities use green room lighting for endoscopic cases.

Continued

TABLE 25.2 Systematic Activities for the Circulating Nurse—cont'd

Baseline Systematic Activity for All Cases	Systematic Patient Care
• Mayo stand • Instrument table • Prep stand • Monopolar ESU and dispersive electrode • Suction collection apparatus • Platform steps for team	
CASE CART CONTENTS	
• Instrument set(s) • Custom pack • Gowns • Sterile towels • Prep supplies • Additional soft goods	Check cart contents. Inspect package integrity. Check for each item listed on case cart sheet. Record preference changes on case cart sheet for computer update.
ITEMS TO HAVE AVAILABLE	
• Suture • Sponges • Sterile towels • Gloves • Staplers • Dressings	Have a few sizes available. Only open if necessary. Charge only for items used.
TABLE SETUP	
• Place packs to be opened on clean dry table surface. • Do not open items into closed container system. Edges are unsterile. • Open adequate gowns and gloves for surgeon and first assistant. • Tie gowns of team. • If blades are opened separately, inform scrub person of location on the field.	Open sterile packs in a position of function. Establish and document baseline: Count instruments, sharps, and sponges with scrub person. Provide additional sterile supplies as needed by scrub person.
MEDICATION AND/OR CHEMICALS ON THE STERILE FIELD	
• Obtain medications and/or chemicals for sterile field using patient identification number. • Dispense medications without aerosolization. • Draw up with needle and syringe. Remove needle before delivering drug to field.	Validate medication type and dose with the scrub person. Validate total amount given and administered. Charge only for drugs used on sterile field.
IRRIGATION ON THE STERILE FIELD	
• Obtain solutions of appropriate temperature for sterile field. • Dispense solutions without aerosolization. Pour in one continuous motion.	Dispense normal saline or other isotonic solution to the field after verifying the date, name, and seal integrity. Do not recap bottles unless saved for nonsterile use. Remaining solution can be used to clean the patient after the dressing is applied and drapes are removed.
ASSISTING THE ANESTHESIA PROVIDER	
• Assist with positioning during regional anesthesia. • Stand at patient's side during induction of general anesthesia, provide emotion support.	Help anesthesia personnel with IV or intubation if needed. Prepare to apply cricoid pressure as needed during intubation.
PATIENT POSITIONING	
• Don nonsterile gloves. • Provide positioning devices as appropriate. • Adequate exposure of surgical site • Appropriate safety restraints • Apply dispersive electrode after patient is positioned. Do not cut or reapply.	The anesthesia provider will indicate when it is safe to start positioning and prepping. The anesthesia provider and surgeon will determine the appropriate safe position for the surgical procedure.
SKIN PREP: DETERMINE PATIENT POTENTIAL FOR SKIN SENSITIVITY	
• One-step • Two-step	Open and set up appropriate skin prep materials. Alcohol-based preps can be a fire hazard if fumes accumulate under drapes. Expose the surgical site without undue exposure. Protect nontarget areas from pooling. Drapes should not be applied until prep has dried completely.

TABLE 25.2 Systematic Activities for the Circulating Nurse—cont'd

Baseline Systematic Activity for All Cases	Systematic Patient Care
PROCEDURAL POSITIONING OF EQUIPMENT AND TEAM	
• Assist scrub person to move sterile table adjacent to surgical field. • Attach cords, cables, and tubing to appropriate devices. • Place suction canister in direct view of anesthesia provider. • Provide standing platforms/steps as needed.	Scrub person will hand off cords and cables in one direction. Determine machine settings per surgeon. Scrub person will place sterile Mayo stand over sterile field.
Procedure Start and Flow	**Documentation**
• Initiate the time out, verifying the patient name, procedure, and correct site. • Prepare specimens for pathology. • Communicate with family or significant other within acceptable parameters for patient privacy.	• Procedural times and time out • Additional items not in the baseline count added to field or placed in patient • Assure that all implants, scans, and procedure-specific items are present before the procedure is started. Validate these items during the time out process and document on the surgical checklist. • Handle specimen containers wearing examination gloves. • Family updates as appropriate.
DRESSINGS AND DRAINS	
• Dispense dressing materials to sterile field at end of procedure. • Don nonsterile gloves to clean skin edges after patient is undraped. • Tape dressings. Avoid affixing to hairy surface.	One-step prep should not be removed.
PROCEDURE COMPLETION	
• Reconcile closing count with scrub person. Begin count from surgical field on patient to Mayo stand to instrument table. Sponges in sponge bucket are counted in increments of size and initial packaging amounts. • Prepare hand-over report for postprocedural area nursing staff. • Transport patient to postprocedural area with anesthesia provider.	Give hand-over report to RN in postprocedural area. • Patient name and age • Allergies or sensitivities • Current procedure and type of anesthesia • Location of incisions, dressings, and drains • Special needs (language, vision, hearing) • Location of family or significant other • Any procedure-specific information • Pertinent comorbidity

12. If a case cart system is used, all or most of the needed supplies should be on the cart. Check the case cart sheet/inventory list to ascertain that everything is there and that the wrappings are intact. Position the case cart near the instrument table. Collect additional instruments and supplies according to the preference card or case cart sheet and from cabinets in the room or from another supply area within the OR suite.
13. Obtain an appropriate set of sterile, wrapped instruments from one of the cart shelves and place on top of the case cart. Some facilities use ring stands for opening instrument trays.
14. Place the sterile, wrapped drape pack (or custom pack) on the instrument table so that when opened, the wrapper will adequately drape the table and the drapes will be in their proper place. Open the drape pack first to establish a sterile place to open other sterile items. A splash basin can be opened onto the field near the working end as a catch basin for opening small packages. If a metal basin is used, do not open metal items or blades into the basin. The metal on metal strikes can cause damage to honed surfaces and cause free fragments that could end up in patient tissues.
15. Select the correct-size gloves and gowns for each member of the sterile team. A prep table can be opened as a sterile gown table. The extra gloves for double-gloving can be opened onto the sterile table.
16. Select the initial sutures to have ready for the surgeon. Open only those needed to begin the case, such as free ties or stick ties. These can be opened into the sterile basin on the main field near the working end of the table. Place unopened but probably needed sutures on top of the case cart for opening as the case progresses.
17. Open the instrument set. If it is a wrapped set, open the wrapper on top of the case cart or ring stand. If the instrument set is in a closed container, open the container by lifting the lid straight up and tilted back toward your body. Do not open any supplies into a rigid instrument container, because the edges are not considered sterile.

Opening Sterile Supplies

The doors to the room should be shut to maintain positive pressure, and each team member present should be wearing appropriate OR attire for the restricted area. Before any sterile supplies are opened, the integrity of each package must be checked for tears and watermarks. If either is present, the package is unsafe to use. The external chemical process monitor should be checked to validate that the package has been through a completed sterilization process. Open packages as follows:

1. Remove tape from packages wrapped in woven fabric wrappers. Laundry machinery can be damaged by wads of tape becoming lodged in the mechanisms. Few facilities use woven wrappers. The tape should be opened by breaking the seal on paper or nonwoven material. Removing tape strips from paper-wrapped items increases the risk for tearing the wrapper and exposing the contents to contamination. Check the external chemical indicator tape to be certain the item has been exposed to a sterilization process.

PROS/CONS

Reliance on Scanners and Machines to Validate Sponge Counts

Pros

- Computer-assisted handheld counting devices using bar codes tagged with radiofrequency identification (RFID) aid in verifying the manual sponge count. Sponges are the most commonly retained surgical item.
- The scanners are easy to use with proper training and standard operating protocols. Staff members are held accountable by live demonstration and competency on how to use the new technology.
- Every sponge has an individual bar code/RFID and number making it easy to detect if a sponge is missing. Scanning sponges takes place before the start of a case and before wound closure.
- In the case of a missing sponge, the staff at the field has the opportunity to look for it before wound closure; the circulating nurse can check the floor, trash cans, or any other unsterile area around the sterile field. The sponge must be accounted for before the closure of the surgical wound.
- Some scanning systems provide a wand device that can be passed over the patient's body to validate the absence of a retained sponge before the patient leaves the room.
- Some scanning systems provide permanent documentation of the counting process.
- Assistive technology has the potential to reduce hospital litigation expenses, unreimbursed surgery, surgical delays, and reduce radiation exposure.
- The technology lowers the risk for retained sponges with the computerized system.

Cons

- During a manual sponge count the paper band should be broken; the sponges should be individually separated from the packed set, counted, and placed on the back table. Scanning the band and fanning the sponges is not an acceptable form of counting.
- Plain radiography is used to locate a retained sponge. It has a false-negative rate of 10% to 25% despite the radiopaque marker.
- Counting is not foolproof. Human errors in arithmetic are a cause for inaccurate counts.
- Risk factors for discrepancies in sponge counts include open procedures, trauma, failure to follow the counting policy, distractions, multitasking, shift change, sponges opened during a case, and poor communication.
- The scanning system can be labor intensive and expensive. The purchase of the equipment, radiopaque sponges, and staff education and training can be costly.
- Reliance on scanning systems should not replace human intervention and common sense. Using counted sponges after the final scanned count can result in a retained sponge.
- Individual variation in counting, timing of counts, poor documentation, communication breakdown, and interpretation of policy can result in counting errors.
- Standardized count policies must be specific to when counts are done, explain the method of counting, and define where to start the count. The policy should contain information for shift changes, emergencies, broken equipment, and what to do if there is a sponge count discrepancy.
- Reeducation of current standards ensures better patient outcomes.

2. Open the drape pack, instrument set, and gown pack on their own individual surfaces so that the inside of each inner wrapper becomes a sterile table cover.

   For an envelope-folded wrapper, open the first flap of the wrapper away from yourself. The area touched falls below table level, and the inside of the wrapper remains sterile. Each flap will look triangular. Do not reach over the inside of the sterile table cover or contents of the pack. Pull open each side by pulling the side flaps open, one at a time. Lift the final edge of the wrapper toward you to complete the opening of the sterile field.

   For a square side-folded wrapper, open one side, followed by the other side, in a sideways motion so both sides are over the edge of the table. The front and back flaps can be difficult. Both team members should do this step together—one person stands on one side of the table, and the second person stands on the opposite side. Each (simultaneously) grasps a lower edge of both the front and back flaps and opens both flaps together to complete the opening of the pack.

   For a square front-back–folded wrapper, the steps for the envelope fold are followed in the same sequences. Each flap will look square. The final square flap will be brought toward your body to create the field (Fig. 25.2).

   a. If packs or sets have sequential double wrappers, both layers are opened by the person opening supplies by following the same sequences twice. The outer wrapper is considered the dust cover and the inner wrapper the sterile barrier. The person opening the inner wrapper need not be sterile.
   b. Open other packages, such as sponges, gloves, and sutures, maintaining a sterile transfer to the appropriate sterile table. Touch only the outside of the outer wrapper. Avoid reaching over sterile contents and the sterile table. Enclose your hand in the wrapper to the extent possible. Do not slide the inner package over the edge of the peel-pack pouch. Sutures and blades should be opened onto the working edge of the table. Always open blades to the same spot for safety and consistency.
   c. If small peel packages are sequentially double-wrapped (i.e., a peel package inside a peel package), only the outer wrapper is removed. Usually the inner wrapper contains several smaller parts that may accidentally fall off the table when dispensed.
   d. Instruments processed in rigid, closed container systems are opened by breaking the seal on the sides of the lid and raising it up and away from the tray. The inner basket of instruments is considered sterile, but the container itself is not. Sterile soft goods, sutures, and other individually wrapped items should not be opened into this pan, because the edges are not considered sterile.
   e. If a sterile package is dropped, the item may be considered safe for immediate use only if it is double-wrapped in an impervious material and the integrity of the package is

• **Fig. 25.2** Opening square-fold sterile pack. Wrapper is lifted back while keeping hands on the outside. Hands are in folded cuff to avoid contaminating contents of pack. Area touched falls below unsterile table level; sterile inside of wrapper (now table cover) remains sterile.

maintained. Both wrappers should be removed to dispense the item to the sterile field.

f. Mechanical items such as staplers and endoscopic trocars should not be flipped onto the field. The mechanisms can be damaged and may malfunction when used in patient care. Do not open these items until a sterile team member can take them directly from the inner aspect of the package immediately before use. These items should be opened last and extracted from the packaging by the scrub person.

g. Blades should be opened on the working end of the sterile field. The scrub person should be aware of exactly where these are opened. Do not open other items near the blades. Do not open blades into metal basins. This dulls the cutting surface. This location should be standardized for systematic safety for the scrub person.

3. The gown and gloves for the scrub person are opened on the Mayo stand or small table separate from the main sterile field. The person establishing the sterile field should not gown and glove from the main field because the risk for contamination is higher than gowning and gloving from a separate surface. The scrub person should glove using the closed gloving method for the first glove layer in double gloving. The outer glove can be applied from the separate table or the main field.
4. The circulating nurse assists the anesthesia provider with patient care preparations if needed as the scrub person sets up the sterile field after scrubbing, gowning, and gloving. If the patient has arrived to the room, the circulating nurse can do the initial assessment and patient check-in.

Scrub Person Duties

When all supplies have been obtained and opened and the room is ready for the patient's arrival, the scrub person prepares for the surgeon's arrival. At all times, the integrity of the sterile field is closely monitored. The principles of aseptic and sterile techniques are followed.

Preparation of the Sterile Field

The gown and gloves are open and ready on a surface separate from the sterile field before the scrub person performs surgical hand hygiene. The scrub person, wearing a mask, dons protective eyewear with side shields and performs a complete surgical hand cleansing according to the facility procedure.[2]

Gown and Glove Using the Closed Gloving Method

If double-gloving, wear gloves one size larger as the first layer and the usual size gloves as the second pair. The larger size underneath provides an air pocket and helps prevent a sensation of tightness around the hands. If hypoallergenic gloves are worn, these should be donned as the first pair, with generic sterile gloves worn as the outside pair. Most facilities no longer use powdered gloves; however, if powdered gloves are used, wipe any powder from gloves with a moist sponge before handling drapes, instruments, and other sterile items. This sponge should be completely opened and dropped into the sponge bucket as part of the count.

When establishing the main sterile field, drape unsterile tables according to the standard departmental setup procedure with drapes from the drape pack. Most facilities will consider the outer wrap of the custom pack as the main sterile table cover. The scrub person may need to drape and set a small table for the patient's skin prep, but more commonly the circulating nurse opens and prepares a disposable or prepackaged prep tray for each surgical site if more than one incision is planned. A second instrument table may be needed for extensive surgical procedures or special types of instrumentation (e.g., tables for preparation of an implant or organ for transplant).

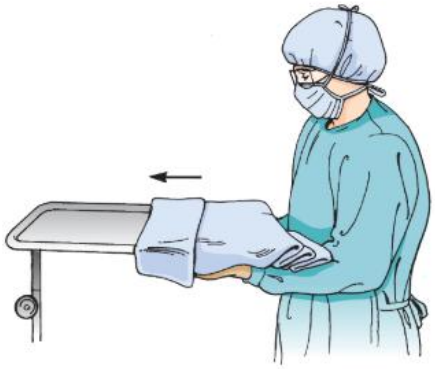
When draping an unsterile table with a separate sterile table drape, unfold it toward yourself to cover the front edge of the unsterile table first; this minimizes the possibility of self-contamination from the edge of the table. Unfold the remainder of the sterile table drape over the surface of the table and away from yourself. The edges are allowed to fall over the ends of the table and are considered contaminated below the tabletop. Avoid leaning over the table.

Place the remaining contents of the drape pack on a corner of the instrument table. Place them once—do not keep moving things from one side to another. Custom packs usually contain disposable supplies that are nested within each other and require minimal handling when setting up the field. Reusable woven fabric drapes may be arranged within the drape pack according to the size or direction of the folds. A standard number of each item is contained within a drape pack. A list of items and their numbers is usually affixed to the outer surface of the pack. The basic drape pack usually contains, at a minimum, the following items:

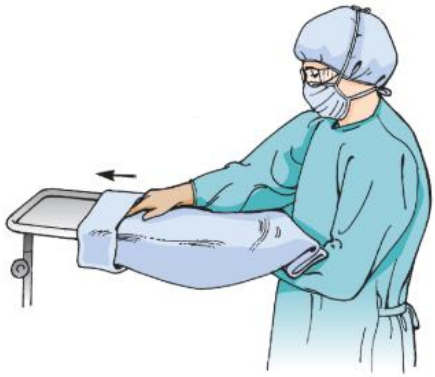
- One Mayo stand cover
- Four to eight towels
- Two to four medium drape sheets (optional)
- One fenestrated sheet

Draping the Mayo Stand

When draping the Mayo stand, drape both the frame and the tray. The Mayo stand cover is like a long plastic pillowcase with a single



• **Fig. 25.3** Starting to drape Mayo stand. Scrub person's hands are protected in cuff of drape. Folds of drape are supported on arms, in bend of elbows, to prevent their falling below waist level. Foot is placed on base of stand to stabilize it.



• **Fig. 25.4** Completing draping of Mayo stand. Hands are protected in cuffs.

sheet of nonwoven fabric that will lie on the flat surface that will hold instruments. It is fan-folded with a wide cuff to protect gloved hands. With hands in the cuff, support the folds of the drape on the arms, in the bend of the elbows, to prevent it from falling below waist level (Fig. 25.3). While sliding the cover on the Mayo stand, place a foot on the base of the stand to stabilize it (Fig. 25.4). Some sterile custom packs contain an impervious plastic disposable Mayo tray as the bottom layer of the pack. At some facilities, a stainless steel Mayo tray is wrapped snugly and sterilized separately. The tray can be set into the draped Mayo stand or placed on the working end of a Mayfield overbed table.

Basin Setup

If reusable basin sets are used, leave the large solution basin in the ring stand and take the remainder of the basins to the instrument table. The wrapper on the basin set serves as the cover for the ring stand with the large basin. Fabric or paper towels separate the basins. The fabric towels can be folded and placed on the stack of towels on the sterile field. They can be used for wiping instruments or cleaning the patient at the end of the procedure. Many facilities consider all towels as counted items.

Many facilities have discontinued the use of ring stands because they are usually lower than the established sterile field (i.e., the instrument table and the draped OR bed). The use of basins as splash basins is discouraged, but a few surgeons still prefer to use them to wash their gloved hands at the start of the case or during the case as blood and debris accumulate on glove surfaces.

If powdered gloves are used, the splash basin is not highly effective for powder removal because the powder redeposits on the gloves as the hand is withdrawn from the water. If basins are used for this purpose, the circulating nurse should fill them with sterile normal saline or sterile water and remove them from use when the water is grossly dirty. Each time someone rinses his or her gloves in the basin, debris can be transferred back to the patient, causing foreign body granulomas. Standing water can collect microorganisms from the air and encourage an infection.

The preferred methods for removing powder or blood from gloves is either to use a sterile towel or sponge moistened with sterile saline or to pour sterile saline or sterile water directly over the gloved hands. The basin should not be permitted to sit after being used to rinse glove powder; it should be emptied into the dirty sink in the utility room by the circulating nurse. Any counted sponge should be unfolded and dropped into the sponge bucket for counting.

Some facilities use the large solution basin directly on the sterile field to collect and rinse used instruments. Only distilled sterile water should be used for this purpose because saline is corrosive. Disposable custom packs usually contain plastic basins that can remain on the sterile instrument table.

Separate 1 or 2-liter sized basins are arranged close to the working edge of the instrument table for holding sterile warm irrigation solution (usually Ringer's lactate or normal saline), for securing the specimen after it is procured, and for moistening sponges.

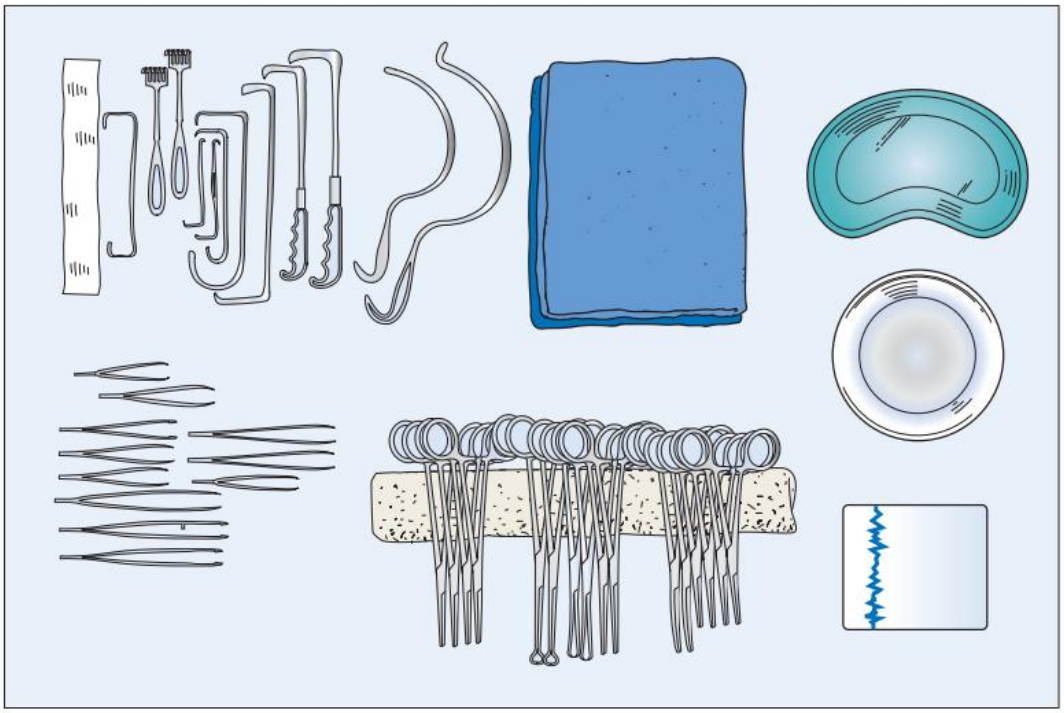
All basins, containers, and delivery devices should be clearly labeled to identify their contents. The practice of dipping sponges into the irrigation solution should be discouraged because this releases lint into the solution, which in turn can be introduced into the patient during irrigation. Lint can contribute to foreign body reactions and granulomas in the tissues of the patient. An Asepto syringe can be used to moisten sponges with warm saline in their own basin. The run-off should not be used as irrigation.

The basin set also may contain solution cups for the skin prep table and/or a basin specifically intended for trash (waste suture packaging) disposal. Attaching a trash bag to the side of the table compromises the sterility of the field because the bag hangs lower than the sterile table surface. If these bags are used, the inside is not considered sterile because it is below the level of the sterile field. These bags can be hazardous if a needle becomes ensnared in the suture debris and perforates the thin exterior surface of the bag. It could puncture the scrub person during handling. Do not reach into the bag at any time. The use of empty suture packets from the trash is not an appropriate method of accounting for needles during the count.

Arranging the Instrument Table

Arrange other instruments and items on the instrument table (Fig. 25.5). Table 25.3 describes the "Eight P's" of table and room organization, which can help the scrub person and circulating nurse improve the efficiency of the setup procedure and the case flow.

The instruments for each surgical procedure are selected and placed according to standard basic sets and the preferences of the surgeon. Instruments of suitable size, shape, strength, and function are needed for each step of the surgical procedure. The styles and numbers of instruments are dictated by the type of surgical procedure. Standardization of instrument sets is cost effective and supports the use of a system for counting and accounting for instruments during the procedure.



• **Fig. 25.5** Example of basic instrument table setup. Contents will vary according to the type of surgical procedure.

TABLE 25.3 The "Eight P's" of Operating Room and Sterile Field Setup and Management

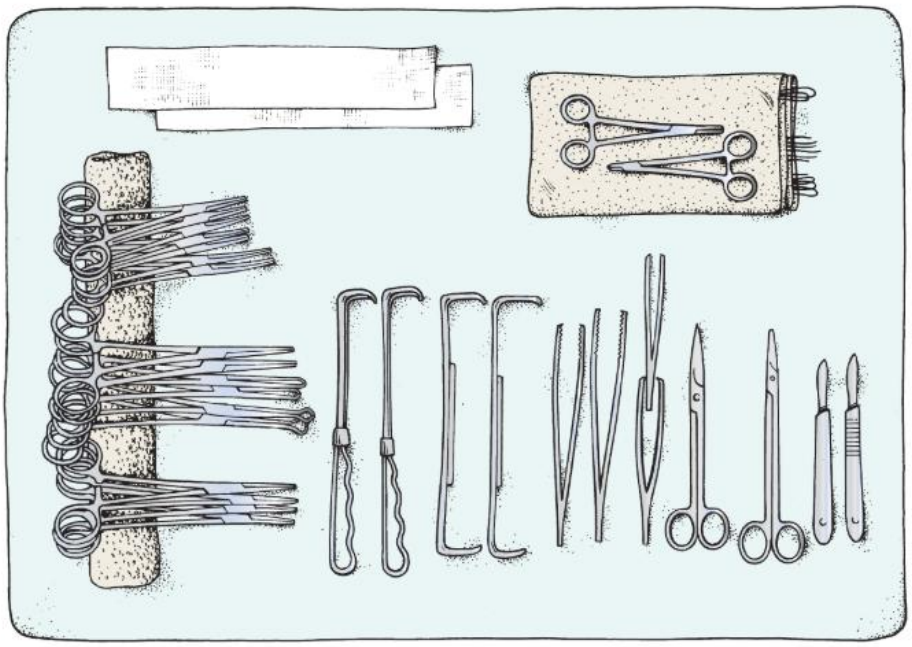
The Eight "P's" to Consider When Preparing for a Surgical Procedure[a]	Environment Considerations for the Circulating Nurse	Sterile Field Considerations for the Scrub Person
PROPER PLACEMENT		
Items should be placed so they will not need to be moved during the procedure.	Suction canisters, tourniquet, and the electrosurgical unit (ESU) need to be stationary. The OR lights should be directed toward the field.	The Mayo stand and instrument table should not be moved during the procedure. Drapes may not be moved on the patient's skin.
PROPER FUNCTION		
Items should be tested for safety and usefulness before they are needed, to prevent delay in the case.	Test the ESU, tourniquet, laser, and other equipment before the patient enters the room.	Test the efficiency of instruments (e.g., scissors, needle holders, clamps) as they are needed.
PLACE IT ONCE		
Items should not be manipulated during the procedure. Energy and attention should not be diverted to resetting the field.	The OR bed should be in the right place for the procedure. The dispersive electrode should not be moved or displaced.	When setting up the field, each item (e.g., a basin) should be placed where it will be used during the procedure with minimal handling.
POINT OF CONTACT		
Items used within the field could cause harm or be rendered useless if they do not reach the intended point of contact.	The circulating nurse should evaluate the delivery of items to the sterile field. Some items (e.g., staplers) should be handed; others can be transferred in other ways.	The scrub person should be aware of the passing of instruments and how they are securely placed in the waiting hand of the surgeon or first assistant.
POSITION OF FUNCTION		
Items should be positioned so they will be usable during the procedure.	The use of a C-arm, laser with articulating arm, or microscope should be preplanned so they may be positioned while the procedure is in progress.	When passing instruments, they should be placed in the surgeon's hand in a usable way. For example, the curve of the instrument should match the curve of the hand.

Continued

TABLE 25.3 The "Eight P's" of Operating Room and Sterile Field Setup and Management—cont'd

The Eight "P's" to Consider When Preparing for a Surgical Procedure	Environment Considerations for the Circulating Nurse	Sterile Field Considerations for the Scrub Person
	POINT OF USE	
Items should be as close to the area of use as possible.	Pour solutions directly into the basins; open and hand sponges or sutures directly to the scrub person as they are needed.	Basins should be placed close to the edge of the table so the circulating nurse can pour without requiring the basin to be repositioned. The ESU pencil holder should be close to the field for safe containment of the tip.
	PROTECTED PARTS	
Items and surfaces should be rendered safe for the patient and the team.	Cords, cables, and tubing should be secured and appropriately directed away from the field. Pad the OR bed and patient as appropriate. Use safety belts.	Apply jaw liners to instruments during setup. Hand instruments with care to avoid causing injury with the tip or sharp surface. Do not lay items on or against the patient's body.
	PERFECT PICTURE	
Items within and around the field should not be at risk for causing harm or becoming damaged. The environment should not be cluttered.	The entire room should appear neat and tidy. The door should be closed, and the temperature and humidity should be appropriate. Forethought to having a clear path for the crash cart or setup emergency equipment is essential.	The sterile field should remain neat and orderly, with instruments and supplies within easy sight and reach. Consistency fosters a sense of comfort and confidence in the scrub role.

[a]The examples used for each "P" will vary according to the type of procedure and equipment, the position of the patient, and the surgeon's preference. The Eight P's apply to both the scrub person and the circulating nurse.



• **Fig. 25.6** Example of setup for Mayo stand.

Arranging the Mayo Stand

Arrange the instruments and accessory items needed to create the primary incision and control initial bleeders on the Mayo stand. A few of each classification of instruments and sponges may be put on the Mayo stand initially. If a local anesthetic will be used, one or two labeled syringes with appropriate-size hypodermic needles also are needed.

One possible setup of the Mayo stand is illustrated in Fig. 25.6. As the surgical procedure progresses, additional instruments and supplies can be added or deleted as necessary. Long-handled forceps and clamps and deep retractors can be substituted for those used on superficial structures.

The Mayo stand should be kept neat throughout the surgical procedure. Do not overload it with sponges and sharps. The needle

• BOX 25.3 Packaging Increments of Common Sponges

Sponges are packaged in increments of 5 or 10 and are embedded with a radiopaque strip. The incremental complement is bound with a paper band or wound onto a cardboard holder or Styrofoam holder. Towels can be specially packed in counted increments for use within the body as retractor padding or as a visceral retainer.

1. Raytec or Raytex with embedded radiopaque string 10 per pack (aka: 4 × 4s, 4 × 8s, pusher, gauze sponge).
2. Laparotomy sponge with radiopaque loop 5 per pack (aka: lap tape, lap sponge, lap pad) available in sizes 4 × 8, 12 × 12, 8 × 36, 18 × 18, 8 × 108.
3. Tonsil sponges with long radiopaque string: 5 per pack (aka: tampon) available in small, medium, and large. Available without the string. Radiopaque element is embedded within the fabric of the sponge.
4. Cottonoids with radiopaque strings: 10 per pack (aka: patties or neuro sponges). Some facilities refer to cottonoids by their size in length in inches (i.e., ¼, ½, 1, 2, or 3).
5. Peanuts with embedded radiopaque element: 5 per pack (aka: pusher, cherry, or dissector).
6. Kitner tightly wound dental tape with embedded radiopaque element: 5 per pack (aka: dissector).
7. Surgical towels with radiopaque element in blue or white. Commercially packaged in counted increments of 3 or 5. Not used as drapes.

counting magnet or box should not be kept on the Mayo stand because it is easily bumped during the procedure and could discharge needles into the surgical field. No one should reach over and take things off the Mayo stand. This can cause instruments to fall.

Establishing Baselines

The scrub person should count sponges, surgical needles, other sharps, and instruments with the circulating nurse according to established facility policy and procedure. After completing the initial baseline count with the circulating nurse, a few appropriate-size sponges for the initial incision are placed on the Mayo stand. Many different types of precounted sponges and special towels are available (Box 25.3). The gauze sponges may be opened to their full length or left folded. Fix two or three sponges on sponge forceps (if these will be used), but leave the forceps on the instrument table. Sponges and counting procedures/technology are discussed later in this chapter.

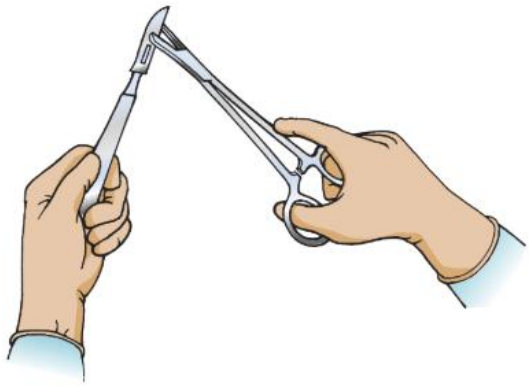
Managing Sharps

After completing the baseline counts with the circulating nurse, the scrub person should secure surgical needles and all other sharps, including knife blades. Blades should be opened onto a consistent spot on the field that is agreed upon by everyone who scrubs and circulates. This will help avoid inadvertent cuts to the fingers of the scrub person, who may be unaware of where blades have been opened onto the field.

Surgical needles and sharps should never be loose on the Mayo stand. If eyed reusable needles are used, each needle must be inspected for cleanliness, burrs, and integrity of the eye before threading. Disposable needles are preferred.

Loading Scalpels

Put blades on knife handles. To avoid injury, always use a heavy instrument, such as a Kelly or Pean clamp, to attach the blade; never use the fingers. Avoid using a needle holder because this can weaken the jaws and damage the needle holding surface. Holding the cutting edge down and away from the eyes and other personnel in the room, grasp the widest and strongest part of the blade above the notch with the heavy clamp, and slip the blade into the groove on the knife handle. A click indicates the blade is in place. To prevent damage to the blade, the instrument should not touch the cutting edge of the blade (Fig. 25.7).



• **Fig. 25.7** Putting scalpel blade on knife handle. To avoid injury, always use an instrument; never use fingers. The blade is attached with a heavy instrument. Grasp blade at its widest, strongest part, and slip it into groove on handle. The handle and blade are pointed down and away from eyes and other personnel.

Scalpels should be loaded early in the setup procedure. This is a good habit to acquire because in emergency surgery the surgeon could be opening the patient while the setup ensues. Time can mean a patient's life. The counting process is handled differently during emergency life and death procedures and is sometimes aborted in favor of an x-ray.

Preparing Sutures and Ties for Use

Prepare sutures in the sequence in which the surgeon will use them. The surgeon may ligate (tie off) large blood vessels with a suture ligature shortly after the incision is made, unless electrosurgery is preferred to seal vessels. Prepare ligatures (free ties) first if they will be used. Remove suture material from the packet, unless the packet is designed for single-strand dispensing. When trimming the ties to size, work over the instrument table and hold on to the ends of the suture material to prevent strands from dropping over the edge of the table and thus becoming contaminated.

Dispensing reels, relay packets, or strands of ligating material can be placed in a fan-folded towel, with the ends extended far enough for rapid extraction. Place the largest size in the bottom layer along the fold that is farthest away when placed on the Mayo stand or the working end of the instrument table. The next smaller size is placed in the next layer so that the ends are not overriding those below; if three sizes are prepared, the medium size can be placed midway between the other two. The smallest size will be along the closest fold. To prevent possible contamination, strands are pulled out toward the surgical field, never away from it.

A few packets of suture may be opened and prepared for suturing. Seldom is it necessary to prepare large amounts of suture material in advance. Surgical gut suture should not be opened before use if possible. It will dry out and lose tensile strength. If it must be opened for the surgical count, tear the corner of the packet enough to visibly count the needle and close the packet without spilling the liquid contents because it is flammable. Gut suture should not be rinsed before use. Suture materials, preparation, and handling are discussed in detail in Chapter 28.

Handling Medications and Solutions on the Sterile Field

Make labels for the sterile container and the syringe. Sterile labels and marking pens are commercially available for labeling containers for medications, contrast media, dyes, and other solutions used in the sterile field. Labeling is done immediately after the drug is dispensed and should include the name and strength of the solution. An appropriate label should be placed on delivery devices, such as syringes, basins, and medicine cups to prevent inadvertent use of the wrong solution in the wrong manner.

Medications and solutions are dispensed to the sterile field by the circulating nurse after confirming drug identification and expiration with the scrub person. The solution basins and medicine cups should be placed near the edge of the sterile field. If a local anesthetic is to be used, the circulating nurse will dispense the drug to the field after drawing it into a syringe. The drug is not dispensed to the field through the needle because it becomes aerosolized and could expose susceptible people. It is not wise to point a needle for any reason in the interest of safety. Do not spear a bottle held by another person. This is risky and equates with the dangers of recapping needles by hand.

Syringes and Their Handling

Fill the syringe, affix the label, attach an appropriate-size needle, and put it on the Mayo stand. This will be the first thing the surgeon will use after the patient is prepped and draped. State the type and percentage of the solution when handing the syringe to the surgeon. Some facilities use a "no touch" technique. This means that the filled syringe is placed in a basin or tray for the surgeon to retrieve. Do not recap any needle by hand. Recapping the needle can be done by laying the cap on the instrument table and sliding the needle inside. Place near the working end of the table with the needle pointing away from you.

Syringes with needles are used for injection and aspiration, and syringes without needles (e.g., Asepto, Toomey) are used for irrigation. Care is taken to determine whether the patient is at risk for latex sensitivity, because some syringe plungers or squeeze bulbs might contain latex. Nonlatex injection and irrigation syringes are commercially available. Glass syringes in the same models and sizes are occasionally used. These will be wrapped separately with the barrel and plunger apart. When using a sterile syringe, be very careful not to touch the plunger. Contamination of the plunger contaminates the inner wall of the barrel and thus the solution that is drawn into it. Glove powder and other debris can act as a contaminant and cause a foreign body reaction.

The following types of syringes are commonly used for injection or aspiration:

- *Luer-Lok tip:* This type of syringe has a tip that locks over the needle hub. It is used whenever pressure is exerted to inject or aspirate fluid. Sizes range from 2 to 100 mL.
- *Ring control:* This type of syringe has a Luer-Lok tip. The barrel has a thumbhold and two fingerholds, which give the surgeon a secure grip when injecting with only one hand. Sizes range from 3 to 10 mL.
- *Luer slip tip:* This type of syringe has a plain, tapered tip that may not give a secure connection on a needle hub. It is necessary when using some catheter adapters or a rubber connection for aspiration. Sizes range from 1 to 100 mL.

The size of hypodermic needles is designated by length and gauge. Gauge is the outside diameter of a needle, which gets smaller as the number gets larger (e.g., a 30-gauge needle is smaller than a 20-gauge needle). The length will depend on the intended injection site. Longer needles are used for thicker tissue areas. Although numerous sizes of needles are available, only a few representative sizes and their uses are mentioned here:

- ½ inch (12.7 mm) × 30 gauge, for intradermal local anesthetic
- ¾ inch (19 mm) × 24 or 25 gauge, the usual needle for any subcutaneous injection
- 1½ inches (3.8 cm) × 22 gauge, for subcutaneous or intramuscular injection
- 2 inches (5 cm) × 18 or 20 gauge, for aspiration
- 4 inches (10 cm) × 20 or 22 gauge, for deep injections into joints or for intracardiac injections

The following types of syringes are used for irrigation:

- *Bulb with tapered barrel:* With this type of syringe (commonly referred to by the trade name Asepto syringe), a plastic or rubber bulb is attached to the neck of the barrel. The barrel has a tapered or blunt end (like a turkey baster) and can be made of plastic or glass. It is used for one-hand control of irrigation during many types of surgical procedures. This type of syringe has a solution capacity of ¼ to 4 ounces (7.6 to 118 mL).
- *Tapered bulb without barrel:* This type of syringe is a one-piece bulb that tapers to a blunt end. It is used to irrigate small structures, and it may be used for suctioning nasal and oral fluids from neonates during deliveries by cesarean section or used for neurosurgery. This variety is usually disposable because it is not possible to clean the interior of the bulb after use.

To fill an irrigation Asepto syringe, depress the center of the bulb, submerge the tip in solution, and release the bulb. The bulb will reinflate, thus drawing solution into the syringe. Take care not to let the bulb express its contents into the air while withdrawing it from the solution. The liquid can hit unsterile surfaces such as the lights and drip onto the sterile field.

Warm, not hot, solution generally is used for irrigation; check the temperature before giving the syringe to the surgeon. Irrigating solution may be stored in a warmer maintained at a temperature that ranges from 98.6° F to 110° F (37° C to 43.3° C). For use, the solution usually should not exceed the temperature of bath water.

After the Surgeon and Assistant(s) Scrub

Gown and glove the surgeon and assistant(s) as soon after they enter the room as possible, if this is a routine procedure. This procedure should take precedence over other setup activities, but do not interrupt a sharps, instrument, or sponge count to do so; such interruptions lead to incorrect counts. The surgeon and assistant(s) may take their gowns from a separate table that has been set up for this purpose. The scrub person should always glove the remainder of the team by the assisted open-glove method. The team should never take towels, gowns, or gloves from the primary sterile field.

Draping the Patient

After the patient is positioned and prepped, assist in draping according to the type of procedure and the surgeon's preference. Some surgeons use towels secured with towel clips to square off the incision. To prevent reaching over the unsterile OR bed, go to the same side of the table as the surgeon to hand towels and towel clips. For hard-to-drape areas, skin towels may be held in place with sutures or staples rather than clips.

Some surgeons use self-adhering plastic incise sheeting directly over the squared-off incision site; the adherent sheeting may be plain (clear) or impregnated with iodophor. To apply this adherent drape, stand on the opposite side of the OR bed to assist as

the surgeon positions the adherent surface over the patient's prepped skin. A large sheet of paper will be pulled from the sticky surface as the sheet adheres to the patient. The circulating nurse should take the paper from the sterile team member and discard it. Take care not to rub the front of the gown on the undraped parts of the OR bed.

The fenestrated drape sheet is placed over this. During the draping process, care is taken not to allow sterile gloves to touch unsterile surfaces such as IV lines or equipment. Drapes are cuffed over the hands as they are positioned. Drapes are not to be moved or repositioned once they are placed. Consider the "place it once" principle.

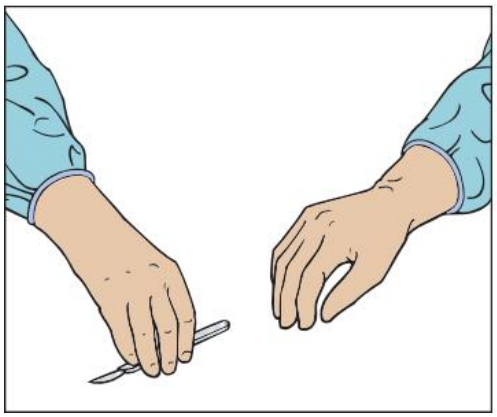
Once a perforating towel clip has been fastened through a drape, do not remove it, because the points are contaminated and the drape now has holes. If it is necessary to remove a perforating towel clip, discard it from the field and cover the punctured area with another sterile drape or towel. A transparent wound dressing (e.g., OpSite) can be stuck over a pinhole from a towel clip in an urgent situation. Nonperforating ball-tip towel clips are preferred for securing drapes.

After patient and OR bed draping is completed, bring the Mayo stand into position over the patient, making sure it does not rest on the patient. Position the instrument table at a right angle to the OR bed. Assist the surgeon in securing sterile light handles for adjustment of the OR light. The beam of light should pass the surgeon's right ear and center at the tip of the index finger of his or her right hand (or left hand for a left-handed surgeon).

Lay a towel or magnetic pad for instruments below the fenestration (opening) in the drape, and lay two dry sponges on the pad. Some drapes have loopholes or Velcro strips for threading suction tubing and ESU cords through. Allow ample length to reach both the incision area and the equipment. Drop the ends off the side of the OR bed nearest the unit to which the circulating nurse will attach them. It is helpful to have the cables and tubing directed over the same side of the field.

Starting the Surgical Procedure

Initiate a "time out" to validate correct site and correct patient. Place two sponges on the field near the incision site. Pass the skin knife to the surgeon (Fig. 25.8), and prepare to pass a hemostat and suction to the assistant. When passing the knife, take care to direct the blade away from yourself and all other personnel. Hold the hand pronated, with thumb opposed against the tip of the index finger, and flex the wrist. Eye contact is recommended when passing the scalpel.



• **Fig. 25.8** Passing the knife with the blade down and protected. The scrub person's hand is pronated.

Some surgeons do not want the knife handed to them but prefer to use a no-passing technique for sharps. When using the no-passing technique, lay the knife on an instrument tray or no-touch pad area for the surgeon to pick up. The surgeon will replace the knife onto this surface or tray after the incision is made.

The scrub person should not allow the scalpel to remain on the field after its use. It is placed on the instrument table near the working end. Skin is never sterile; therefore the initial skin scalpel is considered contaminated, whether or not the surgeon has cut through a plastic incise skin drape. The skin incision exposes deep skin flora of the hair follicles and sebaceous gland ducts. The blade is removed from the handle with an instrument and a fresh blade applied in readiness as time allows. If an existing scar is excised, it may be sent to the pathology department as a specimen for gross identification (accession). Some surgeons discard this tissue. Determine the surgeon's preferences and the facility policies.

Providing Sponges. Hand up moist sterile sponges if requested for covering skin at the edges of the incision. Open and drop soiled sponges into the appropriate sponge receptacle for counting, and add clean sponges to the field as necessary. If sponges or tapes are added by the circulating nurse during the surgical procedure, break the paper bands and count all of them aloud before use. If an RFID counter is used, pass each pack of sponges through the sensor as part of the count. Do not mix types of sponges and tapes on the table. Keep them separated for ease of identification and tracking. Breaking the paper band signifies that the pack of sponges has been counted, a visible cue for the circulating nurse.

Providing the ESU. The tip of the ESU pencil becomes hot and could burn the patient or a team member. Accidental activation can occur if pressure is exerted on the handpiece; this can cause ignition of the draping material or dry sponges. Therefore attach a container (holder/holster) to the drape with a nonperforating clip for containment of the ESU pencil. When not in use, the tip of the ESU pencil is cleaned on a tip polisher/scraper and placed into the holder. Teflon-coated blades are wiped clean with a damp sponge. The ESU tip should not be cleaned with a scalpel blade. The char should not be permitted to fall into the patient.

Towels and the Sterile Field

If the instrument towel on the sterile field becomes bloody, do not remove it but cover it with a fresh, sterile towel. Stick with the "place it once" principle. Remember that drapes should not be repositioned once they have been placed. Take care not to lay the clean towel over a sponge or instrument.

If the surgeon uses a sterile towel as packing within the wound as a retractor pad or visceral retainer, this is relayed to the circulating nurse immediately and the number of towels is tracked with all other counted items. Surgical towels may have an RFID chip embedded to enable the towel count. The circulating nurse is informed when the packing towel is removed, and it is accounted for at the conclusion of the procedure.

The practice of using towels for intraoperative packing is discouraged unless a mechanism is in place for accounting for their removal from the patient at the end of the procedure. Commercially precounted and packed disposable towels with radiopaque and RFID technology are available from several manufacturers. Reusable towels are processed in-house and do not have x-ray–detectable markers.

PROS/CONS

Surgical Towels on the Sterile Field

Pros

- Radiopaque towels may be used as a retractor or visceral retainer.
- Towel manufacturers have designed towels specifically for visceral packing. They are usually blue or white towels that contain a radiopaque strip. Some towels have the same kind of RFID tag as the radiopaque sponges. Other surgical towels for packing have a microchip that acts as a transducer to pick up radio signals.
- Some packing towels are supplied with metal or plastic radiopaque rings on a twill tape tag designed to remain outside the body when used as packing.
- A handheld scanning device can be used along with a wand that can be scanned over the patient's body to detect any missing RFID packing towels.
- Packing towels are absorbent, low-linting, and prelaundered. The material is a tight weave with a radiopaque marker. These towels are labeled for single use only.
- Packing towels should be moistened with sterile saline to avoid drying of tissues by osmosis.
- If a packing towel is used, it must be part of the original beginning count. The circulating nurse must immediately be notified if a towel is placed and document the number of towels packed in the body. When a towel is removed, it must be reported to the circulating nurse and documented.

Cons

- Green, blue, or other colored towels are manufactured to be used as part of the draping procedure or to dry hands. Draping towels usually come in custom packs, packed with gowns, or can be opened as a separate pack.
- Towels for draping are not always included as part of the beginning count at all facilities.
- Draping towels are usually made from a different grade of cotton and may be coarser than packing towels. They also contain dye that could cause an allergic or sensitivity reaction if used inside the patient.
- Draping towels do not have the radiopaque marker and are not intended to be used inside of patients.
- Surgeons often use draping towels as packing because they are present on the sterile table and convenient.
- If draping towels get soiled or wet, do not remove them. Cover them with clean towels or a clean drape. Be sure that instruments and sponges are not left under the new drapes because this could cause a miscount.
- Single-use draping towels should never be laundered for reuse. They are designed for use on one patient only. Reprocessing of any medical item, including towels, is governed by the U.S. Food and Drug Administration. Reusable towels should be laundered, delinted, and inspected for holes, stains, and breaks in fabric. Then proper sterilization policies must be followed.
- Towels without a radiopaque strip cannot be easily detected by x-ray. They have been mistaken for masses, hidden by organs, and cause abscesses. Adhesions and encapsulation eventually can lead to the development of a foreign body granuloma. A gossypiboma is a mass formed by a foreign body reaction made up of a cotton matrix. Retained foreign bodies made from fabric are also referred to as textilomas.
- Scanning systems are not 100% foolproof. Failure in scanning systems is not common; however, organs, bone, or extremities of body habitus can obscure the reading. RFID scanners should not be a substitute for the manual count.
- A policy should be in place about counting radiopaque and nonradiopaque towels and the use of nonradiopaque towels on the sterile field.

Maintaining the Case Flow. Watch the field and try to anticipate the needs of the surgeon and assistant. Keep one step ahead of them in passing instruments, sutures, and sponges and in handing up the specimen basin. Notify the circulating nurse if additional supplies are needed or if the surgeon asks for something not on the table. Ask quietly or signal to the circulating nurse for supplies to avoid distracting the surgeon. Consideration is given to the patient, who has received a local or regional anesthetic and may be awake. The patient may hear words like "needle" or "blade" and can become frightened.

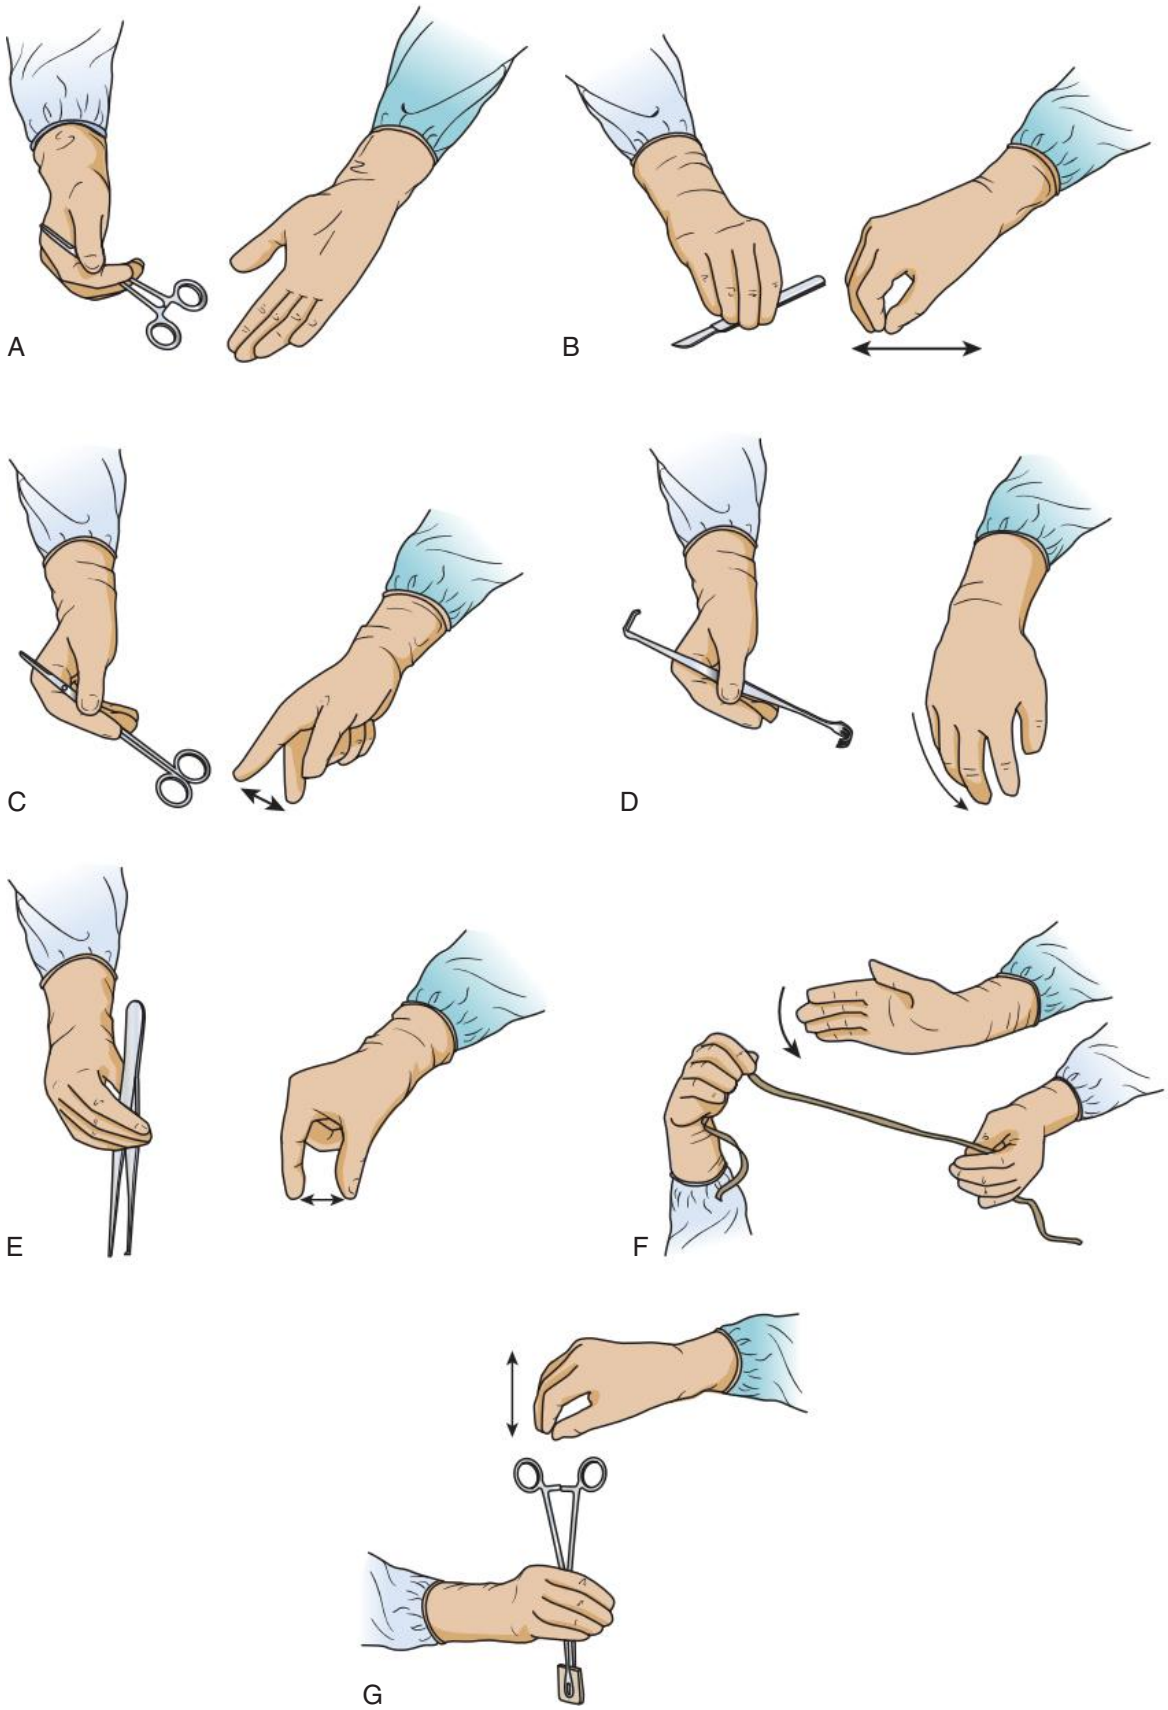
When bleeding is obvious, the surgeon needs a hemostatic forceps and/or the ESU pencil. If the bleeding is in a deep wound, the extended ESU pencil tip may need to be attached quickly. After making a deep stitch, the surgeon may want to tag the ends of the suture with a hemostat. Scissors are needed for cutting the suture. Some surgeons use hand signals to indicate the type of instrument needed (Fig. 25.9). These universal signals eliminate the need for talking, but such signs should be clearly understood. An understanding of what is taking place at the surgical site makes these signals meaningful.

Pass instruments in a decisive and positive manner. When instruments are passed properly, surgeons know they have them; their eyes do not need to leave the surgical site. When the surgeon extends his or her hand, the instrument should be placed firmly into his or her palm in the proper position for use (Fig. 25.10). Return instruments to the Mayo stand or instrument table promptly after use. Their weight or a sharp tip could injure the patient.

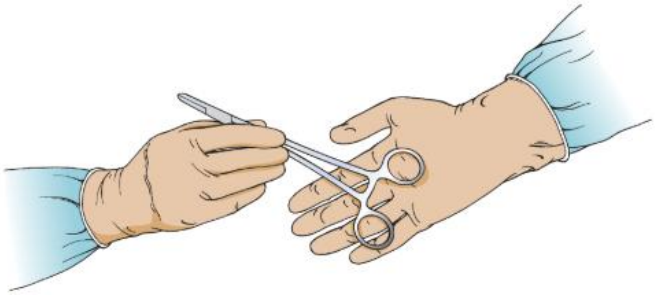
Keep instruments as clean as possible. Wipe blood and organic debris from them with a moist sponge. Remove debris from the ESU tip. To keep the suction tip and tubing patent, periodically flush the suction tip with a few milliliters of saline or sterile water. Keep track of the amount of solution used to clear the line, and inform the circulating nurse. The volume of fluid in the suction canister may be confused with blood loss.

Suture and Tie Management. Place a ligature (tie) in the surgeon's hand. The surgeon keeps both eyes on the field and does not reach for a ligature except to hold out a hand to receive it. Draw a strand out of the packet and direct it toward the sterile field, grasp both ends, and place the strand securely with an upward sweep in the surgeon's outstretched hand.

The end of a ligature may be placed in a long curved forceps, such as Adson tonsil forceps or a right-angled clamp, in a maneuver referred to as a *tie on a passer* (Fig. 25.11). This method is used when the structure will be circumferentially tied off instead of being sutured, such as a vessel in the mesentery. When handing a tie on a passer, place the forceps in the surgeon's hand in the same manner used to pass any hemostat. Trail the end of the ligature until it is taken by the surgeon or the assistant during the tying procedure. Be ready with the suture scissors as appropriate.

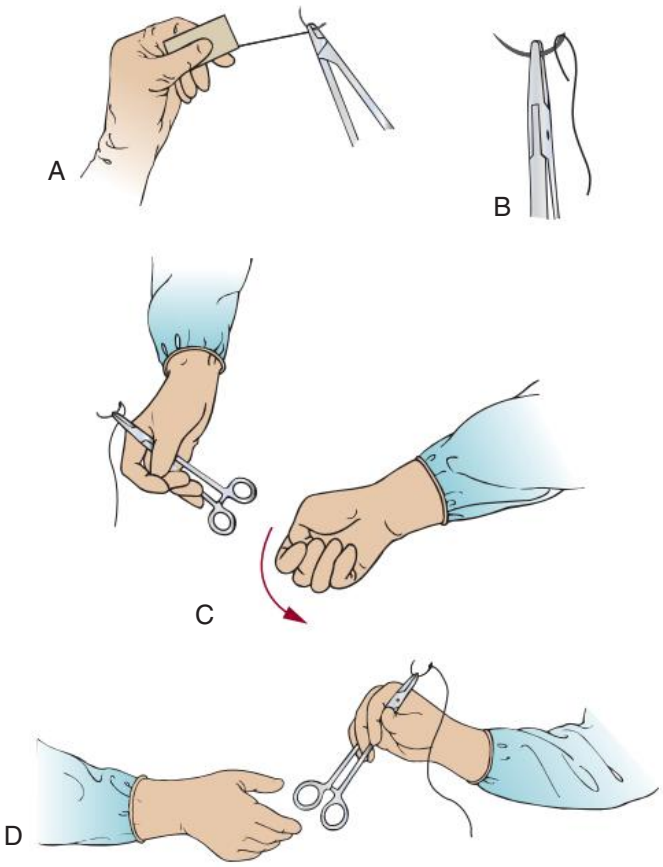


• **Fig. 25.9** Hand signals. **A,** Clamp. **B,** Scalpel. **C,** Scissors. **D,** Retractor. **E,** Pickups. **F,** Free tie. **G,** Pusher-dissector.



• **Fig. 25.10** Passing a ringed instrument. The scrub person holds the instrument by the hinge and avoids entangling fingers in the rings. Tip is visible, and handle is free. Handle is placed firmly and directly into waiting hand. A soft snap may be heard as the instrument contacts the waiting gloved hand.

• **Fig. 25.11** Tie on a passer.



• **Fig. 25.12** **A,** Loading a needle holder for right-handed suturing. **B,** Right-handed needle in needle holder. **C,** Hand signal for suture on a needle. **D,** Passing right-handed needle.

At all times during the surgical procedure have several sutures armed on needle holders ready. Load the needle into the needle holder in a left or right-hand manner according to the hand dominance of the surgeon or the direction of the suturing motion (Fig. 25.12). As the suture is passed to the surgeon, be sure the surgeon has forceps (pickups) to hold the tissue as it is sutured.

After handing a suture to the surgeon, hand the suture scissors to the assistant and immediately prepare another suture just like it. Account for each needle in its entirety as the surgeon finishes with it, because a suture or needle can break. All suture needles should be returned in the needle holder for safety and one-for-one accountability. Check the integrity of the needle as it is returned in the needle holder. Tell the surgeon immediately if a needle is broken so all pieces can be retrieved.

Repeat the size of a suture or ligature when handing it to the surgeon only as appropriate. Obviously, this repetition is not necessary if the surgeon is using a long series of interrupted sutures or many ligatures in rapid succession. Use good judgment.

Be logical in selecting the instruments used for suturing. Give the surgeon long needle holders to work deep in a cavity; short ones may be used for surface work. Give the assistant a needle holder to pull the needle through tissue for the surgeon if the angle of suturing is complex. Have scissors ready when the knot is tied. Hemostats are sometimes used to secure or tag the ends of multiple interrupted sutures placed in rapid succession. Often the knot tying and cutting take place after interrupted (individual) sutures are in position, especially during closure.

Remove the waste ends of suture material from the field, Mayo stand, and instrument table, and place them in the trash disposal container. Put used needles on a magnet, in a numbered needle foam box, or a needle rack (or other container for this purpose) until the needle count is complete. Follow established institutional policy and procedure for securing sharps during the surgical procedure.

Specimen Management on the Sterile Field. Save and care for all tissue specimens according to facility policy and procedure. Some facilities require that all tissue removed from a patient, including exudates, be sent for pathologic examination. Therefore it is advisable to send all tissue to the laboratory even though it may appear to be of no value for examination or diagnostic purposes unless instructed to do otherwise. Any other unusual item such as a retained foreign object should be sent to pathology for accession. Forensic evidence is handled according to facility policy.

Specimens are put in a specimen basin or another container. Never put a large clamp on a small specimen; this may crush cells and make tissue identification difficult. Some specimens have borders or margins that the surgeon will mark with specific colored sutures as tags for the pathologist's identification of and attention to certain areas. Photographs may be taken for the record. In some cases the pathologist may be called to the room for close inspection of the site.

Keep the specimen basin on the field until all tissue has been removed or all contaminated items have been placed in it (e.g., instruments used for appendectomy). Specimens designated as right or left should be kept separate in clearly marked containers (e.g., tonsils, testes, ovaries). Keeping bilateral specimens separated helps prevent confusion if part of the tissue sample is found

to be positive for cancer. The skin marking pen can be used to mark on the side of the cup to indicate right or left if labels are unavailable.

When handing a specimen from the field to the circulating nurse, hand it in a basin or appropriate container; never place it on a surgical sponge. Tell the circulating nurse exactly what the specimen is, if there are any identifying notations for the pathologist, or if the specimen is to have special testing (e.g., frozen section). If there are any doubts about the specimen's identification, markers, or processing, ask the surgeon for clarification.

Irrigation of the Surgical Site. Before closure, the surgeon may request several liters of fresh, warm sterile saline irrigation solution to rinse the abdomen (or smaller amounts to irrigate other surgical wounds). Some surgeons may pour the irrigation directly from the basin, and others may request an Asepto syringe. If a Poole suction is used to evacuate the solution, be sure the guard is slipped over the tip to protect the tissues from suction lesions. Keep track of the amount of irrigation used and report it to the circulating nurse for the permanent record.

During Closure. Alert the circulating nurse that closure is about to begin, and hand up the wound closure suture materials. In accordance with established procedures, count sponges, sharps, and instruments with the circulating nurse as the surgeon begins closure of the wound. Verify with the surgeon and circulating nurse that intraabdominal or other cavity-packing materials and towels have been removed.

As time permits, clear unnecessary instrumentation from the Mayo stand, leaving two pairs of tissue forceps (usually Adson pick-ups with teeth), suture scissors, and four hemostats. Place unneeded instruments and supplies on the instrument table in the original setup position. This makes the instrument count easier than trying to dig through a pile of jumbled instruments. It is also safer by not concealing a sharp tip that could cause a puncture injury.

The instrumentation setup and the Mayo stand should remain sterile until the patient has left the room. Cardiac arrest, laryngospasm, hemorrhage, premature drain extraction, or other emergencies can occur in the immediate postoperative-postanesthesia period. Even though sterile instrument sets are nearby, valuable time can be lost in reopening sterile supplies and every second counts in an emergency situation. Regardless of their previous use, instruments on the Mayo stand can be used for an emergency intervention. These instruments can be lifesaving until other ones become available.

Application of the Dressing. Have a clean, warm, saline-moistened sponge ready to wash blood from the incisional area as soon as skin closure is completed and a separate dry sponge to remove excess solution from the site. Leftover laparotomy tapes and Raytec sponges are useful for cleaning the incision after the count has been completed. Have the sterile dressings ready. Radiopaque sponges are never to be used as dressings. The dressing is held in place by a sterile team member as the patient's drapes are removed. Place the soiled drapes in the appropriate receptacle—not on the instrument table or Mayo stand. The circulating nurse will clean the surrounding skin before applying tape to the dressing.

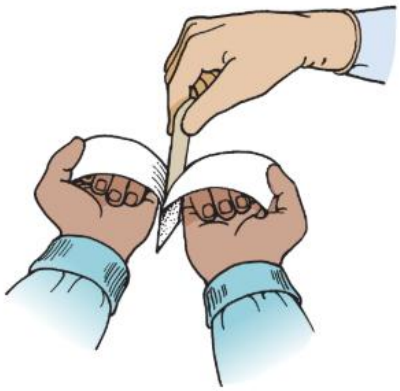
Circulating Nurse Duties

Before entering the OR at the beginning of the day, circulating nurses should wash their hands and arms as required by institutional policy and procedure, but they do not don sterile gowns and gloves. The circulating nurse is an unsterile team member. Personnel who wear sterile attire touch only sterile items; those who are not sterile touch only unsterile items. The circulating nurse should assist the sterile scrub person by providing and opening sterile supplies needed using aseptic technique to prepare for arrival of the patient and the surgeon. The circulating nurse should test all equipment before bringing the patient into the room.[3]

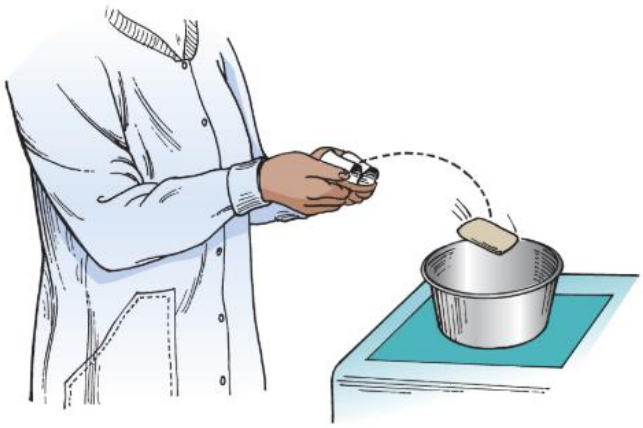
After the Scrub Person Scrubs

Fasten the back of the scrub person's gown and assist with the wrap-around tie. Check with the scrub person to see if additional supplies or instruments are needed. Open any remaining packages of sterile supplies (e.g., syringes, sutures, sponges, gloves) as needed. Use an appropriate method of aseptic transfer to the sterile field. Methods of transfer include, but are not limited to the following:

1. Place the item on the sterile instrument table with the inside of the wrapper everted over your hand. Never reach over the sterile field and shake an item from its package.
2. Expose the contents so the scrub person can remove the item from the wrapper or package by using a forceps or by grasping the item (Fig. 25.13). The scrub person avoids touching the unsterile outside. Remember that the sterile boundary of a peel-open package is the inner aspect, never the edges.
3. Flip only small, rigid items (e.g., suture), and do so with caution (Fig. 25.14). Flipping an item from a package may result in the item missing the intended sterile surface and landing on the floor. Flipping creates air turbulence and thus is the least



• **Fig. 25.13** Scrub person taking contents from suture packet opened and held by circulating nurse. Scrub person avoids touching unsterile outer wrapper.



• **Fig. 25.14** Flipping a packet of suture to the sterile field.

preferred method of sterile transfer. Larger items, such as staplers or implants, can become contaminated or damaged and therefore are never flipped.

Check the list of suture materials and sizes on the surgeon's preference card, but verify with the surgeon before opening excess packets. Avoid opening suture packets in advance that may not be used. The surgical procedure might be canceled at the last minute or the patient's condition may warrant something different, and then the sutures would be wasted. If the surgeon's need for sutures cannot be anticipated and further instructions have not been given, dispense only one or two packets ahead of actual need during the surgical procedure.

The scrub person counts the needles with the circulating nurse. Some suture packets incorporate barcode technology. Each packet is scanned into the computer system to begin a running tally of which suture and needle has been dispensed to the field. This also generates charges to the patient. Once the surgical procedure is started, additional sutures can be dispensed to the field as needed, preventing waste or overcharging the patient. A manual needle count is done at the end of the procedure by the scrub person and circulating nurse.

Pour warmed solution (usually normal saline or Ringer's lactate) into the round solution basin on the instrument table for irrigation and moistening sponges. Pour sterile water into the instrument basin if one is used. The scrub person will label the basins after the solution is poured. For skin preparation using a two-step prep, pour a small amount of antiseptic agent into the solution cups or prep set on the prep table and obtain sterile gloves for the person doing the prep.

To establish a baseline of table contents for the record, count sponges, sharps, and instruments with the scrub person in the manner described in facility policy and procedure. RFID technology may be used. An RFID counting device can be mounted on an intravenous (IV) pole near the field or incorporated into a collection unit. The pack of sponges or towels can be passed in front of the scanner on either type of RFID counter to register the number of items within the pack before dispensing to the sterile field. Some commercial RFID collection devices incorporate a collection bin that scans each sponge back into the system. The readout screen indicates if the total number of each item has been returned after use. If all dispensed sponges or towels are not accounted for by the collection bin at the end of the procedure, the readout will indicate exactly what is missing. Some RFID units have a sensor wand that can be covered with a sterile drape and passed over the field to detect the location of the missing item.

If RFID is not used, record the baseline number of sponges and towels immediately on the tally sheet or wipe-off board to begin the ongoing tally. Leave a sufficient space for the listing of items that may be added during the procedure. The baseline instrument counts will be recorded on the instrument tray sheet packed with the set.

After the Patient Arrives

The circulating nurse attends to the patient while the scrub person continues to prepare the instrument table for the arrival of the surgeon. Although time is limited during the check-in process, the circulating nurse should perform a brief assessment of the patient and go over the surgical checklist. Assessment data about the patient's health status that can be gathered without using equipment or taking an extraordinary amount of time are listed in Box 25.4.

Greet and identify the patient, introduce yourself, and identify your title and role. Offer the patient a blanket from the warming cabinet. Check the wristband for identification by name and number. Ask the patient to verbally identify himself or herself by

• BOX 25.4 Brief Physical Assessment That Can Be Performed by the Circulating Nurse during the Check-in Period before Entering the Operating Room[a]

Review of Body Systems (Brief History)

- Is the patient a reliable historian, or is a family member translating or communicating on his or her behalf?
- Is the patient taking any medication on a regular basis (e.g., heart or blood pressure medications)? This should include vitamins, hormones, or herbal preparations.
- Does the patient have any allergies? What are the patient's reactions when exposed to the offending substance? Is the reaction localized or systemic?
- When was the patient's last meal and oral intake? If this is an emergency, what were the foods in this meal? Red foods may falsely imply gastrointestinal bleeding if the patient vomits.
- Has the patient ever had any surgery before? This may reveal a condition that requires special positioning or other modification to the standard plan of care.
- Has the patient experienced any complications during previous surgeries?
- Does the patient wear contact lenses or prosthetic parts?
- Does the patient have any trouble moving limbs?
- Is the patient extremely large or small? This may indicate the need for additional instruments or a weight-appropriate OR bed.
- Is the patient aware of the procedure being performed?
- Are laboratory studies and blood work reports included with the chart? Are they current?

Head-to-Toe Assessment (Brief Physical)

- Is the patient here for a scheduled procedure, urgent or emergent care, or possibly a redo from an earlier surgery? This may alter the needed supplies for the case.
- Is the patient a child or adult? Is a parent present?
- Observe the color of the patient's skin and body tissues.
- Listen to the sound of the patient's voice as he or she speaks. Is it raspy or breathless? Is the patient coughing? Note any odors on breath or body.
- Touch the patient's skin as the dialog progresses. Is it cool, hot, damp, dry, or in any other condition? This assessment can be performed as part of shaking hands. Does the patient have a weak or strong handshake or grasp? Is the patient shaky?
- Is there eye contact, and do the eyes move appropriately?
- Is one or the other eyelid drooping? Is the patient crying?
- Does the patient have enough physical coordination to point to the surgical site? Has the correct site been marked per facility policy and procedure?
- Does the patient appear to understand what is being said? Can the patient speak and respond appropriately?
- Does the patient have a Foley catheter or an ostomy? Is the patient continent?
- Are intravenous fluids running? Is the line infusing? Are additives in the container?
- Is the correct surgical site marked with the surgeon's initials?

[a]*Most of these assessment activities can be performed simultaneously in just a few minutes and may lead to additional nursing diagnoses that require a modification of the plan of care.*

name (can have patient spell name) and birth date and (in his or her own words) describe an understanding of the surgical procedure. Many patients have similar-sounding names, and a spelling by the patient may be indicated.[4]

If the surgical site is designated left or right, validate the area by having the patient point to the spot. Double-check this spot against the permanent record and the scheduled procedure. The correct surgical site should be marked by the surgeon's initials with an ink marker. If the patient is a minor or is unable to respond, this process is performed in the presence of a parent or legal guardian. Check the plan of care and the patient's chart for pertinent information, including consent and laboratory work. Immediately report any discrepancies or questions to the surgeon and anesthesia provider.

Verify any allergies or environmental and/or chemical sensitivities the patient may have. These may be identified by an additional wristband and by a special notation on the patient's chart. Ask the patient to describe his or her reaction to the drug or substance.

Entering the OR with the Patient

Be sure the patient's hair is covered with a cap; this prevents dissemination of microorganisms and protects the hair from being soiled. Loosen the neck and back ties on the patient's gown, and untuck the blanket from the foot of the transport stretcher. Align the transport cart with the locked OR bed and lock the wheels. Ask the anesthesia provider or other personnel to stand on the opposite side of the bed as the patient moves over.

Assist the patient as needed, taking care that the patient's gown, blanket, IV infusion tubing, and catheter drainage tubing are not caught between the transport cart and the OR bed. Protect the patient's modesty, and use good body mechanics. Additional personnel should be summoned to help if the patient is unable to move over to the OR bed. If the patient requires the use of a patient roller device, ensure that adequate personnel are available to assist with the move from one surface to the other (see Fig. 13-2).

After the patient has transferred to the OR bed, apply the safety belt over the thighs 2 to 3 inches above the patient's knees, and place his or her arms on armboards. The safety belt should be placed over the blanket so it is visible at all times, and it should not impair circulation to the extremities. Avoid placing additional blankets over the belt because there is no way to be sure the belt is secure if it is not visible. Other considerations include the following:

1. The patient's legs should not be crossed. A small pillow may be placed under the patient's knees to decrease strain on the lower back. Patients at risk for pressure injury should have gel sacral and heel protectors applied.
2. Remove the patient's arm from the sleeve of the gown before securing it to the armboard. The angle of abduction of the arm on the armboard should not exceed 90 degrees—a right angle with the body. The brachial nerve plexus can be damaged by lengthy, severe abduction of the arm.

Help the anesthesia provider as needed. Apply and connect monitoring devices, and assist with IV infusion, induction, and intubation as necessary. Some facilities have anesthesia technicians to assist the anesthesia provider. Before the patient arrives, the anesthesia technician will obtain the following equipment:

- Unsterile gloves for the person who will do a percutaneous venipuncture. Sterile gloves are required for a venous cutdown or insertion of arterial monitoring lines.
- A tourniquet to help expose the vein for percutaneous insertion. An unsterile Penrose drain is sometimes used for this purpose.
- Sponges saturated with antiseptic solution for skin preparation. Thorough skin antisepsis is imperative.
- A sterile IV administration tubing set and Angiocaths of assorted sizes.
- 1½-inch (3.8-cm) × 20 or 21-gauge Angiocaths, which generally are used for IV fluids when blood transfusion is not anticipated; 1½-inch (3.8-cm) × 18-gauge or 2-inch (5-cm) × 20-gauge needles are used when blood transfusion is anticipated.
- Tape strips to firmly secure the needle or catheter and tubing to the patient's skin, which prevents motion that may traumatize the vein. If the patient is sensitive to adhesives, paper tape may be used.
- A stopcock to regulate or stop the flow of solution through the tubing into the vein. Ports should remain covered until needed to prevent microbial migration into the system. Many facilities use nonpuncture IV additive attachments for the anesthesia provider to administer drugs during the procedure.
- IV crystalloid solutions, which include normal saline; dextrose 5% or 10% in water (D_5W); dextrose in 0.25% saline; lactated Ringer's solution; and dextrose in lactated Ringer's solution. Dates should be verified. If additives are used, a label is applied stating the drug and dose.
- Fluid warming systems are commonly used to maintain normothermia during the procedure.

When prolonged postoperative fluid therapy or hyperalimentation is anticipated, a radiopaque, plastic, single, double, or triple-lumen catheter is inserted through either a venipuncture through the skin (percutaneous insertion) of the neck or subclavian area or a cutdown through a skin incision to expose the vein.

A venous cutdown is performed in other selected situations or during emergencies: for central venous pressure monitoring or if superficial veins are thrombosed or if they are superficially collapsed as a result of shock or prolonged preoperative IV therapy.

A venous cutdown is a sterile procedure that creates an open wound. Sterile gloves, drapes, and a tray of sterile instruments and sutures are needed. Assorted sizes of IV catheters should be available so the anesthesia provider can choose the size best suited to the vein. A soft, pliant catheter takes the contour of the anatomy and is not easily dislodged by movement of the patient. The long-term IV access port will be sutured to the skin.

Check the expiration date, and gently squeeze the plastic IV bag to detect leaks. Check the solution for clarity or discoloration; a cloudy solution is contaminated. A registered nurse (RN) or physician must check the label on the container before the solution is administered. All solutions given are charted and monitored to see that they are infusing at the proper speed. Usually this is the responsibility of the anesthesia provider.

Some vascular or radiologic imaging procedures require the use of IV solutions on the sterile field for use in IV injection. A plastic bag decanter is used to pour the solution into a basin on the field. The solution should be labeled as IV saline or IV Ringer's. Sometimes heparin or contrast medium is added. The dosage should be indicated on the labeled container.

During the Induction of General Anesthesia

The circulating nurse remains at the patient's side during the induction of anesthesia. The circulating nurse assists the anesthesia provider during induction and intubation. Maintain a quiet environment. Tactile or auditory stimulation may produce excitement in the patient during induction. Hearing is the last sense lost. A strong startle reaction to sound can provoke life-threatening

cardiac dysrhythmias or laryngospasms in any patient. Undue stimulation while the patient is under light anesthesia should be avoided. A quiet, undisturbed induction makes for a much safer and easier maintenance of and recovery from anesthesia. The patient should not be positioned or prepped until the anesthesia provider indicates that it is okay to do so.

After the Patient is Anesthetized

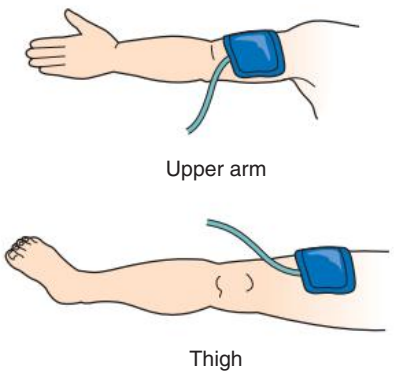
Attach the anesthesia screen and other table attachments as needed. Reposition the patient only after the anesthesia provider says the patient is anesthetized to the extent that he or she will not be disturbed by being moved or touched. If the patient is to be placed in the prone position, the induction process is performed on the transport cart before placing the patient prone. Be sure a transport cart remains outside the door for the duration of the procedure in case of an emergency. In the event of cardiac arrest or other emergency, the patient will need to be rapidly turned to a supine position for treatment.

If an ESU is to be used, place the dispersive electrode pad in contact with the patient's skin after the patient is in the final surgical position (Fig. 25.15). Avoid scar tissue and hairy or bony areas. If an excessively hairy area is to be used for the electrode, the small area of hair may be removed with clippers to ensure the electrode adheres to the skin.

Turn on the overhead spotlight and aim the light over the site of the incision. Preoperative medication affects the protective pupillary reflex, and therefore bright light should not be focused on the patient before he or she is asleep or the eyes are covered.

Expose the appropriate area for skin preparation and/or Foley catheter insertion. Turn the blanket downward and the gown upward neatly to make a smooth area around the surgical site. Other areas are exposed only as necessary. Before prepping and draping begins, note the patient's position to be certain all measures for his or her safety have been observed. Double-check the safety belt for security. The circulating nurse or first assistant then prepares the patient's skin with antiseptic solution using the one-step or two-step method. All prep solutions should be completely dry before the patient is draped. Drapes can sequester alcohol fumes and create a fire hazard if not completely dry.

Bag and discard the sponges from a reusable prep tray immediately after use. Prep sponges are not radiopaque. Because they are not included in the sponge count, they are not discarded in the sponge bucket. A totally disposable prep tray may be bagged for disposal with trash at the completion of the surgical procedure. This is not considered a biohazard, but eyewear should be worn to prevent splashes or aerosolization.



• **Fig. 25.15** Dispersive return electrode placement.

After the Surgeon and Assistant(s) Scrub

Assist with gowning the team. Reach inside the gown to the shoulder seam. If a closed gloving technique is used, pull the gown sleeves only so far that the hands remain covered by the knitted cuffs. If an open technique is used, pull each sleeve over the hands so the gown cuffs are at the wrists. Fasten the waist tie first, followed by the neck closure. Securing the back of the gown in this order allows the upper body more freedom of motion for gloving. The scrub person will assist with open-assisted or closed-assisted gloving of the team (Fig. 25.16).

The circulating nurse, as a nonsterile person, should stand by to help with the wrap back tie-in of the gown. The gowned person holds the short tie in the left hand and the long tie attached to a cardboard tab in the right hand. The cardboard tab attached to the long tie is handed to the nonsterile person. The nonsterile person does not actually touch the long tie—only the cardboard tab. The sterile person still holding the short tie slowly turns away from the nonsterile person, causing the long tie to cross over the back of the gown at the waist. The sterile person carefully takes the long tie from the cardboard tab the nonsterile person is holding and ties the two ends together at the waist along the left side of the body. The circulating nurse discards the cardboard tab.

If gloving with powdered gloves, the surgeon and assistant(s) should wipe their gloves with a sterile damp towel or sponge provided by the scrub person to remove glove powder.

Starting the Procedure

Observe for any breaks in sterile technique during draping. Stand near the head of the OR bed to assist the anesthesia provider in fastening the drape over the anesthesia screen or around an IV pole next to the armboard. The drainage bag of the Foley catheter should be placed in view of the anesthesia provider and the circulating nurse.

The scrub person will move the sterile Mayo stand into position over the table. The circulating nurse will move the instrument table into position, being careful not to touch the sterile surface of the drapes. Place steps or platforms for team members who need them, or place sitting stools in position for the team that needs to operate while seated. If one person sits, the entire team should be seated to protect the level of the sterile field.

Position kick buckets (sponge buckets) on each side of the OR bed. If an RFID system is used, the scanner and collection bin should remain close to the sterile field. Connect suction, the ESU

• **Fig. 25.16** The circulating nurse secures the surgeon's gown as the scrub person performs open-assisted gowning and gloving.

cord, the dispersive electrode cable, or any other powered equipment to be used. If possible, these cords should be directed off the same side of the OR bed to avoid creating a stumbling hazard. Place foot pedals within easy reach of the surgeon's right foot. Tell the surgeon which foot pedal is placed by which foot (if more than one is used), and confirm and document the desired settings on all machines.

The Time Out before the Incision

When the entire team is in place, the sterile and nonsterile teams concur that this is the correct patient for the correct procedure on the correct part of the body. Allergies and other pertinent information are validated. All necessary supplies, implants, and equipment are confirmed present. The incision should not be made until all members of the team are in agreement. If the patient is awake, he or she should be part of the process.

During the Surgical Procedure

Some surgeons want the circulating nurse to communicate updates with family or significant others throughout the procedure. Document the time and the calls in the perioperative nurses' notes.

Be alert to anticipate the needs of the sterile team, such as adjusting the OR light, removing perspiration from brows, and keeping the scrub person supplied with sponges, sutures, warm saline, and other necessary items. Ideally, the circulating nurse watches the surgical procedure closely enough to see when routine supplies are needed and gives them to the scrub person without being asked. The circulating nurse should know how to use and care for all supplies, instruments, and equipment and be able to get them quickly. This is particularly important in emergency situations, such as cardiac arrest or hemorrhage.

Stay in the room. Send a runner for supplies if at all possible. Inform the scrub person if you must leave to get something. Be available to answer questions, obtain supplies, and assist team members.

Sponge Management by the Circulating Nurse

If RFID is not used, keep discarded sponges carefully collected, separated by sizes, and counted according to the increment wherein they are packaged. Examination gloves are used to handle and count sponges. Soiled sponges can be placed in untied clear plastic bags in full view of the scrub person and anesthesia provider. The bags are not tied, in the event a recount must be done. Other collection methods may include a hanging pocket display with an individual pouch for each counted increment of sponges.

Weigh sponges if requested to do so. Gram scales can be brought into the OR for this purpose. Each gram of weight equals 1 mL of blood. The procedure for weighing sponges is described in detail in Chapter 31, Box 31-1.

Monitoring Blood Loss

Assist the surgeon and the anesthesia provider to monitor blood loss. Estimate the blood volume in the suction container by subtracting irrigation and body fluids from the total volume in the container. Determinations of total blood volume may be used for estimation of the surgical blood loss. Obtain blood products for transfusion from the refrigerator as necessary, or send a patient care assistant to the blood bank. If the patient's own blood will be recovered for intraoperative autotransfusion, obtain the necessary equipment.

Know the condition of the patient at all times. Inform the OR manager of any marked changes, unanticipated additional procedure, or delays. In a busy department it may be necessary to rearrange the schedule.

Specimen Management by the Circulating Nurse

Prepare and label specimens for transport to the laboratory. An error in labeling a tissue specimen or culture could cause an inaccurate diagnosis or improper therapy or necessitate another operation. Each container is labeled with the patient's name, identification number, date, surgeon, and type and site of specimen. Avoid labeling the lid, because lids could be accidently switched during processing.

Accompanying the specimen is a requisition that specifies the laboratory test requested by the surgeon. The requisition includes the date, name of the surgeon, preoperative and postoperative diagnoses, surgical procedure, desired test, and tissue to be examined, including its source. In some cases, previous medications such as antibiotics or hormonal therapy are included for the pathologist. Specimens taken from bilateral aspects of the body, such as tonsils, should be separated and labeled as left and right. This is important if there is a potential for the diagnosis of cancer. More information concerning specific specimens is located in Chapter 22.

Documentation

Complete the documentation in the patient's medical record, permanent OR records, and requisitions for laboratory tests or chargeable items. Information to be included in the documentation of direct intraoperative care is shown in Box 25.5.

• BOX 25.5 Documentation by the Circulating Nurse of Direct Intraoperative Patient Care

- Initial assessment of the patient on arrival to the OR. The identity of the patient and verification of the procedure should be validated. Document the time out. Correct surgical site should be marked by surgeon's initials.
- Significant times, such as arrival, time out, start, completion, and room exit times
- Disposition of sensory aids or prosthetic devices accompanying the patient on arrival in the OR
- Position, surgical safety devices, and/or restraints used during the surgical procedure
- Placement of monitoring and electrosurgical unit (ESU) electrodes, tourniquets, and other special equipment and identification of units or machines used, as applicable. The settings and duration of use should be recorded.
- The names and times of all personnel in the room for the procedure
- The type of anesthetic administered, and by whom
- The surgical site preparation, the antiseptic agent administered, and by whom
- Medications, solutions, and doses administered, and by whom
- Time out validation of site, patient, and procedure for the surgical checklist
- A description of the actual surgical procedure performed
- Contact with the patient's family or significant others
- Type, size, and manufacturer's identifying information (lot numbers) of prosthetic implants, or the type, source, and location of tissue transplants or inserted radioactive materials
- Use of x-rays or imaging
- Disposition of tissue specimens and cultures
- Correctness or incorrectness of surgical counts (if incorrect, the remedial measures to locate the lost item)
- Placement of drains, catheters, dressings, and packing. Output is recorded if receptacle is emptied in the OR.
- Wound classification is designated at the end of the procedure
- Charges to patient for supplies, according to hospital routine
- Piece of equipment sent from OR with patient to unit (e.g., tracheotomy set that accompanies patient after thyroidectomy, wire scissors if patient has had teeth wired together). These items are to be returned.
- Disposition of the patient after leaving the OR
- Any unusual event or complication

During Closure

Count sponges, towels, sharps, and instruments with the scrub person. Hospital policies may require additional items to be included in the final counts. Report counts as correct or incorrect to the surgeon. Complete the count records. Collect used sponges for disposal in the appropriately marked biohazard receptacles.

If another patient is scheduled to follow (TF), the following procedures should be observed:

1. Phone or ask the clerk-receptionist to call the unit where the next patient is waiting and request that preoperative medication or antibiotics be given if ordered; this should be done at least 1 hour to 45 minutes before the scheduled time of the surgical procedure. This process usually is not necessary for the first scheduled patient of the day but is important for subsequent patients when the exact time of the surgical procedure is uncertain. For these patients the anesthesia provider usually orders medication or antibiotics "on call."
2. Send a nursing assistant or transporter for the patient, or notify the unit to transport the patient. The patient should be in the OR designated area 30 minutes before the anticipated time of incision. If a holding area is included in the OR suite, the patient may arrive earlier to receive the preoperative medication there.

Check the surgeon's preference card or case cart sheet for the next procedure. Collect supplies that will be needed, and get them organized to the extent possible. These supplies can be assembled and placed on the case cart. They cannot be put on furniture in the room until it is cleaned after completion of the current surgical procedure. Advance preparation for the following case may vary if a case cart system is used. Prepare for room cleanup so that minimal time is expended between surgical procedures:

1. Remove x-rays and scans from the view box, place them in the patient's envelope, and take them to the designated area to be returned to the radiology department. Digital displays should be cleared.
2. Obtain items necessary for the cleanup procedure. Place them on top of the case cart for the scrub person to break down when the current patient leaves the room.

Send for a postanesthesia care unit (PACU) transport cart or an intensive care unit (ICU) bed as appropriate; follow whatever is the institutional procedure. Obtain a transfer monitor and oxygen tank with tubing if needed. Also alert patient care assistants and housekeeping personnel that the surgical procedure is nearing completion so they can be ready to assist in room turnover as needed. This helps shorten the downtime between surgical procedures. Be as systematic as possible so steps are not omitted.

After the Surgical Procedure Is Complete

The scrub person will apply the dressing after the incision is cleaned and dried.

The drapes will be rolled off the patient as a sterile team member holds the dressing in place. Clean the surrounding area of the patient's body before securing the dressing(s) over the surgical wound and the surgical drainage systems. Put a clean, warm gown and blanket on the patient. Place the safety belt over top of the blanket. It needs to be seen at all times.

Open the neck and back closures of the surgeon's and assistants' gowns so they can remove them without contaminating themselves.

Have a patient care assistant bring in the clean transport cart or bed. Check the patient's name on the stretcher or bed if it is the procedure to return the patient to the same one used for transport to the OR suite. Align the cart with the OR bed, and lock the wheels. Remove the leg safety belt.

A lifting frame or patient roller is a great help in moving unconscious and obese patients. The Davis patient roller consists of a series of rollers mounted in a frame long enough to accommodate the trunk of an adult patient. The edge of the roller is placed under the lift sheet and the patient's side. With the patient's head and feet supported by separate team members, the lift sheet is pulled and the patient is rolled onto the stretcher or bed (see Fig. 13-2).

A minimum of four people is required to safely move the patient with this device: one to lift the head and manage the airway (usually the anesthesia provider), one to lift the feet and control the Foley catheter, one beside the stretcher or bed to pull, and one beside the patient to lift him or her from the OR bed. The action of all four people should be synchronized, and the count of three is called by the person controlling the head, usually the anesthesia provider. The following precautions should be taken in lifting or rolling an unconscious patient:

1. Protect the IV, lines, drains, and urinary drainage bag. Secure IV solution bags on an IV pole. It is preferable to attach the IV pole near the head of the stretcher or bed, where there is less danger of injury to the patient if the bag or IV pole should fall or break.
2. Use the lift sheet to support the arms at the sides so the arms do not dangle.
3. The anesthesia provider guards the head and neck from injury and calls the count for the move.
4. Lift or roll the patient gently and slowly to avoid circulatory depression.

After the patient is safely on the transport cart, remove the lift sheet by logrolling the patient gently from side to side. Brush burns result if the fabric is pulled from under the patient. Place the patient in a comfortable position that is most conducive to the maintenance of respiration and circulation. The appropriate position may vary with the type of surgical procedure; usually the patient should:

- Be supine after a laparotomy, with the head of the stretcher elevated 15 degrees, especially if he or she is still intubated
- Be semiprone after a tonsillectomy, for drainage, if extubated
- Be lateral, on the affected side, after transthoracic surgical procedures, thus splinting the side, usually extubated
- Have the affected extremity supported on a pillow

Raise the side rails before the patient is transported out of the OR. Be sure the completed chart and proper records accompany the patient, and send other supplies as indicated (e.g., tracheostomy obturator). Help transport the patient to the PACU or patient care unit.

Patient Transfer from the Operating Room

During transport, the patient should be constantly observed by someone familiar with his or her condition. If the patient has had local anesthesia, the circulating nurse and transporter may accompany the patient during the return to an ambulatory unit.

Hand-over Report to PACU Nurse

Calling to give a hand-over report before leaving the OR is necessary when special monitoring equipment is needed such as a ventilator. If the patient has had general anesthesia, the anesthesia provider and circulating nurse should accompany him or her during transport to the PACU, where they give a verbal hand-over report to the PACU nurse. This postoperative report is important

for the continuity of care. A concise verbal hand-over report from the anesthesia provider and/or circulating nurse includes the following:

- Name and age of the patient
- Type of surgical procedure and name of the surgeon
- Type of anesthesia and name of the anesthesia provider
- Vital signs (baseline, preoperative, and intraoperative), including current body temperature. Body weight should be available in kilograms.
- Types and locations of drains, packing, and dressings. Closure medium should be included.
- Preoperative level of consciousness and current status
- Medications given preoperatively and intraoperatively, as well as those regularly taken by prescription or self-medication
- Medical and surgical history
- Allergies and responses to allergens, substance sensitivity
- Positioning on the OR bed and devices attached to the skin
- Complications during the surgical procedure
- Intake and output, including IV fluids, blood, and urinary output
- Location of the waiting family or significant others
- Special considerations:
  - Sensory and/or physical impairments; eyewear, hearing aids, dentures, or other personal property brought to the OR is returned to the patient when the level of consciousness is appropriate
  - Language barrier and level of understanding
  - Use of tobacco, alcohol, and/or addictive drugs
  - Orders such as "no code," "do not resuscitate (DNR)," "allow natural death (AND), "or "do not attempt resuscitation"

Sponge, Sharps, and Instrument Counts

The counting of sponges, needles and other sharps, and instruments has been mentioned throughout this chapter. These supplies are crucial to the surgical procedure and must be accounted for throughout every procedure, regardless of size or function. Items are counted before and after use. The types and numbers of sponges, needles and other sharps, and instruments vary for each surgical procedure. The process of counting gives the circulating nurse and the scrub person the opportunity to look at all the supplies and the entire instrument set before the procedure begins. Missing or defective items can be obtained or replaced without interrupting the continuity of the surgery.

Accountability for counts is a professional responsibility that rests primarily on the scrub person and the circulating nurse. The surgeon and patient rely on the accuracy of this accountability by the team. There are several reasons why it is important for the scrub person and circulating nurse to count and be accountable for all items used during the procedure (Box 25.6). Counts are performed for patient and personnel safety, infection control, and inventory purposes. A retained surgical item in the surgical site after closure is a possible cause for a lawsuit after a surgical procedure.

• BOX 25.6 More Than One Reason to Count and Be Accountable for Items Used during Surgical Procedures

- Item can be lost in patient's body, causing the need for additional surgery.
- Item can be lost in trash or linen, causing harm to other personnel.
- Item can be lost from inventory, resulting in high replacement costs.

A retained foreign object made of woven textile is referred to as a *gossypiboma* or a *textiloma.* A foreign body unintentionally left in a patient can be the source of wound infection or disruption. The longer the object remains in the body, the more it incorporates ingrowth of tissue. An abscess can form, and fistulas may develop between organs. The foreign body reaction may be immediate or may be delayed for years. Diagnosis is sometimes difficult and costly, and removal of the object usually requires major surgery. The literature reports the removal of some retained sponges through laparoscopic surgery if they are discovered before adhesions develop.[5]

A contaminated sponge or needle that is unaccounted for at the close of the procedure could also inadvertently come into contact with the personnel who clean the room, process instruments, launder the linens, or transport the trash. Blood or body fluids are sources of pathogens such as human immunodeficiency virus (HIV) or hepatitis B virus (HBV). A surgical pattie (cottonoid) that has become saturated with clear cerebrospinal fluid during a neurologic case may be contaminated with Creutzfeldt-Jakob disease (CJD).

Inventory control is monitored by accounting for the instrument set in its entirety. Counting ensures that expensive instruments such as towel clips and scissors are not accidentally thrown away or discarded with the drapes. Injury to laundry and housekeeping/environmental services personnel by the contaminated sharp edges of surgical instruments, blades, and needles is a risk. Surgical instruments also can cause major damage to equipment in the laundry services. Unfortunately, some facilities have felt a need to install metal detectors in the trash and soiled linen areas to monitor for missing instruments.

Counting Procedures

A counting procedure is a method of accounting for items put on the sterile table for use during the surgical procedure. Sponges, sharps, and instruments should be counted and/or accounted for on all surgical procedures. This includes any materials introduced into the patient during the procedure, such as rectal or vaginal packs or sterile towels used to pack off or retain viscera. Inadvertent items such as injection needle caps, cautery tip cleaners, clip cartridges, or suture reels could become retained objects and should be accounted for in their entirety.

Items used during organ procurement procedures should be accounted for in their entirety in the same manner as for any surgical procedure. Respect for the donor should be as important to the surgical team as respect for any patient.

Initial Count When the Instrument Tray Is Assembled

The person who assembles and wraps items for sterilization will count them in standardized multiple units and initial the baseline set contents. Most facilities enclose a copy of this tray inventory count sheet in the instrument set or attach a copy to the outer wrapper.

The effects of enclosing a tray inventory sheet inside the set raises questions of potential exposure of toner and foreign body reaction in the patient. Methods for attaching the tray sheet to the outside of the set should be explored if this is a concern. In commercially prepackaged sterile items (e.g., sponges, disposable towels), this count is performed by the manufacturer and affixed to the outside of the package.

Baseline Count during Setup for the Surgical Procedure

The scrub person and the circulating nurse together count all items before the surgical procedure begins and during the surgical procedure as each additional package is opened and added to the sterile field. These initial counts provide the baseline for subsequent

counts. Any item intentionally placed in the wound, such as towels, is recorded. A useful method for counting is as follows:

1. As the scrub person touches each item, he or she and the circulating nurse number each item aloud until all items are counted.

   There is no need to be disruptive when performing this task. Each pack of sponges will be bound with a paper band that is broken only as each bundle is counted. If RFID devices are used, each item is passed over a scanner. The presence of an intact paper band indicates that the bundle has not been counted yet. Count them one bundle at a time.
2. The circulating nurse immediately records the count for each type of item on the count record or wipe-off board. Preprinted forms are helpful for this purpose.
3. Additional packages should be counted away from counted items already on the table in case it is necessary to repeat the count or to discard an item.
4. Counting should not be interrupted. The count should be repeated if there is uncertainty because of interruption, fumbling, or any other reason.
5. If either the scrub person or the circulating nurse is permanently relieved by another person during the surgical procedure, the incoming person should verify all counts before the person being relieved leaves the room. Personnel who perform the final counts are held accountable for the entire count.

Closing Counts (First Closing Count)

Counts are taken in three areas before the surgeon starts the closure of a body cavity or a deep or large incision. The first count is usually all items except instruments. The instrument count starts as soon as the first count is complete.

1. *Field count:* Either the surgeon or the assistant assists the scrub person with the surgical field count. Additional items (e.g., vaginal or rectal packing, sterile towels used as intraabdominal packing) are accounted for at this time. This area should be counted first. Counting this area last could delay closure of the patient's wound and prolong anesthesia.
2. *Table count:* The scrub person and the circulating nurse together count all items on the Mayo stand and instrument table. The surgeon and assistant may be suturing the wound while this count is in process.
3. *Floor count:* The circulating nurse counts sponges and any other items that have been recovered from the floor or passed off the sterile field to the kick buckets. These counts are verified by the scrub person.

Final Count (Second Closing Count)

The final count is performed to verify any counts and/or if institutional policy and procedure stipulates additional counts before any part of a cavity or a cavity within a cavity is closed. The instrument count is completed once before the second sponge and sharp count begins.

The final count (second count) of sponges and sharps may be taken during subcuticular or skin closure. The circulating nurse totals the field, table, and floor counts. If the final counts match the totals on the tally sheet, the circulating nurse tells the surgeon the counts are correct. In ORs where RFID is used, the circulator can pass a sterile draped circular wand over the patient to verify there are no sponges in the patient.

The scrub person must be alert to the use of a counted instrument such as a malleable retractor for visceral protection. Instruments in use during closure usually are a needle holder, scissors, and pickups unless a stapler is used. Towel clips should not be excluded from accountability.

A count should be reported to the surgeon as correct only after a physical count by number actually has been completed. Intentionally exposing the patient to x-rays is not a replacement for the physical count.

The circulating nurse documents on the patient's record what was counted, how many counts were performed and by whom, and if the counts were correct or incorrect. There is no need to write all the tallies on the permanent record. A registered nurse should participate to verify that all counts are correct, but the personnel actually performing the counts are responsible for the accuracy of the counts. The counting procedure, the outcome, and participating personnel should be documented according to institutional policy and procedure. Signatures of all counting personnel may be required according to facility policy.

Omitted counts because of an extreme patient emergency should be recorded on the patient's record, and the event should be documented according to institutional policy and procedure. If a sponge or sponges are intentionally retained for packing or if an instrument intentionally remains with the patient, the number and type should be documented exactly by type and number on the patient's record. Patients in extremis may be brought back to surgery for repeated procedures, and it is important to know what was intentionally left in during the first operation. Any time a count is omitted, refused by a surgeon, or aborted, the reason should be fully documented.

Records can be subpoenaed and admitted as evidence in court. The accountability for all items used during the surgical procedure is placed on the scrub person and the circulating nurse, who jointly perform the counting procedures as defined by institutional policy and procedure. The surgeon and the first assistant facilitate the counting process. It is not the job of the surgeon or the first assistant to actively perform the counts or sign the count reconciliation record.

Incorrect Count

A specific policy and procedure for any count that is incorrect should be defined by each institution and should include, but not be limited to, the following:

1. The surgeon is informed immediately. If RFID technology is used, the surgical site should be scanned by the detection wand. The RFID process can alleviate the need for repeated counts and room searches if the missing item is found during the scan process.

If RFID technology is not available, the following steps should be followed:

2. The entire count is repeated.
3. The circulating nurse searches the trash receptacles, under the furniture, on the floor, in the laundry hamper, and throughout the room.
4. The scrub person searches the drapes and under items on the sterile field and Mayo stand.
5. The surgeon searches the surgical field and wound.
6. The circulating nurse should call the immediate supervisor to check the count and assist with the search.
7. After all search options have been exhausted, policy should stipulate that an x-ray be taken before the patient leaves the OR. The surgeon may request the x-ray at once, with a portable machine, to determine whether the item is in the wound. Alternatively, the surgeon may prefer to complete the closure first because of the patient's condition or because there is reasonable assurance, based on wound exploration, that the item is not in the patient. Unfortunately, patients' incisions have been reopened after complete closure to retrieve retained objects, such as sponges.

8. The circulating nurse should write an incident report and document on the OR record all efforts and actions to locate the missing item, even if the item is located on the x-ray. This report has legal significance for verification that an appropriate attempt was made to find the missing item. If the item is not found on the x-ray, the report brings to the attention of personnel the need for more careful counting and the control of sponges, sharps, and instruments. A policy and procedure change or update may be advisable.

Sponges

Sponges are used for absorbing blood and fluids, protecting tissues, applying pressure or traction, and blunt dissection. Many types of sponges are available. All sponges on the sterile table and field should be radiopaque. A radiopaque thread or marker made of a barium substance is incorporated into commercially manufactured sponges. RFID-tagged sponges and towels also have a small encoded tag attached.

Types of Sponges

The following list is representative of the types of radiopaque sponges used:

1. Gauze sponges (which are called *swabs* in some countries) are supplied sterile, precounted, and folded. When opened out to a single ply during blunt dissection, fibers along the raw edges could become foreign bodies in the wound. These are also called *Raytec* or *Raytex* sponges. All are packed in groups of 10 and bound with a paper band.
2. Laparotomy tapes, also called *lap pads, tapes,* or *packs,* are used for retaining the viscera and keeping them moist and warm. Tapes are either square or oblong and have a loop of blue twill tape sewn on one corner. A small radiopaque marker is sewn into one corner of the tape. A metal or plastic radiopaque ring, approximately 1½ inches (3.8 cm) in diameter, may be attached on this twill tape. If rings are used, they remain outside the edges of the incision while the tape is inside. Normal saline or Ringer's lactate is commonly used to moisten tapes. Tapes are packaged and paper banded in groups of five.
3. Dissecting sponges have a self-contained, x-ray–detectable element incorporated into the weave.
   a. Peanut sponges are very small, ovoid soft gauze sponges used for blunt dissection or absorption of fluid in delicate procedures. Cherry sponges are firm ball-shaped dissectors. Both types are clamped into the tip of an Adson, Kelly, or right-angle clamp during use. Both are packaged in groups of five nested in a cardboard or foam holder.
   b. Kitner dissectors are small firm cylindrical rolls of heavy, tightly wound cotton dental tape that are held in a Kelly or Kocher (Ochsner) clamp for use during blunt dissection. They are packaged in groups of five.
   c. Tonsil sponges are soft, ball-shaped, cotton-filled gauze sponges with an attached cotton thread. These come in several sizes and are held in the tip of a forceps for use. They are packaged in groups of five. These sponges are available in larger styles without the thread and are referred to as *tampons.* These can be used in place of a Raytec on a sponge forceps.
4. Compressed absorbent cottonoids (also known as *patties*) are small squares or rectangles made of compressed rayon or cotton; they are very absorbent and resemble a strip of felt. They are moistened with Ringer's lactate or a topical hemostatic agent, such as thrombin, for use on delicate structures such as the nerves, brain, and spinal cord.

   They are pressed out flat after moistening and before handing them to the surgeon. The surgeon will pick up the cottonoid with a forceps (commonly bayonet forceps) and apply it to the area of intended use. Some surgeons will use cottonoids to apply intranasal anesthetic. Cottonoids have a radiopaque element and a thread attached so they can be located in the wound. These range in size from ¼ × ¼ inch to 1 × 3 inches.
5. Towels are occasionally but not universally used for protecting the viscera. The scrub person and circulating nurse are responsible for accounting for the tracking and retrieval of towels or anything placed in the patient. The scrub person informs the circulating nurse that a towel has been used for packing or protecting viscera, and the circulating nurse documents the event. Towels placed inside the patient become part of the count.

   During the first closing count at the conclusion of the case, the circulating nurse checks with the scrub person to verify that the towel has been removed before closure. Disposable varieties of sterile, precounted, packaged towels with x-ray–detectable elements are commercially available. Towels can be white, blue, or green. Some have twill-tape tags with rings like those on lap tapes.

   Retained surgical towels have been the subject of several liability suits. Case law demonstrates that the hospital, on behalf of the scrub person and the circulating nurse, has been successfully sued in these cases, whereas the surgeon has been exonerated (*Good Samaritan Hospital v. Dr. Ramondelli;* Court of Common Pleas, Montgomery, Ohio, 1997). The premise for these findings is based on the fact that the scrub person and circulating nurse are responsible for the counts and the fact that the surgeon relies on their accurate performance in this role. Everything temporarily placed inside the patient must be accounted for at the conclusion of the case.

Counting Sponges

Radiopaque, x-ray–detectable gauze sponges, tapes, towels, dissecting sponges, and cottonoid patties are counted in multiples of 5 or 10 per package. The types of sponges and number of different sizes should be kept to a minimum. RFID scanners have helped simplify the sponge counting process. Conventional counting methods incorporate the following procedure by the scrub person:

1. Hold the entire pack of sponges of whatever type, including tapes, in one hand. The thumb should be over the edges of the folded sponges.
2. Break the paper band. Breaking the band is a good way to designate which stacks have been counted and which ones have not.
3. Shake the pack gently to separate the sponges and loosen the twill-tape tails on tapes.
4. Pick each sponge separately from the pack with the other hand, and number it aloud while placing it in a pile on the sterile instrument table.

If a pack contains an incorrect number of sponges, the scrub person should hand the entire pack to the circulating nurse for removal from the room. There should be no attempt to correct errors or to compensate for discrepancies. The pack should be removed from the room and not used.

Methods of Accounting for Sponges

Regardless of the types and numbers of sponges counted, various methods may be used to help ensure one is not misplaced or left in the patient.

By the Scrub Person

1. Keep sponges, tapes, peanuts, and other such materials separated on the instrument table and far away from each other

and from any draping material, especially towels. Dissectors should remain in their holders until needed.
2. Keep sponges far away from small items (e.g., needles, hemostatic clips) that might be dragged into the wound by a sponge or tape.
3. If a moist sponge or towel is given to the surgeon or assistant to wipe his or her gloves, be sure it is completely opened and dropped into the sponge bucket or RFID scan bin after use.
4. Do not cut sponges or tapes. It may be hard to account for the item in its entirety.
5. Do not remove the radiopaque thread or marker. Either the marker or the sponge could be lost.
6. Never mix sponges and tapes in a solution basin at the same time; this prevents the danger of dragging a small sponge unknowingly into the wound along with a tape. Avoid dipping sponges in the basin to prevent lint dispersal. Moisten with the Asepto syringe.
7. Do not give the pathologist a specimen on a sponge to take from the room; instead, put the specimen on a Telfa, in a basin, or on a towel.
8. Discard all soiled sponges into the kick bucket or RFID scan bin after completely opening them and leave no more than two clean sponges on the sterile field at a time. Put up clean ones before removing soiled ones on an exchange basis as part of a systems approach to error prevention.
9. Do not be wasteful of sponges. Besides the economy factor, the more sponges used, the more there are to count and the greater the chance for error.
10. Once the peritoneum is opened or the incision is made and extends deep into a body cavity (where a sponge could be lost), four alternative precautions can be taken:
    a. Remove all Raytec sponges from the field, and use only tapes. Rings, if used, hang outside, over the edges of the wound.
    b. Use folded Raytec sponges on sponge forceps only. Completely unfold and open each one before dropping into the sponge bucket or RFID scan bin.
    c. Give laparotomy sponges to the surgeon one at a time on an exchange basis.
    d. Dissectors are given one at a time clamped inside the tip of an instrument on an exchange basis. Bloody dissector sponges are replaced into the original Styrofoam holder after use. These may not be RFID tagged.
    e. Tonsil sponges (5) and patties/cottonoids (10) should be collected in their packaging increment and rewound on the cardboard supplied in the package. These may not be RFID tagged.
11. With the circulating nurse, count or scan sponges and tapes added during the surgical procedure before moistening or using them. Break the paper band to signify they have been counted. Always start the counts at the field and end at the sponge bucket.
12. Do not add or remove sponges from the surgical field during a sponge count until the count is verified as complete and correct. Before beginning the final count, place one or two tapes or sponges on the field for use while the count is being taken.

By the Circulating Nurse

1. To prevent the possibility of confusion in the count, nonradiopaque gauze sponges used on different trays (e.g., spinal, or prep trays) should be bagged and moved away from the field before the incision is made.
2. Each discarded sponge should be examined briefly to be sure no saturated sponges are tangled with them. To avoid the transmission of bloodborne pathogenic organisms, wear gloves and protective eyewear to separate sponges for counting, stacking, and bagging.
3. Count and bag sponges in the same increment in which they are supplied, such as groups of 5 or 10 of like sponges. These numbers should be recorded on the sponge count record and counted. The bagged units are not tied shut or discarded into the trash. The bags are placed aside in full view of the scrub person and the anesthesia provider until the end of the case and all the numbers are reconciled. The anesthesia provider will be observing for blood loss on the sponges.
4. Give additional sponges or tapes to the scrub person when it is convenient for him or her to count them. The scrub person breaks the paper band as the bundle is counted. Broken paper bands are a signal that that particular pack has been counted. The scrub person separates each sponge bundle and counts them, and the circulating nurse records the numbers immediately.
5. Give dressings to the scrub person after the final sponge count. Radiopaque sponges are not used for dressings because they could distort a postoperative x-ray of the site.
6. Do not discard or remove counted sponges from the room for any reason until the patient is out of the room.

Sharps

Sharps include surgical needles, hypodermic needles, knife blades, electrosurgical needles and blades, and safety pins. Each item must be accounted for. Surgical needles are the most difficult to track and are used in the largest quantity. All surgical needles and other sharps are counted as they are added to the sterile table and/or separated from other instruments in the instrument tray.

Surgical Needle Counts

Surgical needles are used for suturing. The type will determine the method of transfer to the sterile table:

1. Reusable eyed needles put in a needle rack or a suture book are uniformly counted into sets in multiples of two or three of each type and size the surgeon will need. These needles are usually packaged and sterilized separately from the instrument sets. Most facilities have converted to disposable free needles and no longer reuse needles.
2. Disposable suturing needles are precounted, packaged, and sterilized by the manufacturer. The label will specify whether the sterile pack contains single or multiple needles. Closure materials are discussed in detail in Chapter 28.

Counting Needles and Other Sharps

Each needle or packet containing needles is separated for individual counting. Suture packets containing swaged needles can remain unopened. The count is taken according to the label on each packet. Some packets contain multiple needles. The scrub person verifies the count when the packet is opened. Counting empty suture packets at the end of the case is not an appropriate method of reconciling a count.

Methods of Accounting for Sharps

If a needle or blade has broken, both the scrub person and the circulating nurse must make sure all pieces are recovered or accounted for. Sometimes the risk of retrieving a piece of a sharp or needle is more hazardous than letting it encapsulate in tissue. The surgeon makes this determination. This must be documented.

Many smaller gauge needles do not appear easily on x-ray unless the technician uses special density calculations. Needles, knife blades, safety pins, and other small sharps should never be left loose on the Mayo stand, because they could be pulled into the

incision or knocked onto the floor. Smallness of the needle is not a valid reason to fail to account for each one.

By the Scrub Person

1. Leave needles swaged to suture material in their inner folder or dispenser packet until the surgeon is ready to use them. These folders or packets can be placed in the edge of a folded towel on the working end of the table.
2. Give needles to the surgeon on an exchange basis; that is, one is returned before another is passed. Account for each needle as the surgeon finishes with it. Needles should only exchange hands within a needle holder.
3. Use needles and needle holders as a unit. The following is a good rule: No needle on the Mayo stand without a needle holder, and no needle holder without a needle.
4. Secure used needles and sharps in a needle-counting box or magnet holder until after the final count. Many methods for efficient handling are available, as follows:
   a. Sterile adhesive pads with or without magnets facilitate counting and safe disposal. When a large number of swaged needles will be used, the scrub person and circulating nurse may determine the number of needles a pad will hold and work out a unit system. Disposable plastic boxes of various sizes for the containment of sharps are commercially available.
   b. Used eyed needles can be returned to the needle rack. The use of reusable suture needles is not encouraged because they become dulled with use and could harbor microorganisms if not properly cleaned.

By the Circulating Nurse

1. Open only the necessary number of packets of sutures with swaged needles. Overstocking the instrument table not only is wasteful but also complicates the needle count.
2. Counted sharps should not be taken from the OR during the surgical procedure. If a scalpel with a counted knife blade is given to a pathologist to open a specimen, the scalpel must remain in the room after gross examination of the specimen; it is not to be taken to the laboratory with the specimen.
3. A sharp is passed off the sterile field if it punctures, cuts, or tears the glove of a sterile team member. These sharps are retained and added to the table and field counts to reconcile the final sharp count. An empty specimen cup is a good container for a loose sharp.
4. A magnetic roller may be used to locate a surgical needle or blade that has dropped on the floor. A piece of tape is used to retrieve a sharp from the floor. Close the tape over the sharp and place in a specimen cup. Picking up a sharp even with gloved fingers can cause a puncture injury.

Instruments

Surgical tools and devices are designed to perform specific functions that include cutting or dissecting, grasping and holding, clamping and occluding, exposing, or suturing. For each basic maneuver, an instrument of suitable size, shape, strength, and function is needed. Variation in the style and number of instruments will be dictated by the type of surgical procedure and, to some extent, by the personal preferences of the surgeon.

Counting Instruments

Instrument counts are recommended for all surgical procedures. Specific written policies and procedures are followed without deviation. To count instruments, the scrub person should do the following:

1. Remove the top rack of instruments from the instrument tray or container and place it on a rolled towel. Instruments are counted as they are assembled in standardized sets in the processing area. Groups of even numbers of each of the basic clamps facilitate handling and counting.

   Some facilities permit "cluster counting," which is a method of counting all scissors, pickups, needle holders, retractors, and other like groups together without having to name each item with its formal name. For example, the tray may contain two pairs each of three different types of scissors. This cluster would be counted as "six scissors" instead of two Mayo, two Metzenbaum, and two suture scissors. This can speed up the count. If an item is not accounted for in the cluster, an itemized individual count ensues. The same can be done for retractors and pickups.
2. Expose all instruments left in the tray for counting. Remove knife handles, towel clips, tissue forceps, and other small instruments from the tray, and place them on the instrument table. Do not put instruments on the Mayo stand until they are counted; they can be put on the stand as they are being counted.
3. Account for all detachable and disassembled parts, such as screws or ratchets. These must be counted or accounted for during assembly and once again during disassembly at the end of the case.
4. Recover and retain all pieces of an instrument that breaks during use. A replacement instrument is added to the count sheet by the circulating nurse.
5. After the initial count is taken, count any instruments added to the table, with one exception. If the circulating nurse decontaminates and sterilizes an instrument for immediate use that has dropped to the floor or has been passed off the table, an adjustment in the count is unnecessary. Instruments that are recovered from the floor or passed off the table and not sterilized are retained by the circulating nurse and reconciled at the closing count. Sterilization for immediate use is not a recommended practice. It is only used when no other alternative is available.

Simplifying Instrument Counts

Counting is easier if the numbers and types of instruments are reduced and if standardized sets are streamlined. Inform the OR manager if unused, unnecessary instruments are routinely included in basic sets. Keep the surgeons' preference cards up to date. Instruments peculiar to specific surgical procedures or surgeons can be wrapped separately and added to the basic foundation set only when needed.

Standard count sheets for each basic instrument set will facilitate the counting process. The sheet accompanies the set. The person who prepares the set verifies the initial count as listed. The circulating nurse can check the items as they are counted with the scrub person.

Efficiency of the Operating Room Team

A discussion of the duties of the scrub person and the circulating nurse would not be complete without consideration of efficiency, productivity, and work habits. Therefore efficiency depends primarily on individual effort and the working relationship among team members.

Productivity

Productivity and efficiency go hand in hand. Productivity is directly related to what a person does and how he or she does it. Productivity is also the quantity and quality of work (output) in

relation to the costs in terms of labor and time (input). To be productive, perioperative nurses and surgical technologists should develop their psychomotor skills, competencies, and mental capacities. This requires an accurate perception of the factors and conditions that affect the patient, surgeon, and other team members. The concept of situational awareness means staying in touch with the environment and thinking ahead in preparing for and participating in the surgical procedure. Productivity is enhanced by a person's ability to do the following:

1. Organize work efficiently and effectively. Efficiency is important to minimize the length of time during which a patient is anesthetized and the anxious family is waiting.
2. Work rapidly with precision and dexterity. Learn to follow directions quickly and accurately, and give attention to the smallest detail. Carelessness creates waste and unnecessary hazards for the patient and team.
3. Adapt to changes or unexpected situations quickly, calmly, and efficiently. A change in diagnosis during the surgical procedure may require an altogether different setup and a different surgical approach from the one anticipated. Emergencies will arise. Knowing what to do and why to do it in a particular way decreases the anxiety of rapid performance. Exercise good judgment, and learn to prioritize actions and function competently under pressure.
4. Anticipate the needs of the surgeon and the team, and keep one step ahead. The surgeon becomes distracted if handed the wrong instrument or made to wait for supplies. Be alert and try to anticipate procedural needs logically.
5. Maintain physical and emotional stamina. Situational awareness can be compromised by fatigue, poor physical health, and emotional distress. Be sensitive to the health and well-being of other team members.

Time and Motion Economy

Time is money; do not waste it. Know the policies and procedures, and follow them efficiently. Learn to do things right the first time, and continue to do them that way; time is wasted in correcting errors. Motions should be productive.

Time Is Costly

Time is an important element in the OR. If time is wasted between surgical procedures, the day's schedule is slowed down and later procedures are delayed. The surgeons' time is wasted, and they then tend to come late because they anticipate delays. The patients and families become anxious during these delays.

Workers with poor time-management skills tend to become less efficient and drift into poor work habits. Common sense is a great ally. Take time to stop and think. Is there a quicker, easier, or more efficient way of doing the job without compromising technique? Most work habits can be improved. Analyze them in a methodic manner.

Recognizing that a problem exists is the first step toward solving that problem. Gather the facts needed to support the desirability of adopting alternatives. Seek to develop more efficient and more economical work methods.

Associations

Each patient, surgeon, and surgical procedure is unique, but all have commonalities. A logical thought process will simplify the necessary OR preparations for the patient and the surgeon. Supplies and equipment must be ready before the procedure can begin.

Association is a great aid to memory and organization of work. With association, the mention of one article brings to mind the others used with it. For instance, the scrub person knows a suture calls for a tissue forceps to the surgeon, a needle holder to the assistant, and then scissors. Watch for and try to establish associations to increase efficiency. Think of the order in which instruments and supplies are going to be needed, and do first things first (e.g., prepare sutures for closing deep tissue layers before preparing sutures for the skin).

To be proficient, know the organization of work and the relative importance of the factors in accomplishing it. If, as the patient is being prepped, the surgeon requests stainless steel retention sutures for closure instead of the usual sutures, the circulating nurse should realize there is plenty of time to get these sutures after the other duties have been completed. Before getting these closing sutures, the circulating nurse must perform the duties necessary to start the surgical procedure; for example, tie the gowns, supervise the draping, position the instrument table, and connect the ESU and suction. When getting these steel sutures, association tells the circulating nurse to also get wire scissors.

Motion Economy

Wasted motion not only is time consuming but also adds to physical fatigue. Fatigue is the result of body movement. Ten principles of motion economy can reduce fatigue from physical activity and improve personal levels of efficiency:

1. Motion should be productive. Once the steps in a procedure are learned, work to increase speed and the psychomotor skill needed to perform them. Make each movement purposeful; avoid rushed or disorganized motions. Work quietly and quickly. Work as fast as possible without sacrificing accuracy, safety, and technique for speed.

   The corollary to this principle is a place for everything and everything in its place. Keep an orderly work area to avoid fumbling and rehandling items. If everything has a place and is in its place, supplies are easily obtained by instinct when needed. A neat and orderly work area is one of the first requirements for productive motions. Consider the workflow so that minimal motions can be made to accomplish productive work.
2. Motions should be simple. Body movements should be confined to the lowest classification with which it is possible to perform work properly.[6] Movements of the upper extremity are classified into five levels:
   a. Class 1 involves the fingers. The knuckle provides the pivot for motion for such tasks as fingering through a card file, turning a setscrew on an instrument, and using a pair of scissors.
   b. Class 2 involves both the hand and the fingers. The wrist is the pivot for motion for tasks such as passing instruments, counting sponges, and picking up or writing on an intraoperative record.
   c. Class 3 includes the forearm. The elbow is used as a pivot to open a peel-open package, unfold drapes, and unwrap small supplies. More effort and time are expended in the third and succeeding classifications, because the movements of any one class involve the movements of all classes preceding it. It takes longer and requires more effort to turn the pages of a procedure book or a patient's chart than to thumb through a file of surgeons' preference cards.
   d. Class 4 includes the upper arm. The shoulder pivot is used when opening a door, setting up the Mayo stand, and prepping a patient.

e. Class 5 adds the torso. The trunk bends or stretches to lift a patient, take supplies from a low shelf or drawer, hang an IV bag, or count the sponges in a kick bucket.

Upper extremity work should be arranged to reduce work to the lowest possible classification. Finger motion is the least fatiguing, and shoulder motion is the most fatiguing. The scrub person should be positioned at the OR bed so that elbow, wrist, and finger motions can be used. To prevent prolonged shoulder motion for both of them, he or she should be positioned opposite the surgeon so that both can work with their elbows at their sides. The OR bed should be adjusted for height according to the tallest team member. Steps should be supplied for shorter members.

It is quicker for the circulating nurse to stretch to hang an IV bag than to take time to use finger action to loosen the set screw on an IV pole, lower it with shoulder movement, hang the bag with elbow action, and repeat the sequence in reverse. However, stretching is more fatiguing. Increasing fatigue causes slower motion as the day progresses. Maybe 30 seconds was saved with the first patient of the day, but what happens to the last patient of the day? Time is lost because energy wanes.

3. Motions should be curved. Motions should follow curved rather than straight paths whenever possible. A circular motion to clean the flat surfaces of furniture is less fatiguing than straight push-and-pull strokes.
4. Motions should be symmetric. Motions should be rhythmic and flow smoothly; when possible, both hands should be used symmetrically.
5. Work should be within grasp range. To avoid changes in body position, all work materials should be arranged so they are within grasp range. Grasp range is within the radius from the pivot point of the elbow or shoulder, either horizontally or vertically. The minimum grasp range is within the radius of the arcs formed with only the forearms extended, using the elbows as pivot points on the horizontal plane. The optimum grasp range is within the area where the left-hand and right-hand arcs overlap. This is the area in which two-handed work, such as putting a needle in a needle holder, can be performed most conveniently. The maximum grasp range is within the arcs formed from the shoulder pivots. The overlapping of these arcs is the maximum extent at which two-handed work can be performed within reach without changing body position.

   The Mayo stand should be placed over the OR bed at a height and in a position within the minimum and optimum grasp range of the scrub person. It must not rest on the patient, but it can be lowered to an inch or two above the patient. The support pillar of the Mayo stand should be directly in front of the scrub person. The scrub person should be able to adjust the height by using the foot lever.

   The instrument table should be positioned as close as possible to the horizontal plane within maximum grasp range. Instruments or supplies that require two-handed work should be placed on the Mayo stand and instrument table as close to the optimum grasp range as possible.
6. Hands should be relieved of work. Hands should be relieved of any work that can be performed more advantageously by other parts of the body. Many electrical instruments have foot pedals to facilitate operation.
7. Work materials should be prepositioned. Supplies can be arranged for convenient use and minimal handling. Drapes are packaged in order of use so they do not need to be handled by the scrub person, except to move the stack to a corner of the instrument table, until ready to use. Instruments can be arranged in containers so that all of them do not need to be removed until needed.

   Economize time and effort by placing items on the instrument table and Mayo stand in the order in which they will be used, and put them in their proper places without rearranging them. Arrange instruments on the Mayo stand in position to hand to the surgeon or assistant.

   In passing an instrument, place it in the surgeon's hand in the position in which it will be used so that readjustments will not be necessary. Hold the instrument with the thumb and the first two fingers, far enough away from the handle so the surgeon can grasp it. Hand a needle in a needle holder in the same way, supporting the suture so it does not drag; hand it with the needle pointing in the direction in which the surgeon will start to use it. Hand thumb forceps so the surgeon can grasp the handle; do the same with retractors.
8. Gravity should be used. Dispensers for scrub sponges and brushes operate on the principle that gravity should be used whenever possible. Cabinets for smaller packages in the sterile supply room can be vertical and divided into appropriate-size slots. These cabinets can be filled from the top and dispensed from the bottom of each slot. This method is convenient, saves space, and ensures that older items are used first. Shelves for large, heavy packs can be slanted slightly to facilitate handling. Gravity-feed and drop-delivery installations eliminate or reduce motions. The quickest way to dispose of an object is to drop it. Because this also may be the quickest way to break or contaminate the object, the application of this principle requires good judgment.
9. Supplies should be combined. Items should serve two or more purposes whenever possible. For example, sterilizer chemical indicator tape serves a dual purpose: to hold the package closed and to show if it has been exposed to a sterilization process. And only inches, not a yard, of tape accomplish the job. Disposable kits and trays are purchased, or sets are made up of reusable items so that all the supplies and materials needed for a procedure are combined into a single unit. This eliminates opening many separate packages.
10. The worker should be at ease. Tiring body motions or awkward or strained body postures should be avoided. A pleasant, quiet environment is less fatiguing, has fewer psychologic and physiologic adverse effects on team members, and enhances greater efficiency.

Economical Use of Supplies and Equipment

As the cost of supplies increases, circulating nurses and scrub persons should be conscious of ways in which to eliminate wasteful practices. For example, throw away disposable items only. Avoid throwing away reusable items.

The OR suite is one of the most expensive departments of a hospital. Adequate instruments and supplies are necessary for patient care, and cost is not always the primary consideration. Economy becomes a hazard when exercised beyond the point of safety. Nevertheless, supplies do not need to be used lavishly just because they are available. Remember the principles mentioned in the following sections.

"Just Enough Is Enough"

The varieties and numbers of instruments and supplies needed for each surgical procedure can be kept to a minimum. If the

procedure list and surgeons' preferences are kept up to date, articles no longer used can be eliminated. Items to "have available" are not opened unnecessarily. The following procedures should be observed:

1. Pour just enough antiseptic solution for the two-step skin preparation according to the manufacturer's recommendation; it takes only a small amount. Do not open a bottle unnecessarily for a small amount if you know the remainder will not be used.
2. Follow the procedures for draping to provide an adequate sterile field without wasting disposable draping material.
3. Do not open another packet of sutures for the last stitch unless absolutely necessary. A few leftover pieces of the same product may be long enough to complete the closure.
4. Suction tubing, syringes, hypodermic needles, drains, catheters, extra drapes, and other such materials are kept sterile and available. Supplies should be opened only as needed—not routinely "just in case" they may be needed.
5. Do not soak too much plaster or fiberglass casting material when helping with cast applications. Keep just ahead of the surgeon. Ask if more is needed before soaking an extra roll.
6. Turn off lights when they are not needed.
7. Separate trash into contaminated and noncontaminated waste. Contaminated waste is processed at a cost per pound.

Use Supplies and Equipment for Intended Use

1. Use OR bed appliances according to the manufacturer's instructions for positioning and stabilizing patients.
2. Use unsterile gloves for unsterile procedures in which the use of gloves is for hand protection. Open sterile gloves for sterile procedures only.
3. Do not use hemostats to clamp drapes or tubing; doing so ruins both the hemostat and the tubing. Use a stopcock or a special tubing clamp for tubes, and use a nonpiercing towel clip to secure drapes. Custom drapes come with hook and loop tabs or flaps with holes to secure cords and tubing.
4. Give the assistant a needle holder for pulling needles through tissue for the surgeon. A hemostat can be ruined by using it for this purpose, and the needle can be damaged.
5. Use wire scissors for cutting wire, tissue scissors for cutting tissue, dressing scissors for cutting drains and dressings, and suture scissors for cutting sutures.

Avoid Damage

Handle all supplies and equipment carefully to avoid damage and breakage:

1. Slip off the patient's gown sleeve before the preoperative IV infusion is started. This prevents having to cut off a wet, soiled gown at the completion of the surgical procedure.
2. Rotate sterile and older supplies to prevent items from deteriorating or the integrity of packaging from being compromised.
3. Take special care to preserve the edges of sharp instruments.
4. Follow established procedures for the proper sterilization and care of instruments, electrical equipment, and other materials. If uncertain how to sterilize or care for any equipment, find out; do not ruin items by guessing. Items for gas sterilization should be tagged "for gas" or "heat sensitive" to help prevent the possibility of inadvertent steam sterilization. Moisture-sensitive items such as surgical cameras should be labeled accordingly.
5. Check drapes to be certain that instruments are not discarded in disposable drapes or sent to the laundry. At the end of the surgical procedure, the scrub person should look for instruments, needles, and equipment before discarding drapes. This is part of the inventory control reason for counting instruments.
6. If an instrument or piece of equipment is defective, immediately remove it from use. Tag the device with a description of the problem, and report the malfunction promptly for corrective action. In addition, report a surgeon's complaints about the function or quality of an instrument or equipment.
7. Adhere to the routine preventive maintenance schedule for equipment.

Positioning, Prepping, and Draping the Patient

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify the safety hazards associated with moving a patient from one surface to another.
- List the anatomic considerations for positioning.
- Describe the effects of positioning on the patient's body systems.
- Identify key elements of preoperative skin preparation of patients.
- Discuss the implications of chemical and mechanical actions of prepping the patient.
- Describe how a patient is draped using sterile technique.

KEY TERMS AND DEFINITIONS

Abduct Move away from the body.
Adduct Move toward the body.
Anterior In front of.
Antiseptic solution Topical cleansing chemical used to decrease the microbial count on the skin surface.
Body habitus Generalized physiologic configuration of the patient's size, weight, and shape.
Caudad Toward the foot of the patient.
Cephalad Toward the head of the patient.
Circumduct Rotate a joint in a circumferential axis (usually a ball joint).
Circumferential The surface area of the patient's skin that encompasses a limb or other rounded tissue area.
Deep Below the surface layers.
Distal Away from the core.
Dorsal Back of a part.
Extend Flatten a joint (zero-degree flexion).
Flexion Bend at a normal joint, close the angle of the joint.
Hyperabduction Move away from the body in a line more than a safe 90-degree angle.
Hyperadduction Move toward the body, crossing over the neutral plane of the body.
Hyperextend Move beyond the normal flattening of a joint axis.
Inferior Below or beneath.
Lateral Toward the side of the patient.
Medial Toward the midline.
Posterior Behind.
Prone Face down.
Proximal Closer to the core.
Reverse Trendelenburg's position Head-elevated position.
Superficial On the surface.
Superior Above.
Supine Face up.
Trendelenburg's position Head-down position.
Ventral Front surface.

Preliminary Considerations

Positioning for a surgical procedure is important to the patient's outcome. Proper positioning facilitates preoperative skin preparation and appropriate draping with sterile drapes. Positioning requires a detailed knowledge of anatomy and physiologic principles and familiarity with the necessary equipment. Safety is a prime consideration.

Patient position and skin preparation are determined by the procedure to be performed, with consideration given to the surgeon's choice of surgical approach and the technique of anesthetic administration. Factors such as age, height, weight, cardiopulmonary status, and preexisting disease condition (e.g., arthritis, allergies) also should be incorporated into the plan of care.[1] Preoperatively, the patient should be assessed for alterations in skin integrity, for joint mobility, and for the presence of joint or

vascular prostheses. The expected outcome is that the patient will not be harmed by positioning, prepping, or draping for the surgical procedure.

Efficiency of the patient preparation process can be attained by organizing activities in a logical sequence. Table 26.1 illustrates how to coordinate and organize patient preparation activities.

The main objectives for any surgical or procedural positioning are as follows:

- Optimize surgical-site exposure for the surgeon.
- Minimize the risk for adverse physiologic effects.
- Facilitate physiologic monitoring by the anesthesia provider.
- Promote safety and security for the patient.

Responsibility for Patient Positioning

The selection of the surgical position is made by the surgeon in consultation with the anesthesia provider. Adjustments are made as necessary for the administration and monitoring of anesthetic and for maintenance of the patient's physiologic status. The circulating nurse or first assistant may be responsible for placing the patient in a surgical position, with guidance from the anesthesia provider and the surgeon. In essence, patient positioning is a shared responsibility among all team members. The anesthesia provider has the final word on positioning when the patient's physiologic status and monitoring are in question.

In cases of complex positioning or positioning patients who are obese, the plan of care includes the need for additional help in lifting or positioning. Special devices or positioning aids may be necessary. The weight tolerance of the mechanism and balance of the operating room (OR) bed is critical. Manufacturer recommendations should be consulted for guidance in selecting the appropriate bed. To avoid questions or confusion, the weight tolerance should be clearly labeled on every OR bed. Standard OR beds accommodate 350 lbs. Specialty OR beds are available for patients weighing up to 1000 lbs.

Timing of Patient Positioning and Anesthetic Administration

Moving the patient from the transport cart to the OR bed or vice versa requires that both surfaces are securely locked and stable. Someone should be stationed on the far side of the receiving surface to prevent the patient from tumbling off the edge. For any patient under the influence of an anesthetic agent or narcotic medication, personnel should be at the head, foot, and both sides of the patient to prevent dependent parts from sliding off the table. The neck of the patient's gown should be untied to prevent entanglement and choking as the patient moves or is moved from one surface to another.

After transfer from the transport cart to the OR bed, the patient is usually **supine** (face up on the back; a few exceptions apply and are explained subsequently in this chapter). Privacy is maintained with a warm cotton blanket, and the thigh strap is positioned in clear sight of the entire team. The patient may be anesthetized in a supine position and then repositioned for the surgical procedure.[2]

Some patients are positioned and then anesthetized if their physiologic status requires special care. If patients undergo a procedure in a prone position and with general anesthesia, they are anesthetized and intubated on the transport cart. A minimum of four people is required to place the patient safely in the prone position on the OR bed. Commonly, more personnel are needed for a safe transfer between surfaces when the patient is fully under anesthesia and intubated.[3]

Several factors influence the time at which the patient is positioned: the site of the surgical procedure, the age and size of the patient, the technique of anesthetic administration, and whether the patient is conscious and in pain while moving. The patient is not moved, positioned, or prepped until the anesthesia provider indicates it is safe to do so.

Preparations for Positioning

Before the patient is brought into the OR, the circulating nurse should do the following:

1. Review the proposed position by referring to the positioning instructions on the surgeon's preference card in comparison with the scheduled procedure.
2. Ask the surgeon for assistance if unsure how to position the patient.
3. Assess for any patient-specific positioning and padding needs.
4. Check the working parts of the OR bed before bringing the patient into the room.
5. Assemble and test all table attachments and protective pads anticipated for the surgical procedure and have them immediately available for use. Box 26.1 lists areas that may need specific attention during padding.
6. Review the plan of care for unique needs of the patient.

Safety Measures

Safety measures, including the following, are observed while transferring, moving, and positioning patients:

1. The patient is properly identified before being transferred to the OR bed, and the surgical site is confirmed according to facility policy. The surgeon is required to initial the correct site.
2. The patient is assessed for mobility status, which includes determination of the patient's ability to transfer between the transport cart and the OR bed. Do not plan to have patients move themselves toward an affected limb or toward the blinded eye.
3. The OR bed and transport vehicle are securely locked in position, with the mattress stabilized during transfer to and from the OR bed. Untie the ties of the patient's gown, and take care not to allow the patient's gown or blanket to become lodged between the two surfaces or under the bottom of a moving patient. Velcro strips or other means should be used to maintain the stability of the mattresses of the two surfaces.
4. Two people should assist an awake patient with the transfer by positioning themselves on each side of the patient's transfer path. The person on the side of the transport cart assists the patient in moving toward the OR bed. The person on the opposite side prevents the patient from falling over the edge of the OR bed.
5. Adequate assistance in lifting unconscious, anesthetized, obese, or weak patients is necessary to prevent injury. A minimum of four people is recommended, and transfer devices and lifters may be used. The patient is moved on the count of three, with the anesthesia provider giving the signal count. Sliding or pulling the patient may cause dermal abrasion or injury to soft tissues. Dependent limbs can create a counterbalance and cause the patient to fall to the floor. Examination gloves should be worn if the patient is incontinent or offers other risk for exposure to blood and body substances.

TABLE 26.1 Planning the Organization of Patient Positioning, Prepping, and Draping

Type of Procedure	Positioning	Catheterization	Preparation Sequence	Drape Tips
		ABDOMINAL		
Anterior chest, epigastrium, umbilicus, pelvis Laparoscopy	Supine with arms tucked at sides or secured on armboards. Thigh strap is secured. Legs remain flat. Small pillow under knees to take pressure off lower back, pad heels. Trendelenburg's position can increase intraocular and intracranial pressure. Blood pressure and cardiac output decrease. Reverse Trendelenburg's position decreases intracranial pressure. Place padded footboard on lower bed segment to support feet. Lateral tilt can be used to elevate the surgical site.	Catheter is placed before the abdomen is cleansed. The urinary drainage bag is placed in view of the anesthesia provider. Female patient is frog-legged for the catheterization procedure. Support legs to prevent extreme external rotation. Complex patients may need ureteral catheters placed preoperatively. This catheter uses cystoscopy setup and two ureteral catheter drainage bags.	Hair is removed during the prep process as desired by the surgeon. Umbilicus is cleansed in sequence as preferred by the surgeon. Urinary meatus is prepped as part of the catheterization process. Abdominal cleansing begins at surgical site and proceeds to the periphery in a circular motion. Avoid pooling of prep solutions under the patient. Thigh strap is secured after the prep. Before draping, be sure that leg strap is placed over a blanket so it is visible to entire team.	The dispersive electrode for the monopolar ESU is placed when patient is in the final resting position for the procedure. Do not cut or reposition the electrode. Some surgeons like the surgical site squared off with towels. Some surgeons prefer medium sheets placed above and below the abdominal incision before placing a fenestrated sheet. Some surgeons prefer a clear or impregnated incise sheet. Fenestrated laparotomy sheet is positioned over the surgical site. Additional drapes may be needed to cover the armboards if the laparotomy sheet does not have arm flaps.
Combined abdominal and perineal Abdominal, epigastrium, pelvis Laparoscopy Genitourinary	Patient is anesthetized in the supine position unless epidural or spinal is used. Thigh strap is secured during induction. Lithotomy with arms tucked at sides or secured on armboards. Take care not to crush digits in table break. No strap on abdomen. Stirrups should be padded, and the legs should be elevated and lowered simultaneously. Legs are secured in stirrups with straps. Stirrups should be weight appropriate. Pulses should be checked after placement in the stirrups (e.g., popliteal, posterior tibial, dorsalis pedis). Sequential compression devices should remain functional, and tubing unobstructed. Lithotomy position increases autotransfusion from legs. Lowering the legs decreases blood pressure.	Foley catheter is placed before the abdomen is cleansed. The drain bag is placed in view of the anesthesia provider. Rectal irrigation for colon procedures (if necessary) is performed after the catheterization and before the perineal cleansing prep. An impervious, nonsterile, under-buttocks drape should be used to deflect runoff prep solution into a kick bucket. Complex patients may need ureteral catheters placed preoperatively. This catheter uses cystoscopy setup, two ureteral catheters, and a ureteral catheter drainage bag.	Urinary meatus is prepped as part of the catheterization process. Hair is removed during the prep process as desired by the surgeon. Perineum is prepped first, including the vagina, followed by the anus. Abdominal cleansing begins at surgical site and proceeds to the periphery in a circular motion. Thigh strap is secured after the prep. Before draping, be sure that leg strap is placed over a blanket so it is visible to entire team.	The dispersive electrode for the monopolar ESU is placed when patient is in the final resting position for the procedure. Do not cut or reposition the electrode. Under-buttocks, sterile drape is placed first, followed by leggings. Some surgeons like the surgical site squared off with towels. Some surgeons prefer a clear or impregnated incise sheet. Fenestrated laparotomy sheet is positioned over the surgical site. Additional drapes may be needed to cover the armboards if the laparotomy sheet does not have arm flaps. Some surgeons request a sterile drape over the exposed perineum until that portion of the procedure is started. Laparoscopic procedures may require perineal access during the abdominal phase of surgery.

Continued

TABLE 26.1 Planning the Organization of Patient Positioning, Prepping, and Draping—cont'd

Type of Procedure	Positioning	Catheterization	Preparation Sequence	Drape Tips
		LATERAL		
Thorax, kidney, hip	Patient is anesthetized in the supine position unless epidural or spinal is used. Thigh strap is secured during induction. Patient is positioned on the side after the catheter is placed. Padded beanbag vacuum positioning devices may be used. Legs are slightly flexed with pillow between knees. Lower leg is flexed more for stability. Axillary roll is placed under lower axilla. Arms are supported on armboards perpendicular to body. Use wide body strap over the hip and narrow belt loosely over lower leg. Some surgeons prefer to use wide adhesive tape secured to the bed. Table may be flexed to elevate the surgical site.	Catheterization is performed in the supine position. Catheter is placed before the patient is positioned and before the surgical site is cleansed. The drain bag is placed in view of the anesthesia provider. Female patient is frog-legged for the catheterization procedure. Complex patients may need ureteral catheters placed preoperatively. This catheter uses a cystoscopy setup, two ureteral catheters, and a ureteral catheter drainage bag.	Hair is removed during the prep process as desired by the surgeon. Cleansing begins at surgical site and proceeds to the periphery in a circular motion.	The dispersive electrode for the monopolar ESU is placed in the final resting position for the procedure. Do not cut or reposition the electrode. Some surgeons like the surgical site squared off with towels. Some surgeons prefer a clear or impregnated incise sheet. Fenestrated laparotomy sheet is positioned over the surgical site.
		EXTREMITY		
Shoulder, arm, wrist, leg, foot	UPPER: Elbow and distal to elbow may require a hand table attachment as a work surface. Sterile or nonsterile tourniquet may be placed. Shoulder procedures may require the patient to be in a supine posture. LOWER: *Supine:* Special orthopedic table may be used with support for unaffected limb and traction for affected limb. *Lateral:* Standard OR bed can be used.	Some patients with lower extremity fractures or joint replacements may need a Foley catheter. Placement of the Foley catheter may require additional help in holding the female patient's legs in position. Frog-legging is not advised with lower extremity fractures. Procedures lasting longer than 2 hours may require a urinary catheter to monitor intake and output.	Extremity is suspended above the surface of the OR bed. Hair is removed as desired by physician. Prep is circumferential. Prevent backflow of prep solution from clean to dirty. Prep from incision to periphery.	The dispersive electrode for the monopolar ESU is placed when patient is in the final resting position for the procedure. Do not cut or reposition the electrode. Do not place electrode on affected leg. Some surgeons like a sterile stockinette placed over the freshly prepped extremity. When a nonsterile tourniquet is used, a plastic impervious drape is placed around the distal aspect of the cuff to protect from prep solution. U-drapes and split sheets are commonly used to isolate the surgical site from the nonaffected areas.

SITTING				
Cranial, neck, ear, face, anterior throat, posterior cervical area Abdominoplasty	Patient is anesthetized in the supine position unless epidural or spinal is used. Thigh strap is secured during induction. *Many seated variations:* OR bed is in semi-Fowler or high-Fowler position, with the back of the bed elevated between 10 and 45 degrees. Leg break is slightly 5-10 degrees flexed to prevent the patient from sliding down. Sequential compression devices should remain functional and tubing unobstructed to decrease venous pooling in legs. A pillow is placed over the patient's midsection (or overbed table); the arms are placed over the top. Safety strap is placed lightly but securely over the thighs. Footboard may be used to maintain position of feet at right angles to legs, protect heels. Intracranial pressure is decreased in the seated position. Abdominal closure for abdominoplasty is facilitated by the flexed body position.	Foley catheter is placed with the patient supine before placement into a seated position. Take care not to kink when repositioning the patient. Drainage bag should be placed in clear view of anesthesia provider.	Hair is removed during the prep process as desired by the surgeon. Patient may want long head hair saved in a plastic bag for personal reasons. Always do this for pediatric patients and their parents. Cleansing begins at surgical site and proceeds to the periphery in a circular motion. Take extreme care not to get prep solution into eyes, nose, mouth, or ears. Clear plastic dressing materials can be placed over the facial orifices of the patient under general anesthesia to prevent exposure. Some surgeons prefer cotton balls or gauze placed in the patient's ears.	The dispersive electrode for the monopolar ESU is placed when patient is in the final resting position for the procedure. Do not cut or reposition the electrode. Cranial procedures use a fenestrated sheet with round aperture. Disposable sheets commonly have an incise sheet built in. Most have an inferior drainage pouch to catch runoff irrigation. Facial and anterior neck procedures require wrapping the head in a towel drape to isolate scalp hair from the field. Full sheets or split sheets can be used to cover the body.
PRONE				
Rectal, spinal, posterior thorax, cervical Modified spinal procedure prone/kneeling	Patient is anesthetized in the supine position on the transport cart unless epidural or spinal is used. Thigh strap is secured on posterior aspect of calves to prevent leg flexion. Chest rolls or frame prevent constriction of chest and abdomen. Protect genitalia and breasts from compression and shearing force. Gel pads under knees and dorsum of foot to protect the toes. Some special kneeling spinal tables have fabric boots that are fastened around the patient's feet. The boots are attached to the frame to secure the feet. Kneeling tables have padded positioner boards that rest against the patient's buttocks for stabilization.	Foley catheter is placed with the patient supine before placement into the prone position. Drainage bag is placed in the view of the anesthesia provider.	Hair is removed during the prep process as desired by the surgeon. Cleansing begins at surgical site and proceeds to the periphery in a circular motion.	The dispersive electrode for the monopolar ESU is placed when the patient is in the final resting position for the procedure. Some surgeons like the surgical site squared off with towels. Some surgeons prefer a clear or impregnated incise sheet. Fenestrated laparotomy sheet is positioned over the surgical site. Additional drapes may be needed to cover the armboards if the laparotomy sheet does not have arm flaps.

ESU, Electrosurgical unit.

• BOX 26.1 Body Areas That Need Padding during Positioning

Supine Position

Occiput
- Heels
- Elbows
- Sacrum
- Scapulae

Prone or Other Face-Down Position

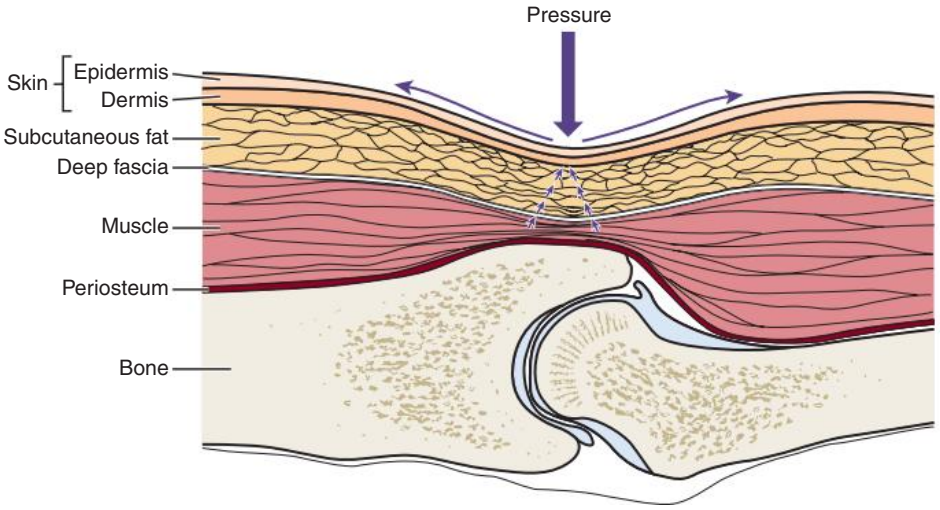
Anterior knees of kneeling patient
- Face (particularly the forehead) and ears
- Dorsum of foot to protect toes
- Genitalia and breasts

Lateral Position

Face and ears
- Medial knees
- Axilla
- Ankles and feet
- Arms

6. The anesthesia provider guards the head of the anesthetized patient at all times and supports it during movement. The head should be kept in a neutral axis and turned as little as possible to maintain the airway and cerebral circulation.
7. The physician assumes responsibility for protecting an unsplinted fracture during movement.
8. The anesthetized patient is not moved without permission of the anesthesia provider.[3]
9. The anesthetized patient is moved slowly and gently to allow the circulatory system to adjust and to control the body during movement.[3]
10. No body part should **extend** beyond the edges of the OR bed or contact metal parts or unpadded surfaces.
11. Body exposure should be minimal to prevent hypothermia and preserve dignity.
12. Movement and positioning should not obstruct or dislodge catheters, intravenous (IV) infusion tubing, oxygen cannulas, and monitors.
13. The armboard is protected to avoid **hyperextending** the arm greater than 90 degrees or dislodging the IV cannula. The surface of the armboard pad and the mattress of the OR bed should be of equal height. **Hyperabduction** is avoided to prevent brachial plexus stretch.
14. When the patient is supine (on the back), the ankles and legs must not be crossed. Crossing of the ankles and legs creates occlusive pressure on blood vessels and nerves, and pressure necrosis may occur. The patient is then at risk for deep vein thrombosis (DVT).
15. When the patient is **prone** (on the abdomen), the thorax is relieved of pressure by using chest rolls (subclavicle to iliac crest) to facilitate chest expansion with respiration. The chest rolls should be adequately secured to the table to prevent shifting. The **anterior** of the pubis should be sufficiently padded to protect the genitalia from pressure.

    The abdomen should remain dependent to decrease abdominal venous pressure and facilitate respiratory excursion. Padding should be placed at the dorsum of the feet to prevent pressure on the toes. In the event of cardiac arrest, a transport cart should be available for immediate emergency repositioning into the supine position and for subsequent resuscitation.
16. When the patient is positioned **lateral** (on the side), a pillow is placed lengthwise between the legs to prevent pressure on bony prominences, blood vessels, and nerves. This positioning also relieves pressure on the **superior** hip. The legs are slightly **adducted**, but not in hyperadduction. Pressure reduction padding is placed beneath the axilla on the unaffected side to protect the arm from body weight. Care is taken to assure that the padding is not creating undue pressure directly into the axilla.
17. During articulation of the OR bed, the patient is protected from crush injury at the flex points of the OR bed.
18. When the OR bed is elevated, the patient's feet and protuberant parts are protected from compression by overbed tables, Mayo stands, and retractor frames. An adequate clearance of 2 to 3 inches is maintained.
19. Surfaces should not create pressure on any body part. Alternating or pressure-relieving surfaces should be used. Rolled blankets and towels can create pressure because they do not allow for relief of compression at the contact surface. A gel pad or other alternating pressure pad should be used. Fig. 26.1 depicts the tissue layers as they are compressed against a bony prominence.



• **Fig. 26.1** Tissues are affected by pressure, which causes deep tissue damage and necrosis.

Anatomic and Physiologic Considerations

A patient's tolerance of the stresses of the surgical procedure depends greatly on normal functioning of the vital systems. The patient's physical condition is considered, and proper body alignment is important. Criteria are met for physiologic positioning to prevent injury from pressure, crushing, pinching, obstruction, and stretching. Each body system is considered when planning the patient's position for the surgical procedure. Complications of positioning are listed in Box 26.2.

Respiratory Considerations

Unhindered diaphragmatic movement and a patent airway are essential for maintaining respiratory function, preventing hypoxia, and facilitating induction by inhalation anesthesia. Chest excursion is a concern because inspiration expands the chest anteriorly. Some positions limit the amount of mechanical excursion of the chest. Some hypoxia is always present in a horizontal position because the anteroposterior diameter of the ribcage and abdomen decreases.

The tidal volume, the functional residual capacity of air moved by a single breath, is reduced by as much as one third when a patient lies down because the diaphragm shifts cephalad. Therefore there should be no constriction around the chest or neck.

The patient's arms should be at his or her side, on armboards, or otherwise supported—not crossed on the chest, unless absolutely necessary for the procedure. Patients have additional respiratory compromise if they are obese, smoke, or have pulmonary disease.

Circulatory Considerations

Adequate arterial circulation is necessary for maintaining blood pressure, perfusing tissues with oxygen, facilitating venous return, and preventing thrombus formation. Occlusion and pressure on the peripheral blood vessels are avoided. Body support and restraining straps must not be fastened too tightly. Anesthetic agents alter normal body circulatory mechanisms, such as blood pressure. Some drugs cause constriction or dilation of the blood vessels, which is further complicated by positioning.

Peripheral Nerve Considerations

Prolonged pressure on or stretching of the peripheral nerves can result in injuries that range from sensory and motor loss to paralysis and muscle wasting. The extremities and the body should be well supported at all times. The most common sites of injury in the upper body are the divisions of the brachial plexus and the ulnar, radial, peroneal, and facial nerves; the axons may be stretched or disrupted. Extreme positions of the head and arm greater than 90 degrees can easily injure the brachial plexus and other **superficial** nerves.

Peripheral nerve injury of the lower body can involve the sciatic, ilioinguinal, and peroneal nerves. If the patient is improperly positioned, the ulnar, radial, and peroneal nerves may be compressed against bone, stirrups, upright retractor posts, or the OR bed.

Arthroscopy leg holders and tourniquets can cause crushed or transected nerve injury. Femoral nerve injury can be caused by retractors during pelvic procedures. Sciatic nerve injury may be caused by tissue retraction or manipulation during hip surgery or extremes of lithotomy position. Facial nerve injury may result from a head strap that is too tight or from manually elevating the mandible too vigorously to maintain the airway.

• BOX 26.2 Complications Caused by Positioning

- Hemodynamic instability from orthostatic position
- Poor ventilation from thoracic compression
- Peripheral nerve injury from compression or stretch
- Tissue damage from crush or shearing force
- Ischemia of hair-bearing scalp, which causes bald spots
- Compartment syndrome
- Pressure necrosis
- Digit amputation in table bends
- Blindness from optic nerve ischemia
- Corneal abrasion
- Ischemic limbs from arterial occlusion
- Venous emboliVertebral injury
- Panic attacks and feelings of claustrophobia in awake patient

Musculoskeletal Considerations

A strain on muscle groups results in injury or needless postoperative discomfort. A patient who is anesthetized lacks protective muscle tone. If the head is extended for a prolonged time, the patient may have more pain from the resulting stiff neck than from the surgical wound. Care is taken not to hyperextend a joint, which not only causes postoperative pain but also may contribute to permanent injury to an extremity. Elderly or debilitated patients with osteoporosis or other bone disease may suffer fractures.

When turning a patient, always keep the spine in alignment by grasping the shoulder girdle and hip in a logrolling fashion. Do not turn or elevate a patient by grasping only a hip or shoulder and twisting the spine. Proper body alignment is maintained.

Soft Tissue Considerations

Body weight is distributed unevenly when the patient lies on the OR bed. Weight that is concentrated over bony prominences can cause skin pressure ulcers and **deep** tissue injury. These areas should be protected from constant external pressure against hard surfaces, particularly in patients who are thin or underweight. In addition, tissue that is subjected to prolonged mechanical pressure (e.g., a fold in the skin under an obese or malnourished patient) is not adequately perfused.

Wrinkled sheets and the edges of a positioning or other device under the patient can cause pressure on the skin. Foam pads are not adequate to relieve pressure because they compress and do not alternate pressure. Towels and sheet rolls do not relieve pressure because they are unyielding to the patient's body weight. Gel pads are preferred. According to the AORN (The Association of periOperative Registered Nurses) *Guidelines for Perioperative Practice,* positioning devices should maintain normal capillary interface pressure of 23 to 32 mm Hg or less to prevent pressure injuries. Blood flow and tissue perfusion are restricted at higher capillary pressures.

Pressure injuries are more common after surgical procedures that last 1 hour or longer. During lengthy procedures, the head and other body parts should be repositioned if possible. Patients who are debilitated, poorly nourished, or diabetic are at particularly high risk for pressure ulcers and alopecia (permanent bald spots from pressure).

Accessibility of the Surgical Site

The surgical procedure and patient condition determine the position in which the patient is placed. To minimize trauma and

operating time, the surgeon must have adequate exposure of the surgical site.

Accessibility for Anesthetic Administration

The anesthesia provider should be able to attach monitoring electrodes, administer the anesthetic and observe its effects, and maintain IV access. The patient's airway is of prime concern and must be patent and accessible at all times. The anesthesia provider needs to continuously assess urinary output, blood loss, and irrigation use. Consideration for visibility of measuring devices and drainage bags should be incorporated in the plan for positioning.

Individual Positioning Considerations

If patients are extremely obese (e.g., the torso occupies the width of the OR bed), their arms may be placed on armboards. Heavy-duty OR beds are available with side extenders to accommodate wide patients. Patients with arthritis or previous joint surgery may need special individualized care because of limited range of motion in their joints. A patient who has cardiac problems or is obese may experience orthopnea or dyspnea when lying flat.

Pediatric patients, especially infants, need less OR bed length. Some surgeons like the foot portion of the bed lowered to decrease the length of the working surface for accessibility.

Equipment for Positioning

Operating Room Bed

Many different OR beds with suitable attachments are available, and practice is necessary to master the adjustments. OR beds are versatile and adaptable to a number of diversified positions for many surgical specialties; orthopedic, urologic, and fluoroscopic tables are often used for specialized procedures. Fig. 26.2 depicts a typical general-purpose OR bed.

The patient's **body habitus** may necessitate the use of a specialty OR bed with an increased weight limit. Manufacturer recommendations should be consulted for the operation of each model of OR bed.

Most OR beds consist of a rectangular metal top that measures 79 to 89 inches long by 20 to 24 inches wide (201 to 225 cm × 51 to 61 cm) and rests on an electric or hydraulic lift base. Some models have interchangeable radiopaque tops for various specialties.

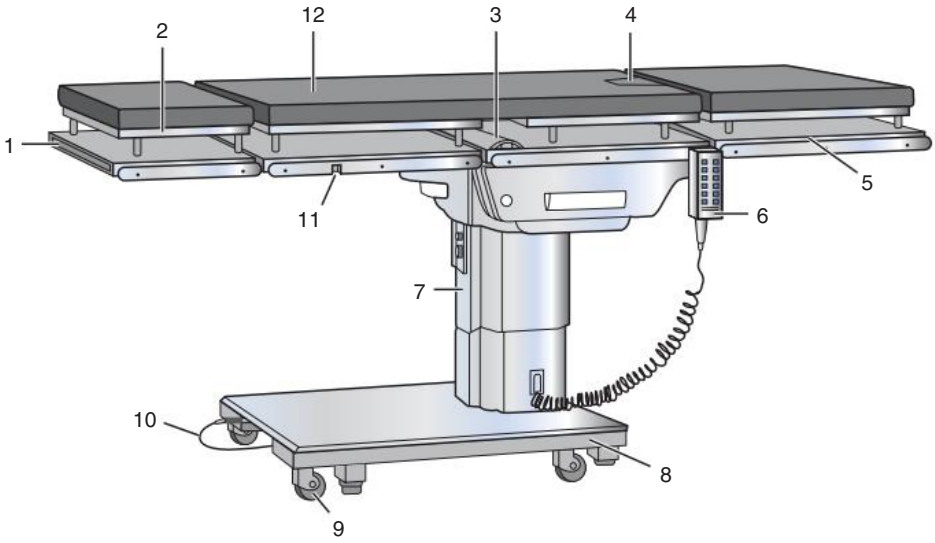
The surface of the OR bed is divided into three or more hinged sections: the head, the body, and the leg sections. The joints of the OR bed are referred to as *breaks.* Each hinged section can be manipulated, flexed, or extended to the desired position in a procedure called *breaking the OR bed.* Fig. 26.3 shows the range of flexibility of an average general-purpose OR bed.

Some OR beds have a metal body elevator plate between the two upper sections that may be raised up to 5½ inches (14 cm) to elevate an area for a gallbladder or kidney procedure. Care is taken when using this elevator because it can decrease the ability of the chest to expand during ventilation.

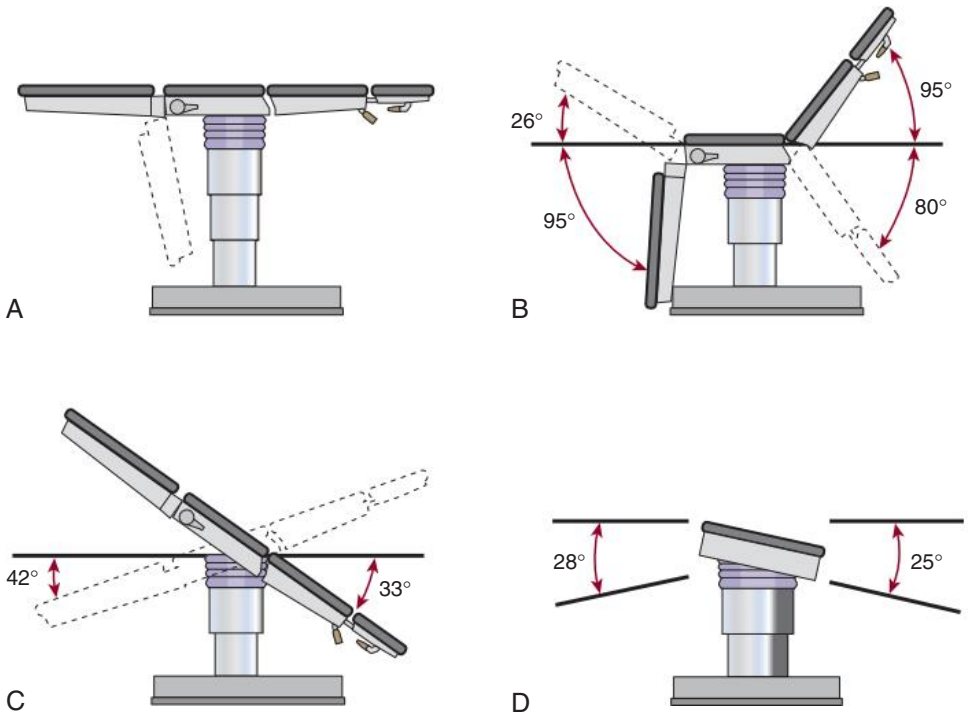
The head section is removable, which permits the insertion of special headrests for cranial procedures. An extension may be inserted at the foot of the OR bed to accommodate an exceptionally tall patient. A radiopaque cassette-loading top extends the length of the bed and permits the insertion of an x-ray cassette holder at any area. A self-adhering, sectional, conductive mattress (at least 3 inches [8 cm] thick) covers the surface of the OR bed. Gel-filled alternating surface mattress and pads are commercially available to cover the surface of the OR bed.

Standard OR beds have controls for manipulation into desired positions. Some beds are electrically controlled by either remote hand-control or foot-control switches or a lever-operated electrohydraulic system; older OR beds are controlled with manual hand cranks. Most electric styles have a rechargeable battery that can be used for several weeks without recharging.

The desired sections of the OR bed surface can be articulated by setting the selector control on "back," "side," "foot," or "flex." By activating other selector controls, the surface of the OR bed may be tilted laterally up to 28 degrees from side to side and raised or lowered in its entirety. A tiltometer indicates the degree



• **Fig. 26.2** General-purpose OR bed. *1,* Movable head section; *2,* x-ray cassette tunnel; *3,* kidney elevation bar; *4,* perineal cutout; *5,* lower extremity section; *6,* control box; *7,* pedestal; *8,* base; *9,* casters; *10,* power cord; *11,* side rails; *12,* pads.



• **Fig. 26.3** Flexibility range of general-purpose OR bed. **A,** Lower extremity section lowered. **B,** Range of positions for raised and lowered body and lower extremity sections. **C,** Trendelenburg's position and reverse Trendelenburg's position. **D,** Lateral tilt.

of tilt between horizontal and vertical for variations in Trendelenburg's position. Most styles offer 30 to 40 degrees of Trendelenburg's position full-table tilt down or up. All OR beds have a brake or floor lock for stabilization in all positions.

Special Equipment and Bed Attachments

The equipment used in positioning is designed to stabilize the patient in the desired position and thus permit optimal exposure of the surgical site. All devices are clean, free of sharp edges, and padded to prevent trauma or abrasion. Each OR bed has attachments for specific purposes. Many positioning devices to protect pressure points and joints are commercially available. If the devices are reusable, they are washable; some may be terminally sterilized for asepsis between uses.

Safety Belt (Thigh Strap)

For restraint of leg movement during surgical procedures, a sturdy, wide strap of durable material (e.g., nylon webbing with hook and loop closure, conductive rubber) is placed and fastened over the thighs, above the knees, and around the surface of the OR bed. Placement in this location prevents the large muscle groups of the legs from flexing and causing the patient to fall from the OR bed.

Some straps are attached at each side of the bed and fastened together at the center. This belt should be secure but not so tight that it impairs circulation; the circulating nurse should be able to pass two fingers between the strap and the patient. Placement of the belt depends on body position. For prevention of injury to underlying tissue, padding (e.g., a blanket) should be placed between the skin and the belt. The strap should be placed over, not under, this blanket for easy visualization before prepping and draping.

The safety belt is used during surgical procedures except for certain positions (e.g., lithotomy and seated). Belting across the patient's abdomen during the lithotomy position can cause compression of the abdominal structures. The safety belt is used before and after the procedure, when the patient's legs are in the down position.

Anesthesia Screen

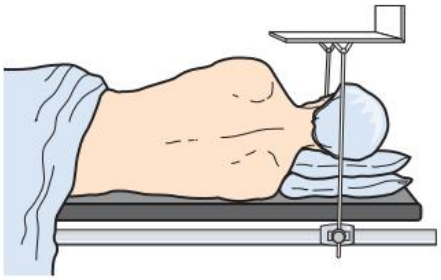
A metal bar attaches to the head of the OR bed and holds the drapes from the patient's face. It is placed after the induction of anesthesia and the positioning of the patient and is used to separate the nonsterile from the sterile area at the head of the bed. The bar is adjustable and allows rotation or angling. Some facilities use two IV poles to secure the drapes at the head of the bed.

Special procedures may require the use of an overbed table that mounts in the same fashion as an anesthesia screen. The socket attachments are secured to the side rail of the bed and are locked onto the frame of this table (Fig. 26.4).

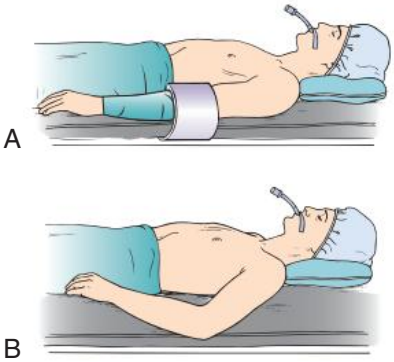
Lift Sheet (Drawsheet)

A double-layer sheet is placed horizontally across the top of a clean sheet on the OR bed. After patients are transferred to the OR bed, their arms are enclosed in the lower flaps of this sheet, with the palms against the sides in a natural position and the fingers extended along the length of the body. The upper flaps are brought down over the arms and tucked under the patient's sides. The sheet should not be tucked under the sides of the mattress because the combined weight of the mattress and the patient's torso may impair circulation or cause nerve torsion.

The full length of each arm is supported at the patient's side, protected from injury, and secured. The hands should not extend into the flex point of the bed or a crush injury may ensue. In



• **Fig. 26.4** Overbed table attachment.



• **Fig. 26.5** The patient's arms can be placed at the sides with the lift sheet pulled over the length of the arm and tucked under the patient's body. **A,** Correct way to secure arm at patient's side. **B,** Incorrect placement of patient's arm results in ulnar nerve injury.

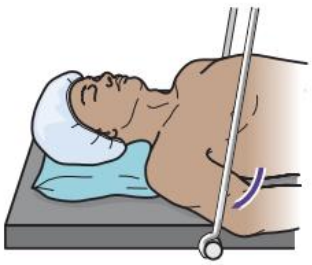
addition, a plastic curved shield, referred to as a sled, can be padded and used to protect and secure the arms from injury (Fig. 26.5).

Tucking of the patient's arms and use of a sled help prevent inadvertent pressure from upright bars of anesthesia screens, table attachments, and stationary retractor poles (Fig. 26.6).

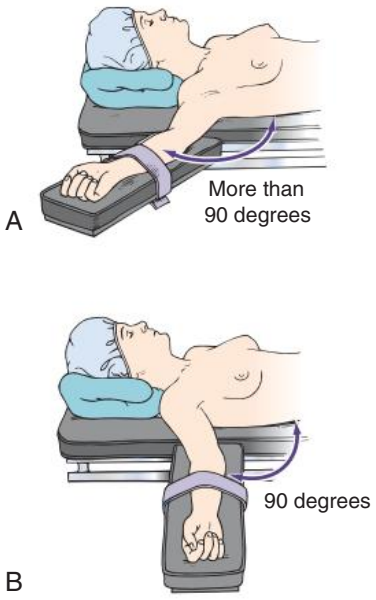
Patients should be told that these methods are used to support the arms when they are anesthetized and relaxed. The word *restraint* is avoided. At the end of the surgical procedure, this sheet, if not soiled or wet, may be used to lift the patient from the OR bed.

Armboard

Armboards are used to support the arms if IV fluids are being infused, if the arm or hand is the site of the surgical procedure, if the arm at the side would interfere with access to the surgical area, if space is inadequate on the OR bed for the arm to rest beside the body (as with an obese patient), and/or if the arm requires support (as in the lateral position).



• **Fig. 26.6** Tucking the arms can prevent accidental compression against an upright post attached to the bed frame.



• **Fig. 26.7** Position of arm on armboard should not exceed 90° or injury to the brachial plexus may result. **A,** Incorrect positioning. **B,** Correct positioning.

The armboard is padded to a height that is level with the OR bed mattress. To minimize the risk for ulnar nerve pressure and abnormal shoulder rotation, the patient's arm is placed palm up (supinated), except when the patient is in the prone position.

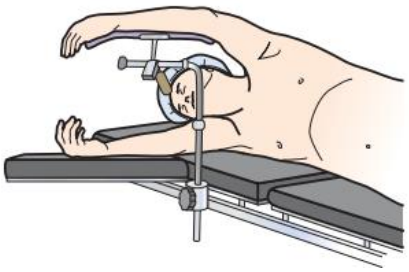
The armboard has adjustable angles, but the arm is never **abducted** beyond an angle of 90 degrees from the shoulder or brachial nerve plexus injury may occur from hyperabduction (Fig. 26.7). A self-locking type of armboard is safest to prevent displacement.

Double Armboard

With a double armboard, both arms are supported, with one directly above the other in lateral position. This type of armboard resembles the wings of a biplane and is sometimes called an airplane support or overbed arm support. Both levels of the armboard are padded (Fig. 26.8). An axillary roll is used to prevent pressure from the weight of the thorax.

Wrist or Arm Strap

Narrow straps at least 1½ inches (3.8 cm) wide are placed around the wrists to secure the arms to the armboards. The straps are secured without pressure or a tourniquet effect to the hands or arms. Tubing and monitoring lead wires should not be kinked or dislodged.



• **Fig. 26.8** Double armboard with elevated arm positioner.

Upper Extremity Table

For a surgical procedure on an arm or hand, an adjustable extremity table may be attached to the side of the OR bed and used in lieu of an armboard. This attachment is sometimes referred to as a hand table. Some types of extremity tables slip under the mattress **proximal** to the surgical site and extend perpendicular to the patient's trunk, with the **distal** end supported by a metal leg. Some models attach directly to the OR bed and require no additional floor support.

A solution drain pan may fit into some extremity tables. After skin preparation or irrigation, the pan is removed and the top panel is reinserted to cover the opening. A firm foam-rubber pad equal to the height of the mattress is placed on the table and draped to receive the arm, which is then draped. The upper extremity table provides a large firm surface for the surgical procedure. The surgeon and sterile team usually sit for these types of procedures. The level of the patient determines the level of the sterile field. If one team member sits, the entire team should sit to maintain the level of the sterile field.

Shoulder Bridge (Thyroid Elevator)

When a shoulder bridge is used, the head section is temporarily removed and a metal bar is slipped under the mattress between the head and body sections of the OR bed. The bridge can be raised to hyperextend the shoulder or thyroid area for surgical accessibility. This position can be achieved also by placing a positioning roll transversely under the shoulders, which causes the neck to hyperextend. A perpendicular roll can be placed between the shoulders to cause the shoulders to fall back bilaterally, which elevates the sternum.

Shoulder Braces or Supports

Adjustable well-padded concave metal supports are occasionally used to prevent the patient slipping when the head of the OR bed is tilted down, such as in the Trendelenburg's position. Braces should be placed equidistant from the head of the OR bed, with a ½-inch (13-mm) space between the shoulders and the braces to eliminate pressure against the shoulders. The braces are placed over the acromion processes, not over the muscles and soft tissues near the neck. Care is taken to assure that the patient's total body weight is not borne by the shoulder braces. The leg section can be lowered slightly to minimize shifting of body weight.

To avoid nerve compression, a shoulder brace is not used when the arm is extended on an armboard; in such cases, ankle straps may be used to stabilize the patient. Many surgeons have modified positioning routines to avoid the use of shoulder braces because of inadvertent nerve injury.

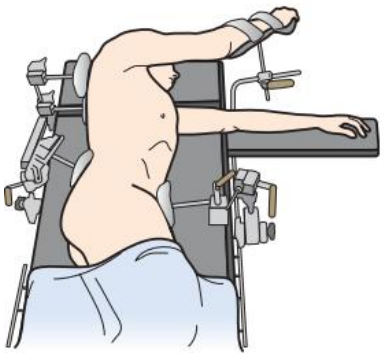
Body Rests and Braces

Body rests and braces are made of metal and have a foam-rubber or gel pad covered with conductive waterproof fabric. These devices are placed in metal clamps on the side of the OR bed and are slipped in from the edge of the OR bed against the body at various points to stabilize it in a lateral position.

Lateral Positioner (Kidney Rests)

Kidney rests are concave metal pieces with grooved notches at the base; they are placed on the body elevator **flexion** of the OR bed. They are placed snugly against the body for lateral stability in the side-lying kidney position.

Although the kidney rest is padded, care should be taken so that the upper edge of the rest does not press too tightly against the body. Some OR beds have built-in kidney rests that are raised and lowered electrically or with a hand crank.



• **Fig. 26.9** Anteroposterior positioning frames for lateral positioning.

Anteroposterior positioning frames attach to the bed in the socket attachments for use during spinal endoscopy. All other aspects of positioning should be considered, such as arms, legs, neck, and head (Fig. 26.9).

Body (Hip) Restraint Strap

With a body restraint strap, a wide belt with a padded center portion (to protect the skin) is placed over the patient's hips and secured to the sides of the OR bed. This strap helps hold the patient securely in the lateral position. Some surgeons prefer to use 2 to 3-inch wide bands of adhesive tape to secure the shoulders and hips of patients in the lateral position. A towel can be placed over the patient's skin before the tape is applied. The ends of the long strips of tape are secured to the underside of the OR bed. Care is taken not to cause compression, stretching, or folding of the skin under the tape.

Positioning for Anal Procedures with Adhesive Tape

For anal procedures, the patient is placed in a prone position (Kraske position). To separate and retract the buttocks, a piece of 3-inch (7.5-cm) adhesive tape is placed on each buttock, 4 inches (10 cm) lateral to the surgical site. For greater security of tape adhesion, benzoin or adhesive liquid is applied to each buttock before the tape strips are applied. Each end of the tape is fastened to the frame of the OR bed.

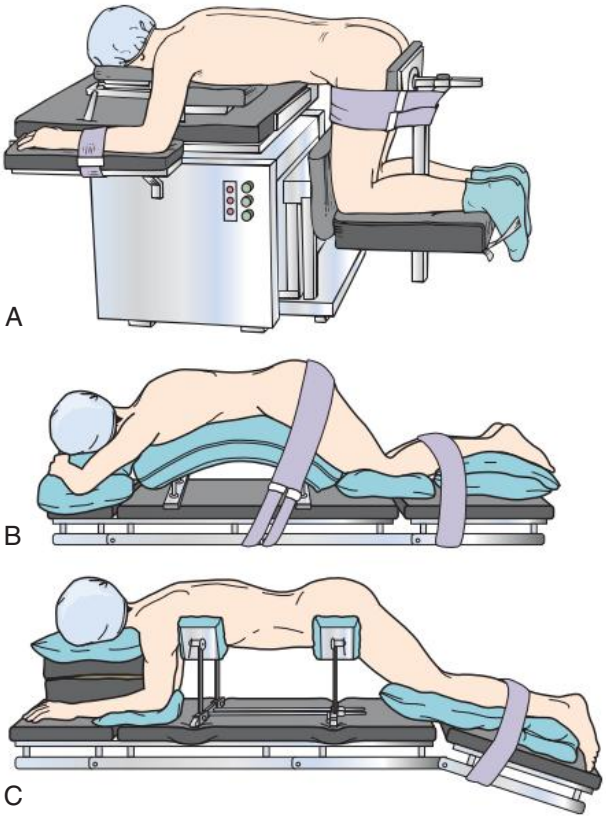
Adjustable Arched Spinal Frame

An adjustable arched spinal frame consists of two padded arches mounted on a frame that is attached to the OR bed. The patient is placed in the prone position with the **ventral** surface of the abdomen over this device (referred to as a Wilson frame). The pads extend from the shoulders to the thighs, with the abdomen hanging dependently between the arches. The desired degree of flexion for spinal procedures is achieved by adjusting the height of the arch by means of a crank. Other types of prone positioning frames are available (Fig. 26.10).

Stirrups

Metal stirrup posts are placed in holders, one on each side rail of the OR bed, to support the legs and feet in the lithotomy position. The feet are supported with canvas or fabric loops that suspend the legs at a right angle to the feet. These stirrups are sometimes called "candy cane" or "sling" stirrups (Fig. 26.11).

During extensive surgery, special leg holders may be used to support the lower legs and feet (e.g., Allen or Yellow Fin). Leg



• **Fig. 26.10** Frames for spinal surgery. **A,** Andrews. **B,** Wilson. **C,** Four-poster Relton frame.

holders are made in different sizes and are weight-specific to support the legs safely. Also available are metal or high-impact-plastic knee-crutch stirrups that can be adjusted for knee flexion and extension. Even if well padded, these stirrups may create some pressure on the back of the knees and lower extremities and may jeopardize the popliteal vessels and nerves. Gel and foam pads are available for patient protection when stirrups are used (Fig. 26.12).

Metal Footboard

The footboard can be used flat as a horizontal extension of the OR bed or raised perpendicular to the OR bed to support the feet, with the soles resting securely against it. It is padded when the patient is placed in reverse Trendelenburg's position. The patient's full body weight should not rest on the soles of the feet.

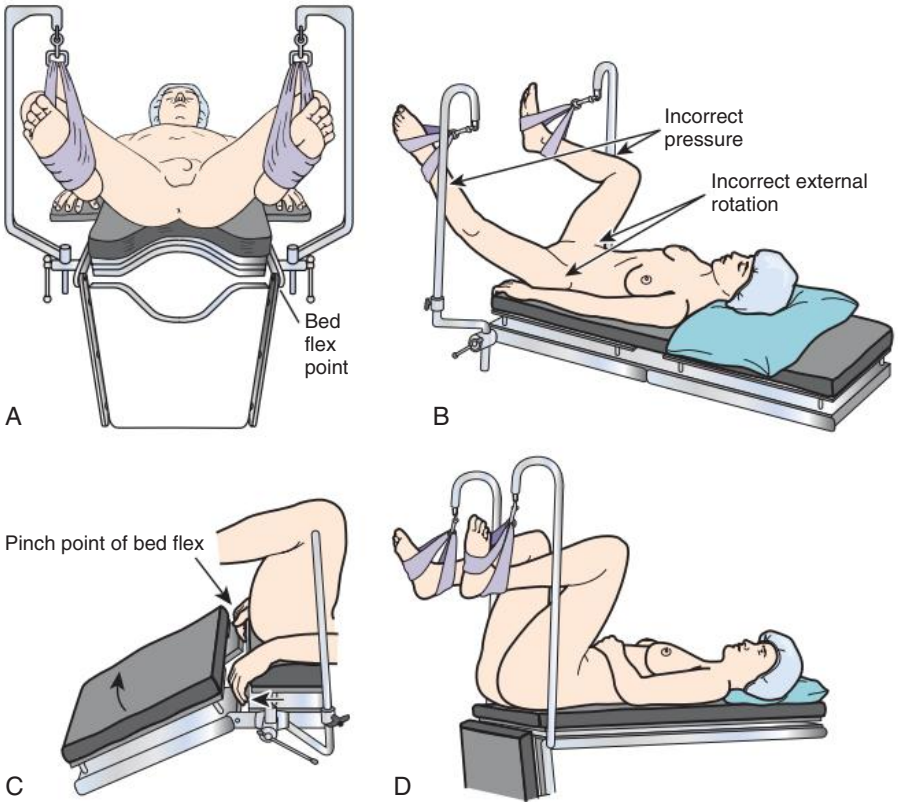
Headrests

Padded headrests are used with supine, prone, sitting, and lateral positions. They attach to the OR bed to support and expose the occiput and cervical vertebrae. The head is held securely but without the pressure that could cause pressure injury to the ears or optic nerve ischemic blindness.

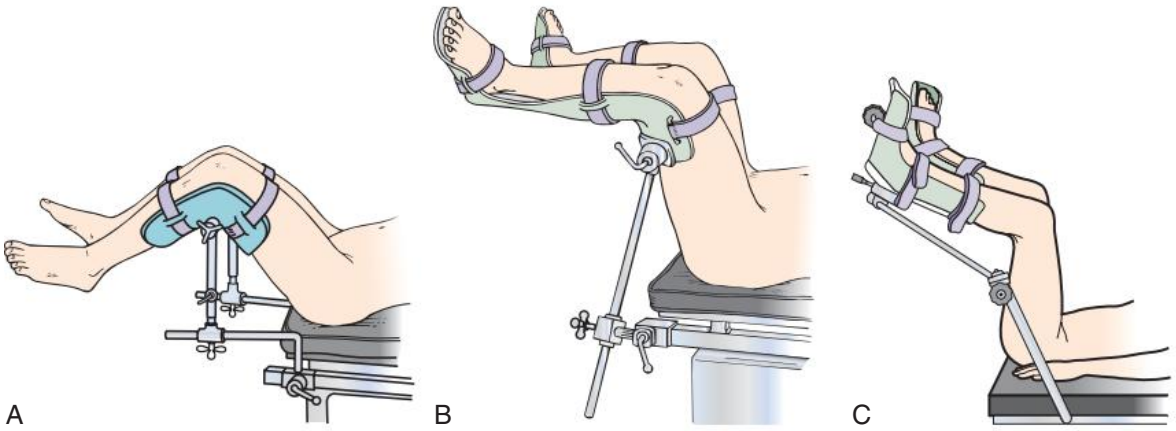
Headrests can be shaped like a donut or horseshoe for head and neck procedures; other styles are flat or concave to stabilize the head and neck in alignment. Nonpadded Mayfield metal headrests have sterile skull pins that are inserted into the patient's head for neurologic procedures (Fig. 26.13).

Accessories

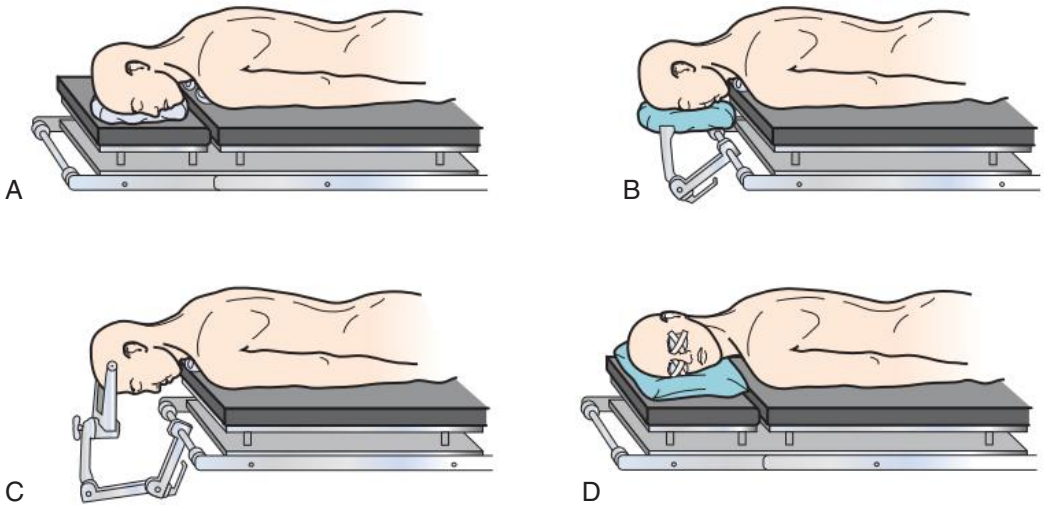
Various sizes and shapes of pads, pillows, and beanbags that fit various anatomic structures are used to protect, support, and



• **Fig. 26.11** **A,** Correct use of candy cane stirrups with feet suspended in cloth slings. **B,** Legs should not rest on stirrup posts or lower leg nerve injury could result. **C,** Hands should be positioned away from bed flex points. **D,** Correct flexion of legs in stirrups.



• **Fig. 26.12** Additional types of stirrups. **A,** Urologic stirrups. **B,** Stirrups used for abdominoperineal and obstetric procedures. **C,** Allen-style stirrups.



• **Fig. 26.13** **A,** Prone position with face in foam or gel-filled donut head positioner ring. **B,** Horseshoe head holder used for prone or supine procedures. **C,** Mayfield headrest with sterile metal pins inserted into patient's scalp for stability. **D,** Prone position with head placed on pillow. Patient can experience ear compression using this method. Donut should be used in place of pillow to allow for zero pressure on ear.

immobilize body parts. Foam-rubber, polymer pads, silicone gel pads, vacuum-shaped bags, and other accessories are covered with washable materials unless designed for single-patient use.

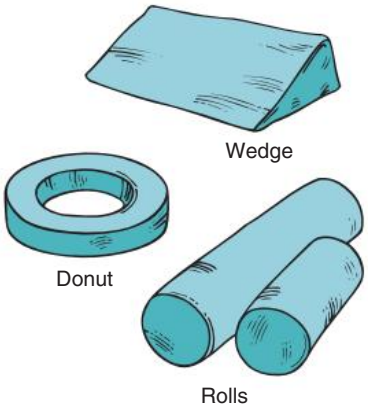
A donut (a ring-shaped foam-rubber or silicone gel pad) may be used during procedures on the head or face to keep the surgical area in a horizontal plane. Donuts are used also to protect pressure points such as the ear, knee, heel, and elbow. Protectors made of foam-rubber, polymers, silicone gel, or other material also may be used to protect the joints from pressure. Many other types of protectors are available. Some foam padding may be flammable. Some foam pads can create a fire hazard if alcohol prep solution soaks into the surface and remains damp.

Bolsters are used to elevate a specific part of the body (e.g., Kraske pillow to elevate the buttocks for anal procedures). Solid positioning rolls or firm foam under each side of a patient's chest, referred to as chest rolls, raise the chest off the OR bed to facilitate respiration and decrease intraabdominal pressure. Chest rolls extend from the clavicle to the iliac crest bilaterally. Large gel rolls also can be used for this purpose and for axillary elevation during lateral positioning. Commercially available bolsters and elevating pads are commonly used. Because patients may have a latex sensitivity, the manufacturer's literature should be checked for latex content (Fig. 26.14).

Pressure-Minimizing Mattress

To minimize pressure on bony prominences, peripheral blood vessels, and nerves during prolonged surgical procedures (more than 2 hours for the average patient, less for a debilitated patient), an alternating pressure mattress is put over the mattress on the OR bed before the patient arrives. This mattress may be a positive-pressure air mattress, a circulating-water thermal mattress, a foam-rubber mattress (with indentations similar to an egg crate), a gel pad, or a dry polymer pad.

Unless designed to be placed next to a patient's skin, pressure reduction mattresses and thermal blankets used to induce hypothermia or hyperthermia should be covered with an absorbent sheet or thin pad. Folds and creases in the covering should be



• **Fig. 26.14** Common positioning pads.

avoided to prevent pressure indentations in the skin. Manufacturer instructions should be followed when using these devices.

Surgical Vacuum Positioning System

With the surgical vacuum positioning system, soft pads filled with tiny plastic beads (i.e., beanbags) are placed under or around the body part to be supported. Suction is attached to the vacuum port on the beanbag pad; as air is withdrawn, the pad becomes firm and molds to the patient's body. The suction is then disconnected. A vacuum is created inside the pad, which causes the beads to press together. Friction between the beads prevents them from moving and creates a solid mass that keeps its molded shape. Adequate pressure reduction padding should be placed between the patient's skin and the beanbag. The firm edges of the beanbag should not rest against the patient's skinfolds such as the axilla or groin.

Various sizes and shapes of pads provide firm support while relieving pressure points. To change the patient's position during the surgical procedure, the valve on the pad is squeezed until the pad is slightly soft. The patient is repositioned, and suction is reapplied to remold the pad.

Surgical Positions

Many positions are used for surgical procedures; the most commonly used positions are discussed in the following sections. If IV fluids are infused in the arm during the surgical procedure, the arm is placed on an armboard. This fact is assumed in the following discussion because IV fluids are usually given. If electrosurgery is used, the patient return electrode should be placed after the patient is in the final position for the surgical procedure and the electrode should not be moved, shifted, or cut to size. Take care not to kink catheter tubing or dislodge monitoring devices during positioning.

Supine (Dorsal) Position

Fig. 26.15 shows the patient in the supine (**dorsal**) position—the most natural position for the body at rest. The patient lies flat on the back with the arms secured at the sides with the lift sheet; the palms extend along the side of the body in their natural resting position. The elbows may be protected with padded plastic sleds. The legs are straight and parallel and are in line with the head and spine; the hips are parallel with the spine. A safety belt is placed across the thighs 2 inches above the knees.

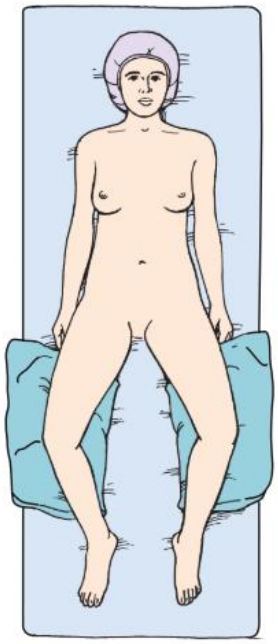
• **Fig. 26.15** Supine position. Patient lies straight on back, face upward, with arms at sides, legs extended parallel and uncrossed, and feet slightly separated. Strap is placed above knees. Head is in line with spine. Note small pillow under ankles to protect heels from pressure. Arms are secured with lift sheet or placed on armboards.

Small positioning pads may be placed under the head and popliteal area to relieve pressure on the spine as needed. The heels are protected from pressure with a pillow, gel pad, or donut. The feet must not be in prolonged plantar flexion, or nerve stretch injury could result. To prevent footdrop, the soles may be supported by a pillow or padded footboard.

The supine position is used for procedures on the anterior surface of the body, such as abdominal, abdominothoracic, and some lower extremity procedures. Modifications of the supine position are used for the following specific body areas:

- *Procedures on the face or neck:* The neck may be slightly hyperextended by lowering the head section of the OR bed or by placing a shoulder roll. With the patient in the supine position, the head may be supported in a headrest or donut or turned toward the unaffected side.

  The eyes are protected from injury, laser light, and irritating solutions with corneal shields, goggles, or moist eye pads with nonallergenic tape. During skin preparation and the surgical procedure, contact lenses should be removed, and the eyes should be lubricated with sterile ophthalmic gel and secured with eye pads taped in place. The eyes should be inspected periodically by the anesthesia provider during the case and at the end of the surgical procedure. No pressure should impair circulation to the optic nerve. If the eyeball becomes ischemic, the patient can be rendered blind.
- *Shoulder or anterolateral procedures:* With the patient in the supine position, a small sandbag, water bag, roll, or pad is placed under the affected side to elevate the shoulder off the OR bed for exposure. The length of the body is stabilized to prevent the spine from rolling or twisting. Hips and shoulders should be kept in a straight plane. The OR bed also can be tilted laterally to elevate the affected part.
- *Dorsal recumbent and modified recumbent position:* For some vaginal or perineal procedures, the patient is in the supine position except that the knees are flexed upward (frog-legged) and the thighs are slightly externally rotated. The soles of the feet rest on the OR bed. Pillows or foam wedges may be placed under the knees for support and prevention of external rotation of the hip (Fig. 26.16). Positioning devices for frog-legging the patient are commercially available. The thighs are widely externally rotated, and the soles of the feet face each other at the **medial** line of the body. The blanket is placed over the lower legs, and the safety strap is placed over the blanket anterior to the shins to secure the legs from sliding forward.
- *Arm extension:* For surgical procedures of the breast, axilla, upper extremity, and hand, the patient is placed in the supine position; the arm on the affected side is placed on an armboard or upper extremity table extension that locks into position at a 90-degree right angle to the body. The affected side of the body is close to the edge of the OR bed for access to the surgical area.



• **Fig. 26.16** Modified dorsal recumbent position. Patient lies on back with arms at sides. Knees are slightly flexed, with a pillow under each. Thighs are externally rotated. Referred to as frog-legged.

If the axilla is involved, the arm is placed even with the lower edge of the armboard for accessibility. Hyperextension of the arm is avoided to prevent neural or vascular injury, such as brachial plexus injury or occlusion of the axillary artery. The armboard is well padded.

Trendelenburg's Position

With **Trendelenburg's position**, patients lie on their back in the supine position with the knees over the lower break of the OR bed (Fig. 26.17). The knees must bend with the break of the OR bed to prevent pressure on the peroneal nerves and veins in the legs. The thigh strap is positioned 2 inches above the knees over the blanket. The entire OR bed is tilted approximately 30 to 45 degrees downward at the head, depending on the surgeon's preference. The foot of the OR bed is lowered to the desired angle to help counterbalance the patient's body weight.

Trendelenburg's position is used for procedures in the lower abdomen or pelvis when shifting the abdominal viscera cephalad away from the pelvic area for better exposure. Although surgical accessibility is increased, lung volume is decreased and the heart is mechanically compressed by the pressure of the organs against the diaphragm. Intracranial and intraocular pressure is increased. Therefore the patient remains in this position for as short a time as possible. When returning the patient to a horizontal position, the leg section should be raised first and slowly while venous stasis in the legs is reversed. The entire OR bed is then leveled.

A modification of this position may be used for patients in hypovolemic shock. Many anesthesia providers prefer to keep the trunk level and to elevate the legs by raising the lower part of the OR bed at the break under the hips. Others prefer to tilt the entire OR bed downward toward the head. Either position reduces venous stasis in the lower extremities and promotes venous return.

Reverse Trendelenburg's Position

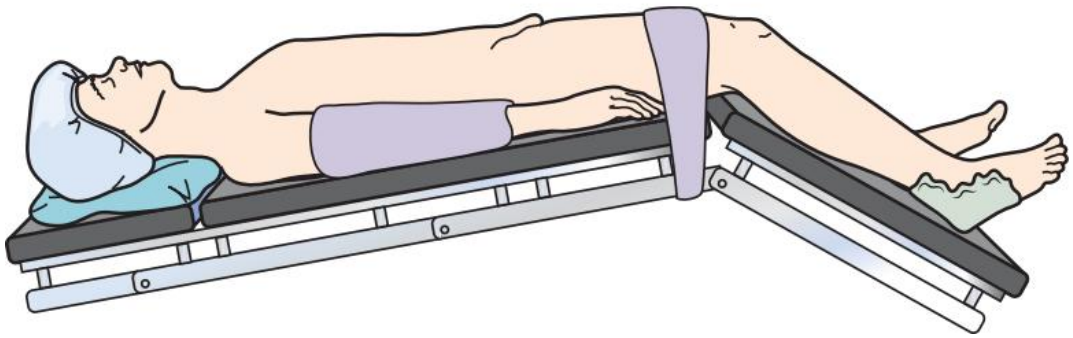
With **reverse Trendelenburg's position**, patients lie on their back in the supine position (Fig. 26.18). The entire OR bed is tilted 30 to 40 degrees so the head is higher than the feet; a padded footboard is used to prevent the patient from sliding toward the tilt. The thigh safety belt is positioned 2 inches above the knees over the blanket. Small pillows may be placed under the knees. A small pillow or donut is used to stabilize the head.

This position is used for thyroidectomy to facilitate breathing and decrease blood supply to the surgical site (blood pools caudally). It is also used for laparoscopic gallbladder, biliary tract, and stomach procedures to allow the abdominal viscera to fall away from the epigastrium, providing access to the upper abdomen.

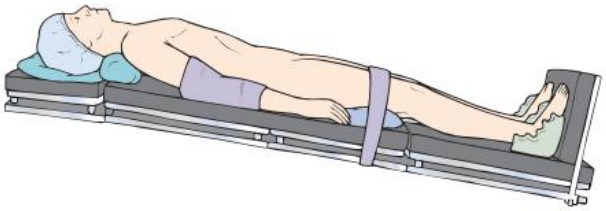
Venous stasis can cause complications, and prevention of deep vein thrombosis (DVT) is an important consideration. The use of sequential compression devices, antiembolic stockings, or foot pumps is suggested to improve venous return.

Semi-Fowler's Position

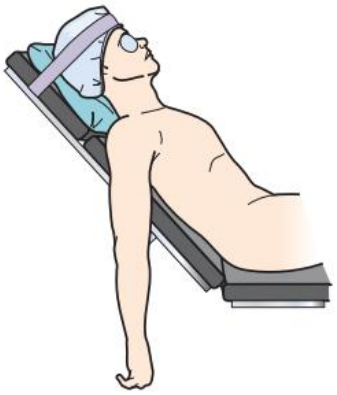
With semi-Fowler's position, the patient is supine with the buttocks at the flex in the OR bed and the knees over the lower break. The foot of the OR bed is lowered slightly, flexing the knees. The body section is raised 45 degrees and thereby becomes the backrest. Arms may rest on armboards parallel to the OR bed or on a large soft pillow on the lap. Care is taken that the arms do not fall dependent from the body during the procedure. The safety belt is secured 2 inches above the knees over the blanket. Pressure points such as the coccyx and heels should be padded in seated positions. The entire OR bed is tilted slightly with the



• **Fig. 26.17** Trendelenburg's position. Note knees are over lower break in OR bed, with knee strap above knees. Arms are secured. Shoulder braces are not usually needed with this method of Trendelenburg's position.



• **Fig. 26.18** Reverse Trendelenburg's position, with soft roll under shoulders for thyroid, neck, and shoulder procedures.(From Rothrock JC: *Alexander's care of the patient in surgery,* ed 14, St. Louis, 2011, Mosby.)



• **Fig. 26.19** Modified Fowler position with the shoulder dependent over the edge of the bed for shoulder procedure. Sometimes referred to as the captain's chair.

head end downward to prevent the patient from slipping toward the foot of the OR bed. Feet should rest on the padded footboard to prevent footdrop. For cranial procedures, the head is supported in a headrest.

In this position, the OR bed looks like a modified armchair. This position may be used for shoulder, nasopharyngeal, facial, and breast reconstruction procedures (Fig. 26.19). Complications of this position include air embolus into the venous system, pelvic pooling or venous stasis, hypotension, positional orthopedic injury, and tissue pressure injury and necrosis.

If an air embolus should enter the patient's right atrium, the patient is immediately repositioned in the left lateral position and the bed is lowered into steep Trendelenburg's position. This emergent posture is referred to the Durant position or Durant maneuver. This immediate action causes the air embolus to move from the right ventricular outflow tract. The anesthesia provider places a central venous catheter into the right atrium to aspirate the trapped air bubble and restore cardiac function.

Sitting Position

With the sitting position, the patient is placed in the Fowler's position except that the torso is completely in an upright position. The shoulders and torso should be supported with body straps but not so tightly that respiration and circulation are impeded. Pressure points (especially ischial tuberosities) are padded to reduce the risk for sciatic nerve damage.

The flexed arms rest on a large pillow on the lap or on a pillow on an adjustable table in front of the patient (see Fig. 26.4; this table attachment can be secured in the bed sockets in front of the patient as a padded armrest).

The head is seated forward in a cranial headrest for neurosurgical procedures. A padded footboard may be placed to maintain the patient's feet in an upright position and deter sliding down on the bed.

This position is used on occasion for some otorhinologic and neurosurgical procedures. Air embolism is a potential complication and is treated in the same manner as described for the semi-Fowler position. Antiembolic stockings or sequential compression devices are used to counteract postural hypotension and decrease venous pooling in the extremities and pelvis.

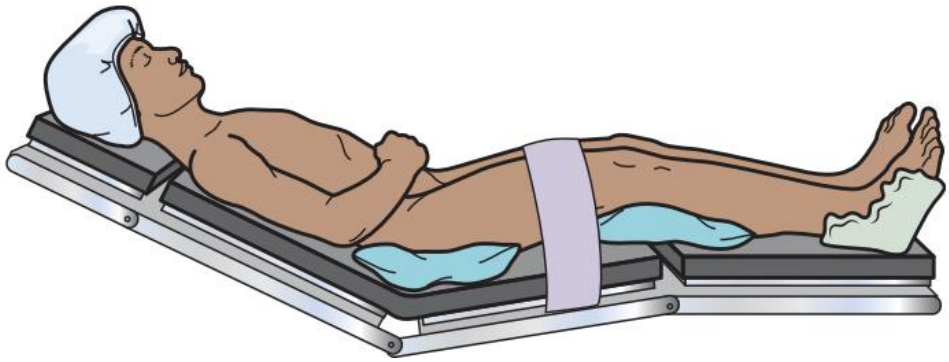
Beach Chair or Modified Sitting Position

With the beach chair or modified sitting position, the patient is supine with the back and legs slightly elevated. The entire spine is somewhat contoured, with the angle of flexion at the hip decreased. Both the head and the feet are elevated 10 to 20 degrees above the level of the heart. The arms are placed across the abdomen, and the safety belt is secured over the thighs. This position is used for several shoulder, nose, and throat procedures.

Abdominoplasty and lower abdominal TRAM (trans rectus abdominis muscle used for breast reconstruction) closure is performed using this position to bring the skin edges closer together after resection of a large abdominal skin flap. The xyphoid-pubic distance is shortened. The arms can be secured with the lift sheet if the hands are not at risk for crush injury at the bed flexion points (Fig. 26.20).

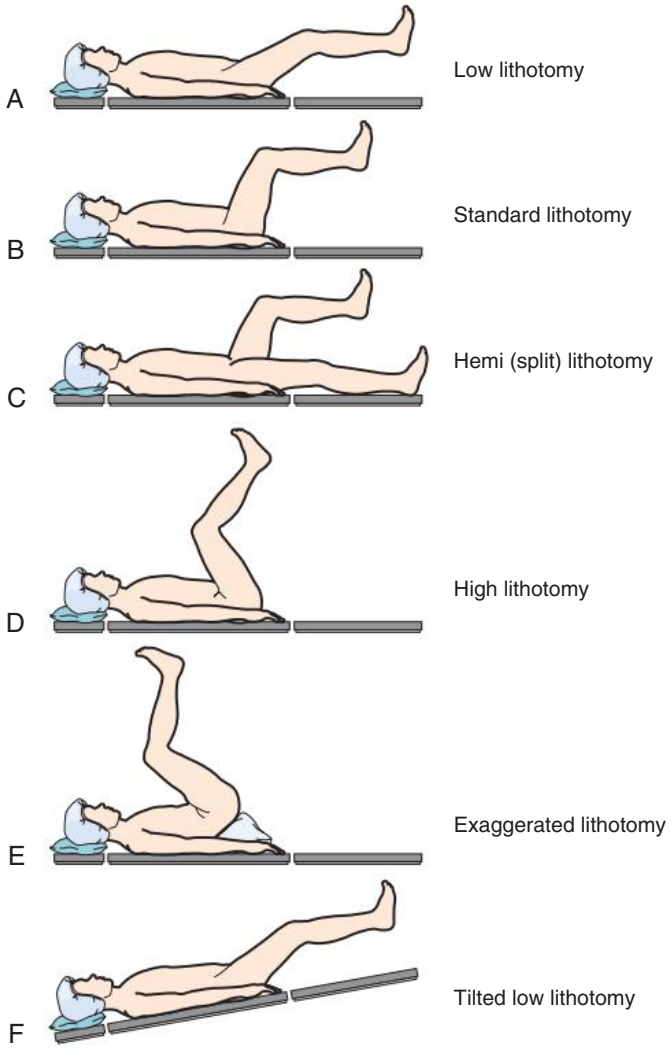
Lithotomy Position

The lithotomy position is used for perineal, vaginal, urologic, and rectal procedures. The patient's buttocks rest along the break between



• **Fig. 26.20** Beach chair position. The arms are typically placed across the abdomen, and a safety strap is across the thighs.

• **Fig. 26.21** Lithotomy position. Patient is supine with foot section of OR bed lowered to right angle. Knees are flexed, and legs are elevated to the degree necessary for the type of surgical procedure. Note that buttocks are even with edge of the OR bed and that sometimes a roll is needed under the buttocks to elevate the hips above the level of the bed.



• **Fig. 26.22** Commonly used lithotomy positions.

the body and the leg sections of the OR bed. A padded metal footboard is used as an OR bed extension so the patient's legs do not extend over the foot of the OR bed before the legs are placed in the upright position.

Stirrups are secured in sockets on each side of the OR bed rail at the level of the patient's upper thighs. They are adjusted at equal height on both sides and at an appropriate height for the length of the patient's legs to maintain symmetry when the patient is positioned. After the patient is anesthetized, the safety belt is removed and the patient's legs are raised simultaneously by two people (Fig. 26.21). The safety belt should not remain in place over the abdomen with the patient in the lithotomy position. It causes increased abdominal venous pressure, which in turn increases the risk for blood loss.

Each person grasps the sole of a foot in one hand and supports the calf at the knee area with the other. The knees are flexed, and the legs and feet are placed inside the stirrups simultaneously. Avoid overflexing the hip toward the abdomen to prevent ilioinguinal nerve compression. For sling or candy cane stirrups, the feet are placed in the fabric slings of the stirrups at a 90-degree angle to the abdomen. One padded loop encircles the sole; the other padded loop goes around the ankle.

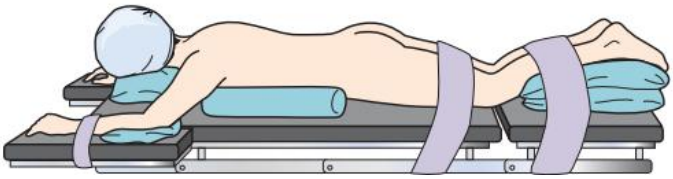
Simultaneous movement as the knees are flexed is essential to avoid straining the lower back and causing sudden hemodynamic changes in the venous system. If the patient's legs are properly placed, undue abduction and external rotation are avoided. The leg or ankle must not touch the metal stirrup. Padding is placed as necessary. If the legs are put in stirrups before the induction of anesthesia, the patient can identify discomfort and pressure on the back or legs. The positioning procedure is similar for other types of stirrups. There is no scientific evidence to support raising one leg at a time. The level of the lithotomy position needed for the surgical procedure is determined by the surgeon (Fig. 26.22).

After the patient's legs are placed in the stirrups, the lower section of mattress is removed and the bottom section of the OR bed is lowered. The buttocks must not extend beyond the edge of the OR bed, which would strain the lumbosacral muscles and ligaments as the weight of the body rests on the sacrum.

The hands should not extend beyond the buttocks if tucked alongside the patient. Hands have been crushed in the break as the leg section of the OR bed was raised at the conclusion of the surgical procedure. Arms may be placed on armboards or loosely cradled over the lower abdomen and secured by the lower end of the blanket. Arms must not rest directly on the chest, which could impede respiration. Lung compliance is decreased by pressure of the thighs on the abdomen, which hinders the descent of the diaphragm.

Venous blood pools in the lumbar region of the torso, especially during prolonged surgical procedures in the lithotomy position. Antiembolic stockings may be worn, or legs may be wrapped in sequential compression devices or foot pumps during the surgical procedure to prevent the formation of thrombi or emboli. The legs should be checked periodically for distal pulses (pedal or posterior tibial), skin color, and evidence of edema. In the lithotomy position, nerve damage or compartment syndrome can occur from direct pressure or ischemia of the muscles, which compromises the viability of tissues.

At the conclusion of the surgical procedure, the leg section of the OR bed is raised and the lower section of the mattress is



• **Fig. 26.23** Prone position. Patient is placed on abdomen. Chest rolls are placed under axillae and sides of chest to the level of the iliac crest to facilitate respiration. Knees should be padded, and a pillow is placed under dorsum of feet.

replaced. The patient's legs are removed simultaneously from the stirrups with a minimum of two people. The legs are brought together and lowered slowly to prevent hypotension as blood reenters the legs and leaves the torso. To prevent external rotation of the hips, the legs are fully extended and brought together as they are lifted from the stirrups. The blanket and safety belt should be reapplied over the thighs during the patient's emergence from anesthesia.

Prone Position

Prone position is used for all procedures with a dorsal or **posterior** approach (Fig. 26.23). When the prone position is used, the patient is anesthetized and intubated in the supine position on the locked transport cart. The patient's arms are along his or her sides. When the anesthesia provider gives permission, the patient is slowly and cautiously shifted toward the OR bed in the supine position and then turned onto the abdomen onto the OR bed. The patient's body is rotated as if rolling a log; a team of at least four to six people is needed to maintain body alignment during this transfer. The anesthesia provider calls the count. The anesthesia provider controls the patient's head and airway while the rest of the patient's body is moved by the team.

Chest rolls or bolsters under the axillae and along the sides of the chest from the clavicles to the iliac crests raise the weight of the body from the abdomen and thorax. The weight of the abdomen falls away from the diaphragm and keeps pressure off the vena cava and abdominal aorta. This facilitates respiration, although vital capacity and cardiac index are reduced. To ensure cardiac filling and reduce hypotension, venous return from the femoral veins and **inferior** vena cava is uninterrupted. Female breasts should be moved laterally to reduce pressure on them. Male genitalia should be free from pressure. Pendulous skinfolds should not be crimped under the patient in any manner.

The arms may lie supported along the sides of the body, with the palms up or inward toward the body. An alternative position is to place the arms into a diver's pose by lowering them toward the floor and rotating (**circumducting**) them upward in a natural range of motion. Care is taken not to dislocate the shoulders. The armboards are reversed on the table, pointing toward the anesthesia provider. The elbows are padded and are slightly flexed no greater than 90 degrees to prevent overextension, and the palms are down. The arms may extend beyond the head, but not so far as to cause brachial plexus compression or stretch.

The head can be turned to one side or positioned face down on a padded headrest to prevent pressure on the ear, eye, and face. Clearance of the airway must be ensured. A serious complication of the prone position is blindness caused by ischemia of the vascular system of the eye.

A pillow or padding under the anterior aspect of the ankles and the dorsa of the feet prevents pressure on the toes and elevates the feet to aid venous return. Do not permit the patient's toes to extend beyond the foot of the bed. Donuts under the knees prevent pressure on the patellae. The safety belt is placed over the calves to prevent flexion of the lower legs. Care is taken not to compress the lower legs. An additional belt can be positioned over the posterior thighs as an added precaution.

Modified Prone Positions

For surgical procedures on the spine, the mattress on the OR bed is adjusted so the hips are over the break between the body and leg sections. A large soft pillow is placed under the abdomen at the lower pelvis. The upper break of the OR bed is flexed, and the OR bed is tilted so the surgical area is horizontal. Some surgeons prefer a special assembly for the orthopedic OR bed, such as an adjustable arch (Wilson frame), a Hastings frame, or an Andrews frame for spinal surgery. In a kneeling Andrews frame, the flexion at the knee with tibial support is between 60 and 90 degrees.

After the administration of anesthesia in the supine position on the transport cart, the patient is carefully lifted and properly positioned on a special table or frame. The patient may be placed in a prone extreme forward-sitting or kneeling position with the torso at a right angle to the thighs. The midsection of the abdomen is allowed to hang free. This allows the anesthesia provider to use the hypotensive anesthetic technique for hemostasis.

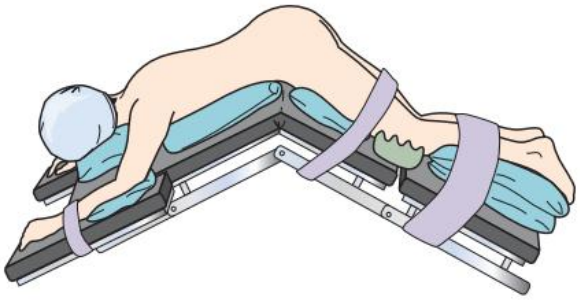
For neurosurgical procedures, the head rests in a cranial headrest to expose the occiput and cervical vertebrae. The eyes are protected; ophthalmic ointment is applied to protect the corneas and keep the lids closed before turning the patient onto the headrest. The ears are protected with foam support. When the patient is face down on a headrest, the head should be raised periodically to prevent pressure necrosis of the cheeks and forehead. Some anesthesia providers use a small mirror to periodically inspect the face and endotracheal tube position.

Kraske (Jackknife) Position

With the Kraske position, the patient remains supine until anesthetized and is then turned onto the abdomen (prone position) via rotation. The hips are positioned over the center break of the OR bed between the body and leg sections. Chest rolls or bolsters are placed to raise the chest if the patient is under general anesthesia. A Kraske pillow can be placed at the level of the anterior thighs to elevate the buttocks.

The arms are extended on reverse angled armboards with the elbows flexed and the palms down. The head is to the side and is supported on a donut or pillow. The dorsa of the feet and toes rest on a pillow. The safety belt is placed below the knees. The leg section of the OR bed is lowered the desired amount (usually about 90 degrees), and the entire OR bed is tilted head downward to elevate the hips above the rest of the body.

The patient is well balanced on the OR bed (Fig. 26.24). For procedures in the rectal area (e.g., pilonidal sinus, hemorrhoidectomy), the buttocks are retracted with wide tape strips. Because of the dependent position, venous pooling occurs **cephalad** (toward the head) and **caudad** (toward the feet). It is important to slowly return the patient to horizontal from this unnatural position to minimize circulatory complications.



• **Fig. 26.24** Kraske (jackknife) position. (From Rothrock JC: *Alexander's care of the patient in surgery,* ed 14, St. Louis, 2011, Mosby.)

Knee-Chest Position

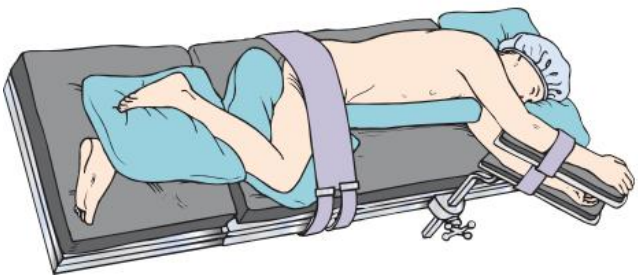
The knee-chest position is sometimes used for sigmoidoscopy or culdoscopy. For this position, an extension is attached to the foot section. The OR bed is flexed at the center break, and the lower section is broken until it is at a right angle to the OR bed. The patient kneels on the lower section; the knees are thus flexed at a right angle to the body.

The upper portion of the OR bed may be raised slightly to support the head, which is turned to the side. The arms are placed around the head with the elbows flexed in a diver's posture, and a large soft pillow is placed beneath them. The chest rests on the OR bed, and the safety belt is placed above the knees. The entire OR bed is tilted head downward so the hips and pelvis are at the highest point—a modified jackknife position.

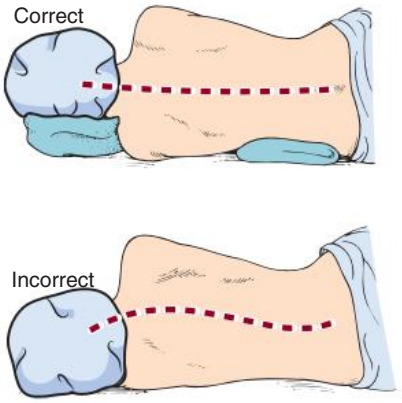
Lateral Positions

For lateral positioning, the OR bed remains flat. The patient is anesthetized and intubated in the supine position on the OR bed and then turned to the unaffected side. In the right lateral position, the patient lies on the right side with the left side up (for a left-sided procedure); the left lateral position exposes the right side (Fig. 26.25).

The patient is turned by no fewer than four people to maintain body alignment and achieve stability. The patient's back is drawn to the edge of the OR bed. The knee of the lower leg is flexed, and the upper leg is straight. The knees require padding to prevent pressure and shearing force. In addition, a large soft pillow is placed lengthwise between the legs to take pressure off the upper hip and lower leg to prevent circulatory complications and pressure on the peroneal nerve.



• **Fig. 26.25** Left lateral position is when the patient is lying on the left side. Note strap across hip to stabilize body. Pillow between legs relieves pressure on lower legs. Both legs are flexed slightly to alleviate any pressure or stretch. Note that bed is flat, not flexed. Right lateral is directly the opposite position.



• **Fig. 26.26** Proper alignment of spinal column in lateral position.

The ankle and foot of the upper leg should be supported to prevent footdrop. Bony prominences are padded. For added stability, a safety belt or a 3-inch-wide (7.5 cm) tape is placed over the hip.

The patient's arms may be placed on a padded double armboard, with the lower arm palm up and the upper arm slightly flexed with the palm down. Blood pressure should be measured from the lower arm. As an alternative, the upper arm can be positioned on a padded Mayo stand. A pressure reduction pad under the axilla protects neurovascular structures. The shoulders should be in alignment.

The patient's head is in cervical alignment with the spine. The head should be supported on a small pillow between the shoulder and neck to prevent stretching the neck and brachial plexus and maintain a patent airway (Fig. 26.26).

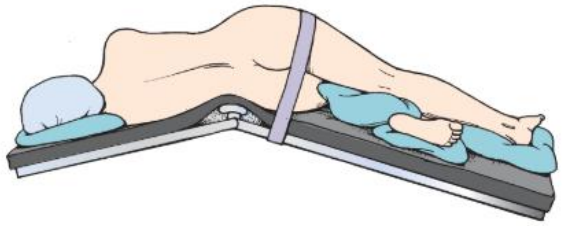
Referred to synonymously as the lateral, lateral decubitus, or lateral recumbent, this position is used for access to the hemithorax, kidney, and retroperitoneal space. This position contributes to physiologic alterations. Respiration is affected by differing gas exchange ratios in the lungs. Because of gravity, the lower lung receives more blood from the right side of the heart; the lower lung therefore has increased perfusion but less residual air because of mediastinal compression and the weight of the abdominal contents on the diaphragm. Positive pressure to both lungs helps control respiratory changes. Circulation is also compromised by pressure on the abdominal vessels. In the right lateral position, compression of the vena cava impairs venous return.

Sims Recumbent Position

With the Sims recumbent position (a modified left lateral position), the patient lies on the left side with the upper leg flexed at the hip and knee; the lower leg is straight. The lower arm is extended along the patient's back, with the weight of the chest on the OR bed. The upper arm rests in a flexed position on the OR bed. This position is preferred for a colonoscopy or sigmoidoscopy.

Kidney Position

With the kidney position, the flank region is positioned over the kidney elevator on the OR bed when the patient is turned onto the unaffected side (Fig. 26.27). The short kidney rest is attached to the body elevator at the patient's back. The longer rest is placed in front at a level beneath the iliac crest to minimize pressure on the abdominal organs. Both rests are well padded. In an obese patient, folds of abdominal tissue may extend over the end of the anterior rest and be bruised if caution is not taken. The OR bed



• **Fig. 26.27** Right kidney position for a procedure on the right kidney. Patient is in lateral position with kidney region over OR bed break, or body elevation bar. The table is flexed. Note strap across hip to stabilize body, raised kidney elevator for hyperextending surgical site, and pillow between legs. The lower leg is flexed more than the upper leg. Patient's side is horizontal from shoulder to hip. The arm is supported with a double airplane armboard (not shown).

is flexed slightly at the level of the iliac crest so the body elevator can be raised as desired to increase space between the lower ribs and iliac crest.

A body strap or wide adhesive tape is placed over the hip to stabilize the patient after the OR bed is flexed and the elevator is raised. The entire OR bed is tilted slightly downward toward the head until the surgical area is horizontal; the upper shoulder and hip should be in a straight line. The upper arm is supported in a double airplane-style armboard. A gel pad is used to support the chest and protect the breasts. An axillary roll is placed to take body weight off the deltoid muscle in the shoulder. Before closure, the OR bed is straightened to allow better approximation of tissues.

The term kidney position is used to designate the lateral flexion used to elevate the surgical site. Documentation should clearly state either right or left to indicate which kidney is elevated for the procedure. The kidney position is used for procedures on the kidney and ureter; this position is not well tolerated. Skin and underlying tissue can be damaged by excessive pressure during flexion of the OR bed. OR bed flexion combined with use of the kidney elevator may cause cardiovascular responses. Blood tends to pool in the lower arm and leg. Circulation is further compromised by increased pressure on the abdominal vessels when the kidney elevator is raised. The spine is stressed in a lateral flexed position and can cause strain on the vertebral structures.

Lateral Chest (Thoracotomy) Position

Modifications of the lateral position are used for unilateral transthoracic procedures with a lateral approach. After the patient is turned onto the unaffected side and positioned as described for the lateral position, a second strap may be placed over the shoulder for stability, unless doing so would interfere with skin preparation. The arms may be extended on a double armboard, or the lower arm is extended on an armboard with the palm up while the upper arm is brought forward and down over a pad to draw the scapula from the surgical area. Position depends on site and length of the chest incision. A gel pad under the axilla elevates the surgical site and relieves pressure on the lower arm.

One lateral body rest is placed at the lumbar area to facilitate respiratory movements and provide support. Another body rest is placed along the chest at the axillary level. This body rest is well padded to avoid bruising the breasts. Vacuum beanbag positioning devices or bolsters may be used instead of body rests. The shoulders and hips should be level. Slight lowering of the head of the OR bed assists postural drainage during the surgical procedure. This position is restrictive to the cardiopulmonary system, especially if used for a prolonged period.

Anterior Chest Position

For thoracoabdominal procedures with an anterior approach, the positioning is more supine than for the lateral chest position. After the patient is anesthetized, a gel pad is placed under the lower axilla; another pillow or wedge is placed behind the buttocks and spine to support the torso. The upper knee is flexed slightly, and a large soft pillow is placed beneath it to relieve strain on the abdominal muscles and upper hip.

The OR bed can be tilted laterally to raise the surgical site. A safety belt is placed across the hip and another above the knees. The lower arm on the unaffected side is supported at the side by an armboard. The upper arm on the affected side is padded well and secured; it can be bandaged loosely to the anesthesia screen above the patient's head with a Kerlix roll. To avoid injury to the brachial plexus, the arm must not be hyperextended or hyperabducted. The head of the OR bed is lowered slightly for postural drainage.

Modifications for Individual Patient Needs

Anomalies and physical defects are accommodated according to each patient's needs. Whether the patient is unconscious or conscious, the avoidance of unnecessary exposure is an essential consideration for all patients. The patient's position should be observed objectively before skin preparation and draping to see that it adheres to physiologic principles.

Protective devices, positioning aids, and padded areas should be reassessed before draping because they could have shifted during the skin preparation procedure or during insertion of an indwelling urinary catheter. Careful observation of patient protection and positioning facilitates the expected outcome.

Documentation

The circulating nurse should document any preoperative limitations in the patient's range of motion, the condition of the skin before and after the surgical procedure, and the position in which the patient was positioned during the surgical procedure, including the use of special equipment. Personnel performing the positioning should be listed by name, role, and title.

Physical Preparation and Draping of the Surgical Site

The type of surgical procedure to be performed, the age and condition of the patient, and the preferences of the surgeon determine specific procedures to be carried out before the incision is made. Consideration must be given to the control of urinary drainage, skin antisepsis, and establishment of a sterile draped field around the surgical site.

Urinary Catheterization

The patient should void to empty the urinary bladder just before transfer to the OR suite unless the procedure requires the bladder to be full, such as for special bladder tone testing procedures. If the patient's bladder is not empty or the surgeon wishes to prevent bladder distention during a long procedure or after the surgical procedure, urinary catheterization may be necessary after the patient is anesthetized.

An indwelling Foley catheter may be inserted by a member of the team. This retention catheter maintains bladder decompression to avoid trauma during a lower abdominal or pelvic procedure, to permit accurate measurement of output during or after the surgical procedure, and to facilitate output and healing after a surgical procedure on genitourinary tract structures. Catheterization is performed after anesthesia is administered and before the patient is positioned for the surgical procedure, except for a patient who will remain in the lithotomy position.

The Foley catheter should be inserted before the vaginal or abdominal skin preparation to prevent perineal splash to the surgical site. The vagina can be prepped immediately after the Foley catheter is placed. Gloves should be changed and a new prep set used for the abdominal skin prep.

Urinary tract infection can be caused by contamination or trauma to structures during urinary catheterization.[4] Sterile technique must be maintained. A sterile disposable catheterization tray is used unless the patient is being prepared for a surgical procedure in the perineal or genital area. For these latter procedures, a sterile catheter and lubricant may be added to the perineal skin preparation setup. For other surgical procedures, the perineal and meatal areas should be cleansed with an antiseptic agent to reduce microbial flora and remove gross contaminants before the catheterization procedure.[5] Sterile gloves are donned using the open gloving technique (Fig. 26.28).

The catheter should be small enough to minimize trauma to the urethra and prevent necrosis of the meatus; usually a size 16- or 14-Fr catheter is inserted in a woman, and a 16- or 18-Fr catheter is inserted in a man. Silicone Foley catheters are preferred. Some Foley catheters may contain latex, and care is taken not to use these if the patient is latex sensitive. Some manufacturers incorporate silver in the catheter as an antimicrobial agent.

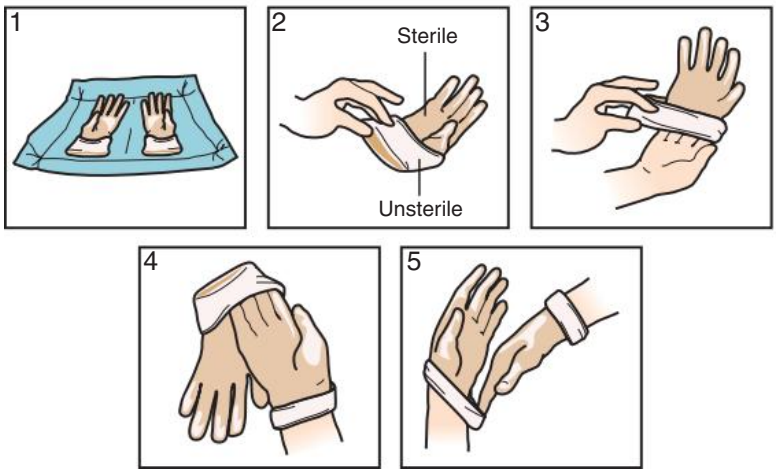
The inflatable balloon size may be 5 or 30 mL (5 mL is used most frequently in adults); 10 mL of sterile water is needed to properly expand a 5-mL balloon, to compensate for volume required by the expansion channel. Foley catheters have a Luer-Lok valve over the lumen to the expansion channel that is filled using a Luer-Lok syringe. Foley catheter manufacturers do not recommend testing the balloon before insertion. They maintain that doing so causes the balloon to weaken and the small folds of the balloon may cause urethral irritation that could lead to a urinary tract infection. The balloon is tested in the factory at the time of manufacture.

The hand used to spread the labia or stabilize the penis is considered contaminated and should not be used to handle the catheter or prep sponges (Fig. 26.29). To facilitate insertion and minimize trauma, the tip of the catheter is lubricated with a sterile water-soluble lubricant. Urine starts to flow when the catheter has passed into the bladder. The balloon of a Foley catheter is expanded with sterile water only after urine is seen in the tubing, and the bladder is allowed to drain.

If difficulty is encountered during catheter insertion, especially in a geriatric male patient with an enlarged prostate, the catheter should not be forced into the urethra. Stop the catheterization procedure and request help from the surgeon. A flexible catheter stylet of plastic or stainless steel may be needed to pass the catheter through the prostatic segment of the urethra to minimize trauma to the structures.

The catheter is attached to a sterile drainage system, and the drainage bag is positioned in the direct view of the anesthesia provider. The tubing is later attached to the patient's leg, with enough slack in it to prevent tension or pull on the penis or urethra at the conclusion of the case (Fig. 26.30).

Attention is paid to the catheter and tubing during positioning of the patient for the surgical procedure to prevent compression or kinking. Dependent loops of tubing should not be permitted to hang on the floor because this could cause a trip hazard. If the container must be raised above the level of the bladder during



• **Fig. 26.28** Donning sterile gloves by open glove method for performing patient skin preparation or catheterization. *1,* Open sterile glove wrapper. Gloves are in a palm-up position with a short prefolded cuff. *2,* To glove the right hand, grasp the inner aspect of the right cuff with the bare left forefinger and thumb. Take care to touch only the inner cuff surface with bare skin. The outer surface of the glove is sterile. *3,* Slide right hand into the opening of the glove, taking care not to touch the outer sterile surface. Do not adjust cuff once the glove is on. This is done later. *4,* To glove the left hand, use the gloved right hand and slide gloved fingers under the inner sterile aspect of the left cuff. Steady the fingers of the right hand as the bare left hand is slid into the glove. The left cuff is straightened with the right fingers as the final act of donning the glove. *5,* Use the sterile fingers of the left hand on the sterile aspect of the right glove to slide the remaining right glove cuff into position. Do not touch the inner aspect (the skin side) of either glove with the outer sterile gloved surface.

positioning, the tubing is clamped or kinked until the container can be lowered and secured under the OR bed to avoid contamination by retrograde or backward flow of urine.

If the catheter is to be removed at the end of the surgical procedure, don examination gloves and use a syringe to withdraw and measure the solution from the Foley balloon expansion port. Cutting the end off with scissors may cause the inflation port to collapse, trapping fluid within the expanded balloon. The urethra can be damaged by withdrawing the expanded balloon.

Principles of Patient Skin Preparation

The purpose of skin preparation is to render the surgical site as free as possible from transient and resident microorganisms, dirt, and skin oil so the incision can be made through the skin with minimal danger of infection from this source.

Many surgeons prefer to have patients bathe with antimicrobial soap the morning of the surgical procedure. The patient should be advised to avoid the use of body emollients, oils, creams, and lotions after washing. Some products decrease the efficacy of antimicrobial soap, and other products prevent adherence of the return electrode and electrocardiographic (ECG) electrodes to the skin.

The perioperative nurse should assess the patient's skin before, during, and after the prepping process. Documentation of the condition of the patient's skin with notation of lesions or other pertinent markings is important. Abnormal skin irritation, infection, or abrasion on or near the surgical site might be a contraindication to the surgical procedure and is reported to the surgeon.

Some patients may have body piercing jewelry that is located on the face, tongue, nose, lip, eyebrow, ears, or other easily identified places. In some cases, the piercing jewelry is located under clothing on the nipples, umbilicus, or genitalia. Body piercing jewelry should be removed for safety reasons before surgery. Certain piercings cannot be removed without a specialized tool. Facilities with patients who commonly have this type of adornment may want to have a removal tool available.

Piercing jewelry could encourage an infection or could cause positioning/pressure injuries. Metals are known to be conductors of electricity and could cause an alternative path burn from a stray current. Oral piercings could become dislodged and enter the patient's airway. Genital jewelry can interfere with urinary catheterization and cause a urinary tract infection. Each facility should have a policy and procedure in place concerning body piercing jewelry. The perioperative nurse should inquire about piercings during the assessment process.

Patients who have been involved in accidents or injured during the commission of a crime may bear physical marks or materials important to the investigation. Objective description of injuries that may include sketches on the record is part of the chain of evidence. Photographs may be taken for the record. Any material on the patient's person could be evidence and should be handled according to facility policy for forensic evidence.

Preliminary Preparation of the Patient's Skin

Hair Removal

Hair removal can injure skin, and many surgeons no longer request hair removal. Though hair that surrounds the surgical site may be so thick that removal is necessary. Hair should be removed with clippers. Hair may interfere with exposure, closure, or the surgical site dressing. It may also prevent adequate skin contact with patient return electrodes or ECG leads.

Hair removal is carried out per the surgeon's order as close to the scheduled time for the surgical procedure as possible. Examination gloves are worn. The patient is covered to expose only the area to be clipped. Bath blankets are useful for preventing unnecessary exposure and prevent excess body heat loss during the procedure. The patient may be clipped in the OR after the anesthetic has been administered. Care is taken to not let stray hair remain in the surgical field. A wide piece of adhesive tape can be used to collect stray hair.

Clippers

Electric clippers with fine teeth cut hair close to the skin. The short stubble, usually about a millimeter in length, does not interfere with skin antisepsis or exposure of the surgical site. Clipping can be done using short strokes against the direction of hair growth. The blade lies flat against the skin surface. After use, a reusable blade assembly is disassembled, cleaned, and terminally sterilized. The clipper handle is cleaned and disinfected. Cordless handles with rechargeable batteries are available. Disposable clipper heads are preferred over reusable styles for sharpness and optimal function.

Razor

Shaving is not the preferred method of hair removal and should be performed as near the time of incision as possible if this

method must be used. Avoid making nicks and cuts in the skin. Gloves should be worn to prevent blood exposure if a nick should occur. Nicks made immediately before the surgical procedure (i.e., up to 30 minutes) are considered clean wounds. However, nicks and abrasions made several hours before the procedure may present as inflamed wounds at the time of surgical incision. The surgeon should be notified if the skin is not intact at the surgical site. This could be cause for cancellation of the surgical procedure. The time lapse between the preoperative shave and the surgical procedure may increase the risk for postoperative infection.

Wet shaving is preferable to dry shaving, which can leave the skin abraded. Soaking hair in lather allows keratin to absorb water, which makes hair softer and easier to remove. A sharp clean razor blade should be used. The skin is held taut and is shaved by stroking in the direction of hair growth. Blades are discarded in the appropriate sharps container.

• **Fig. 26.31** Contents of a two-step skin prep tray depicted with textured sponges.

Skin Degreasing

The skin surface is composed of cornified epithelium with a coating of secretions that include perspiration, oils, and desquamated epithelium. These surface sebaceous lubricants are insoluble in water. Therefore a skin degreaser or fat solvent may be used to enhance adhesion of ECG or other electrodes. It also may be used before skin preparation to improve adhesion of self-adhering drapes or to prevent smudging of skin markings. Isopropyl alcohol and acetone are effective fat solvents. A fat-solvent emollient is incorporated into some antiseptic agents. Some solvents, such as alcohol, are flammable and must be allowed to completely dry before draping. Vapors can become a fire hazard if trapped beneath surgical drapes.

Surgical Skin Cleansing Fundamentals

Before beginning the positioning and prepping sequence, ask the patient to verbally state the location for the procedure and to point to and touch the site if possible. The correct site should have been marked with indelible ink by the surgeon before the patient was brought to the OR, as part of the identification process. Before amputation of an extremity, expose the opposite limb also for comparison. Check with the surgeon, the permit, and the notes in the chart. Confirm that the correct area is identified by the surgery schedule as well. Double-check the radiographs to be sure they have not been hung in the view box backward.

After the patient is anesthetized and positioned on the OR bed, the skin at the surgical site and an extensive area surrounding it is exposed and cleansed with an antiseptic agent immediately before draping. The person performing the prep must wear personal protective equipment (PPE) to prevent a splash to the eyes.

Towels should be tucked in at the patient's sides to catch any runoff. The two-step skin prep employing scrub soap and paint is performed wearing sterile gloves. The one-step skin prep is essentially a layer of alcohol-based solution performed while wearing nonsterile examination gloves. The end result of antisepsis of the skin is essentially the same. Keep in mind that skin is never sterile regardless of surgical cleansing method used.

Care is taken when prepping areas of the body that may be delicate or where prepping may be potentially harmful to the patient, such as carotid arteries, occluded vessels, tumor masses, distended abdomen, traumatic wounds, eyes, ears, trachea, and questionably stable tissues. Never rub a tumor or infectious mass. Areas marked by the surgeon preoperatively should be gently cleansed, so as not to wash off the markings. Some surgeons use surgical marking pens or surgical dyes, such as methylene blue, brilliant green, or alcohol-based gentian violet. Others may use heavy-duty black markers to delineate the surgical site.

Setup and Procedure for a Two-Step Skin Prep

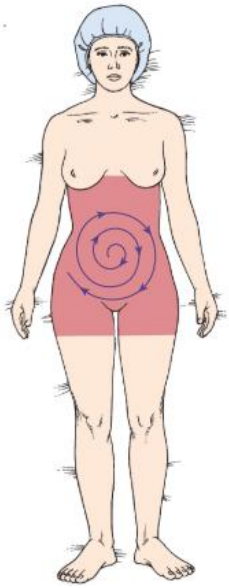
Some disposable skin preparation trays include gloves, disposable towels, prep sponges, and cotton-tipped applicators. Some disposable trays have containers of premeasured antiseptic cleansing solution (Fig. 26.31). Disposable trays without antiseptic agents can be packaged sterile or unsterile. These are referred to as *dry trays* and require the addition of the antiseptic cleansing solution of choice. If prepackaged disposable trays are not used, a sterile table is prepared by the scrub person with the following sterile items:

- Small table drape to create the sterile field.
- Sterile gloves.
- Two absorbent towels used to prevent pooling under body parts along the sides of the area and to define the upper and lower limits of the area to be prepped.
- Two or three small basins for solutions (antiseptic scrub detergent, antiseptic paint solution, and sterile water or alcohol if requested by the surgeon). About 1 or 2 ounces of solution in each basin usually is sufficient.
- Gauze sponges (nonradiopaque). The number varies according to the size of the area intended for the surgical procedure. These are not counted sponges from the instrument table and should be discarded in a trash container separate from the sponge bucket. Textured foam sponges may be preferred.
- Cotton-tipped applicators as necessary.

The **antiseptic solutions** are poured into each of the basins. Do not preheat the prep solutions because the fluid portion can evaporate and cause concentration of the antiseptic chemical. One-half ounce of warm sterile water is added to the scrub soap basin to allow sudsing action of the agent. Do not pour the remainder of the water into a basin on the sterile field because once the water is poured, the lip is considered contaminated. The water can be recapped and used for cleaning the patient's skin at the end of the surgical procedure before tape is applied.

Sterile gloves are donned by the person doing the prep using the open glove method for the two-step prep. A sterile prep setup is commonly used. Studies have shown that a clean but unsterile setup may be used for intact skin without compromising antimicrobial activity. Skin is mechanically cleansed and chemically decontaminated to reduce skin flora.

The surgical site is bordered by sterile towels after donning the sterile gloves. The sides of the patient are protected by towels to



• **Fig. 26.32** Abdominal antiseptic skin preparation. Patient is in supine position. Area includes breast line to upper third of thighs, from table line right to table line left. *Shaded area* shows anatomic area to be cleansed with antiseptic. *Arrows* within area show direction of motion for skin preparation.

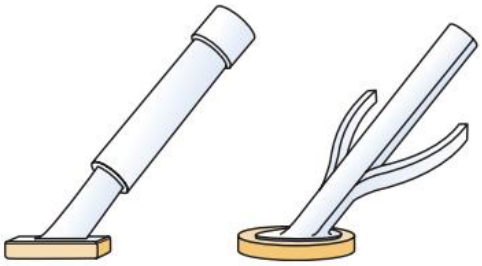
prevent runoff of excess solution. The cotton-tipped applicators are dipped into the soapy solution and used to cleanse the umbilicus if the umbilicus is part of the surgical site. The soiled applicators are discarded into the trash. Several sponges are placed into the soapy solution, and several are placed into the paint solution. A few sponges are reserved for use at the end of the prep if the surgeon incorporates an alcohol rinse. Each sponge is squeezed into the corresponding basin so as to not soak the patient and the surrounding bed linens.

The soapy antiseptic sponges are used to mechanically and chemically cleanse the skin in a circular or linear motion from the incisional site to the periphery (Fig. 26.32). The soap decreases the surface tension of the skin and permits the sponge to pick up and remove dirt and microbes from the skin. The sponge should not backtrack over the already prepped area. Each sponge is discarded in the trash after use and not placed in the sponge bucket. A towel is used to blot the soap from the site. It is fully opened and placed over the site and carefully lifted off without rubbing or dragging the fabric over the cleansed area.

The paint-style antiseptic solution is applied in the same manner, with a circular motion from the incisional site to the periphery. This solution is not blotted or wiped off. It should be allowed to dry. If the surgeon prefers, an alcohol sponge is sometimes used to complete the skin prep procedure. If alcohol is used, it is allowed to dry completely before drapes are applied, to minimize the risk for fire from trapped vapors.

Setup and Procedure for a One-Step Skin Prep

A one-step skin prep is a self-contained unit constructed of a sponge applicator tip (like a shoe polish dauber) and a chamber that contains antiseptic solution (Fig. 26.33). The unit is packaged in a blister pack with two cotton-tipped applicators. A pack of sterile towels is opened and used to tuck in at the patient's sides and periphery of the surgical site. When taken from the package, the applicator is not handled under sterile conditions. Users wear nonsterile examination gloves to prevent the solution from getting



• **Fig. 26.33** One-step skin prep applicator.

on their hands. The product should not be permitted to come into contact with reusable equipment such as basins because it does not readily wash off.

To apply the prep solution, the unit is compressed at the working end to break the seal of the inner chamber and allow the solution to saturate the applicator tip. The cotton-tipped applicators are dipped into the saturated sponge and used to clean the umbilicus; these cotton-tipped applicators are then discarded. The sponge end is inverted and allowed to become the applicator end.

The area to be prepped is painted in the same stroke direction as for a two-step skin prep. These one-step prep antiseptics have a thicker texture, dry like shellac, and are not blotted off in any manner after application. Some preps are tinted pink, blue, or orange for easy visibility and verification that all areas of the surgical site have been prepped. The risk for pooling is minimized with these products because of their consistency. They mechanically hold cells in place over the skin surface and chemically kill microorganisms. The alcohol-based skin prep products form a barrier over the skin.

The manufacturer recommends not removing the product after the procedure but, instead, allowing it to wear off over time to provide a lasting antisepsis for up to 3 days. Alcohol can be used to remove the product if necessary, or remover solution is commercially available. A package insert includes patient take-home instructions about the product and the purpose for its presence on the skin.

The chemical action is the actual antiseptic agent (iodophor or chlorhexidine) in combination with an alcohol base. The alcohol base can pose a fire hazard if not permitted to dry completely before draping. These items should not be heated in any way. They contain an ampule that can pressurize and explode in the presence of heat. Prepackaged antiseptic soapy prep sponges are available without alcohol for sensitive areas such as the face or perineum. These one-step soapy prep sponges are used in urology rooms.

Preparing Areas Considered Contaminated

Umbilicus

Although the umbilicus is considered a contaminated area, prepping this central area of the abdomen after the surgical site can cause contamination of a freshly prepped abdomen. Most surgeons prefer the umbilicus to be cleaned with cotton-tipped swabs before the main abdominal incision is prepped to prevent debris from the contaminated site splashing on the freshly prepped incision. This is a logical conclusion.

Stoma

Intestinal stomas are contaminated with fecal material and intestinal flora. The stoma should be isolated with a sterile clear plastic adhesive dressing and prepped last. If the stoma is to be incorporated with the surgical incision, it is prepped and dried last and

covered with a sterile clear plastic adhesive dressing to prevent fecal material from entering the wound. Some surgeons pack the open end of the stoma with a povidone-iodine (Betadine)-soaked radiopaque sponge. This sponge should be accounted for in the count tally at the end of the procedure. A nonradiopaque gauze sponge should not be used as stoma packing in the sterile field because it could become misplaced and be unaccounted for in the procedure.

Other Contaminated Areas

Other areas such as draining sinuses, skin ulcers, the vagina, and the anus are also considered contaminated areas. In all of these areas, the general rule of scrubbing the most contaminated area last with separate sponges applies. Use logic when determining the sequence for surgical skin prep.

Foreign Substances

Adhesive, grease, tar, and similar foreign materials are removed from skin before the area is mechanically cleansed with an antiseptic agent. A nonirritating solvent should be used to cleanse the skin. The solvent should be nonflammable and nontoxic. Do not allow the solution to collect underneath the patient. Take care that the foreign substance in itself is not hazardous or flammable. Some chemicals can ignite when exposed to water or moisture.

Traumatic Wounds

In the preparation of an area in which the skin is not intact because of a traumatic injury, wound irrigation may be part of the skin preparation procedure. The wound may be packed or covered with sterile gauze while the area around it is thoroughly scrubbed and shaved if necessary. The extent and type of injury determine the appropriate procedure. Protective gloves, eyewear, and a mask should be worn during the irrigation.

Solutions that are irritating to a denuded area must not be used. Small areas may be irrigated with warm sterile normal saline solution with a bulb syringe. When a bulb syringe is used, care must be taken not to force debris and microorganisms deeper into the wound. The wound is irrigated gently to dislodge debris and flush it out. Soft nylon brushes are sometimes used. This is useful for industrial injuries and motorcycle accidents.

Copious amounts of warm sterile solution may be needed to flush out a large wound. A container of warm sterile normal saline or Ringer's lactate attached to IV tubing can be hung on an IV pole near the area to be copiously irrigated. If the area is on an extremity, a sterile irrigating basin with a plastic drape fitted over the top is placed under the extremity. During irrigation, solution runs from the wound into the basin. Suction tubing placed in the basin removes the irrigating solution into a kick bucket, suction canister, or machine.

Dry towels or sheets may be necessary under the patient if the area has not been protected during irrigation. A moisture-proof pad placed under the wound before irrigation helps channel solutions into a drainage pan.

Debridement of the wound (excision of all devitalized tissue) usually follows irrigation. The surgeon may request to have sterile tissue forceps and scissors on the prep table for removal of nonviable tissue.

Areas Prepared for Grafts

Separate setups are necessary for skin preparation of recipient and donor sites before skin, bone, or vascular grafting procedures. The donor site is usually scrubbed first.

The donor site for a skin graft should be scrubbed with a colorless antiseptic agent so that the surgeon can properly evaluate the vascularity of the graft postoperatively. The recipient site for skin grafts is usually more or less contaminated (e.g., after a burn or other traumatic injury). Items used in preparation of the recipient site must not be permitted to contaminate the donor site. Also, microorganisms on the skin of the donor site must not be transferred to a denuded recipient site.

Antiseptic Solutions

The infection control committee usually determines the chemical antiseptic or antimicrobial agents to be used in the OR for skin preparation. Products selected by the OR committee are commonly the same ones selected for use as hand and skin antisepsis of the sterile team. The maximum concentration of a germicidal agent that can be used on skin and mucous membranes is limited by the agent's toxicity for these tissues. The ideal antiseptic skin cleansing agent should have the following qualities:

- It has broad-spectrum antimicrobial action and rapidly decreases the microbial count. It should be virucidal and active against protozoa and yeasts.
- It can be quickly applied and remains effective against microorganisms.
- It can be safely used without skin irritation or sensitization. It should be nontoxic.
- It effectively remains active in the presence of alcohol, organic matter, soap, and detergent.
- It should be nonflammable when dried for use with laser, electrosurgical, and other high-energy devices.

Chlorhexidine Gluconate

Chlorhexidine gluconate was discovered in 1950 in England. A solution of 2% to 4% chlorhexidine gluconate is used as an antiseptic skin cleansing soap preoperatively. A tincture of 0.5% chlorhexidine gluconate in 70% isopropyl alcohol (Hibitane) is sometimes used. A broad-spectrum, rapid-acting antimicrobial agent, it binds to negative charges on microbial cell walls to produce irreversible damage and death. It has minimal activity against yeasts, spores, and tuberculosis. It is effective against most viruses.

Activity is adversely affected by traces of soap and is reduced in the presence of organic matter. If chlorhexidine is used in combination with personal soaps and shampoos for preoperative bathing, it is inactivated. The patient should be instructed to shampoo the hair with personal shampoo and thoroughly rinse before applying chlorhexidine as a body wash. Body lotion should not be applied after bathing because this nullifies the residual bacteriostatic properties of the compound. The patient should be instructed to keep chlorhexidine out of the eyes and ears.

This agent is not absorbed through intact skin but binds with mucous membranes. It significantly reduces and maintains a reduction of microbial flora, such as bacteria and yeasts, for at least 4 hours.[6] The prolonged effect is inhibited if chlorhexidine is combined with iodine preparations. Its activity increases at elevated temperature because it binds with the stratum corneum. It is available either tinted for color demarcation of the skin area being prepped or nontinted if the surgeon needs to observe the skin color. Because it is an irritant to the eyes and ototoxic, it is contraindicated for facial antisepsis. If chlorhexidine gets on clothing, chlorine bleach is avoided because it permanently stains the fabric. Clothing should be rinsed with cold water until all traces of the product have been removed.

Iodine and Iodophors

Discovered in 1812, iodine was first used in wound care in 1839. A solution of 1% or 2% iodine in water or in 70% alcohol is an excellent antiseptic. However, potential hazards of skin irritations and burns led to a decline in its use. If used, iodine should dry and then be rinsed off with 70% alcohol to neutralize the damaging effect.

Iodophors are iodine compounds that may be combined with detergents. Povidone-iodine has a surfactant, a wetting and dispersive agent, in an aqueous solution such as Betadine surgical scrub, a commonly used detergent form of iodophor. The detergent form should be rinsed off. Iodophor solution without detergent can be used for rinsing. Iodophor in 70% alcohol also is available. Iodophors are excellent cleansing agents that remove debris from skin surfaces while slowly releasing iodine. They are broad-spectrum antimicrobial agents that have some virucidal and sporicidal activity. Iodophors are relatively nontoxic and virtually nonirritating to skin or mucous membranes.

The brown film left on the skin after application of the solution clearly defines the area of application. This should not be wiped off because microbial activity is sustained by the release of free iodine as the agent dries and color fades from the skin. The solution should remain on the skin for at least 2 minutes. To hasten drying of the skin, alcohol may be painted on the area without friction before a self-adhering drape is applied. The alcohol must not be permitted to pool and must be completely dry before draping.

Iodophors are used with caution to prep the skin of patients who are sensitive or allergic to iodine. True iodine allergy is very rare. The association with an actual allergy is more an issue with systemic problems as opposed to topical sensitivity and is exceedingly rare. Studies have shown that seafood allergy is associated with fish protein and not iodine.[7]

The type of preparation, concentration of iodine, and presence of surfactants affect the microbial activity of products. Povidone-iodine complexes are available in solution, spray, and gel forms. Tinctures are in an alcohol-based solution. Manufacturer instructions are strictly followed for the product in use. The concentration of povidone-iodine may be altered by evaporation if the solution is warmed. Skin irritation may be caused by an increase in iodine concentration. Manufacturer recommendations should be followed.

Alcohol

Isopropyl and ethyl alcohols are broad-spectrum agents that denature proteins in cells. A 70% concentration with continuous contact for several minutes is satisfactory for skin antisepsis if the surgeon prefers a colorless solution that permits observation of true skin color. Because alcohol coagulates protein, it is not applied to mucous membranes or used on an open wound. Isopropyl alcohol is a more effective fat solvent than is ethyl alcohol. Both are volatile and flammable. They must not pool around or under the patient, especially if an electrosurgical unit (ESU) or laser will be used. Vapors can accumulate under the drapes and become a fire or explosion hazard.

Parachlorometaxylenol

Originally developed in 1948 in Europe as a hair conditioner, parachlorometaxylenol (PCMX) has bactericidal properties useful for skin antisepsis. It is effective against some fungi, tuberculosis, and viruses. PCMX has residual properties with repeated use. It is nontoxic to the skin, eyes, and ears.

Skin Preparation for Specific Anatomic Areas

Head and Neck

Eye

1. The eyebrows are never shaved or removed unless the surgeon deems this essential. Eyebrows do not grow back completely or evenly.
2. The eyelashes may be trimmed, if ordered by the surgeon, with fine iris scissors coated with sterile water-soluble lubricant to catch the lashes.
3. The eyelids and periorbital areas are cleansed with a nonirritating antiseptic agent and then rinsed with warm sterile water. The prep starts centrally and extends to the periphery (i.e., from the center of the lid to the brow and cheek).
4. The conjunctival sac is flushed with a nontoxic agent, such as sterile normal saline solution, with a bulb syringe. Some surgeons use a dilute iodophor solution (not the detergent or alcohol form). The patient's head is turned slightly to the affected side. The solution is contained with sponges or an absorbent towel. Care must be taken to prevent prep solution from entering the patient's ears.

Chlorhexidine is contraindicated for facial preps. Chlorhexidine gluconate can cause corneal damage if accidentally introduced into the eyes and can cause sensorineural deafness if the agent enters the inner ear (e.g., through a perforated tympanic membrane).

Ears, Face, and Nose

1. Usually, defining the area with towels is not easy. As much of the surrounding area is included as is feasible and consistent with aseptic technique. Skin surfaces should be cleansed at least to the hairline.
2. Cotton applicators are used for cleansing the nostrils and external ear canals.
3. Protect the eyes with a piece of sterile plastic sheeting. If the patient is awake, ask that the eyes be kept closed during the prep. Cotton balls or nonradiopaque gauze should be placed in the ears to prevent runoff. Cotton balls may leave small fibers in residual cerumen in the ear that can cause irritation.

Neck

1. One sterile towel is folded under the edge of the blanket and gown, which are turned down almost to the nipple line.
2. The area includes the neck laterally to the table line and up to the mandible, tops of the shoulders, and chest almost to the nipple line.
3. For combined head and neck surgical procedures, include the face to the eyes; the shaved areas of the head, ears, and posterior neck; and the area over the shoulders.

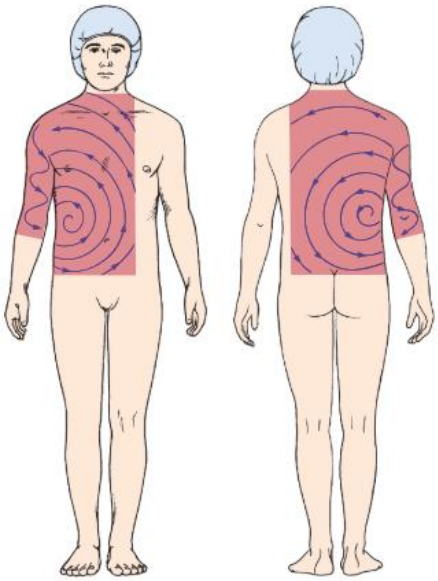
Chest and Trunk

Lateral Thoracoabdominal Area

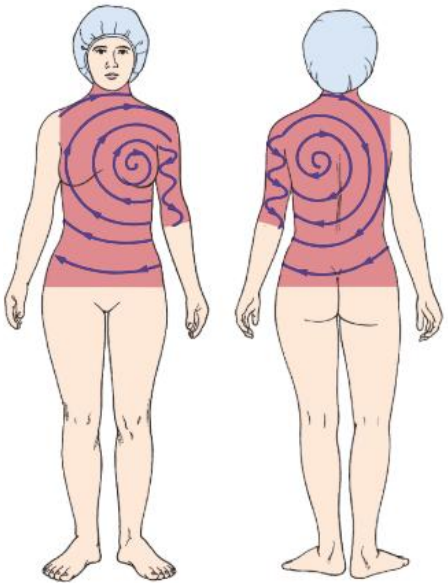
1. The gown is removed. The blanket is turned down well below the lower limit of the area to be prepared. A towel is folded under the edge of the blanket.
2. The arm is held up by an assistant during the prep.
3. Beginning at the site of incision, the area may include the axilla, chest, and abdomen from the neck to the iliac crest. For a surgical procedure in the region of the kidney, it extends up to the axilla and down to the pubis. The area also extends beyond midlines, anteriorly and posteriorly, and may include the arm to the elbow (Fig. 26.34).

Chest and Breast

1. The anesthesia provider turns the patient's face toward the unaffected side.



• **Fig. 26.34** Lateral thoracoabdominal antiseptic skin prep. Patient is in lateral position. Area includes axilla, chest, and abdomen from neck to iliac crest. Area extends beyond midline, anteriorly and posteriorly.

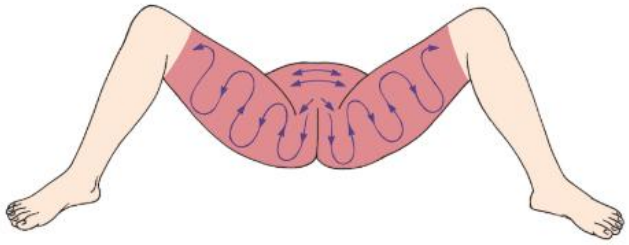


• **Fig. 26.35** Chest and breast antiseptic skin prep. Area includes shoulder, upper arm down to elbow, axilla, and chest wall to table line and beyond sternum to opposite shoulder. If patient is in lateral position, back is prepped also.

2. One towel is folded under the blanket edge, just above the pubis. Another is placed on the OR bed under the shoulder and side.
3. The arm on the affected side is held up by grasping the hand and raising the shoulder and axilla slightly from the OR bed.
4. The area includes the shoulder, upper arm down to the elbow, axilla, and chest wall to the table line and beyond the sternum to the opposite shoulder (Fig. 26.35). Breast procedures generally require both breasts to be prepped.

Shoulder

1. The anesthesia provider turns the patient's face toward the opposite side.



• **Fig. 26.36** Rectoperineal and vaginal antiseptic skin prep. Area includes pubis, vulva, labia, perineum, anus, and adjacent area, including inner aspects of upper third of thighs. The inner aspect of the vagina is prepped after the external vulva is prepped. The anus is prepped last.

2. A towel is placed under the shoulder and axilla.
3. The arm is held up by grasping the hand and elevating the shoulder slightly from the OR bed.
4. The area includes the circumference of the upper arm to below the elbow, from the base of the neck over the shoulder, scapula, and chest to the midline.

Rectoperineal Area

1. With the patient in the lithotomy position, a moisture-proof pad is placed under the buttocks and extends to the kick bucket that receives solutions and discarded prep sponges.
2. The area includes the pubis, external genitalia, perineum and anus, and inner aspects of the thighs (Fig. 26.36).
3. Begin the scrub over the pubic area, scrubbing downward over the genitalia and perineum. Discard the sponge.
4. The inner aspects of the upper third of both thighs are scrubbed with separate sponges, working from groin to distal aspect of thigh.
5. The anus is prepped last.
6. The rectoperineal area is prepped before the abdomen, using a separate prep set and gloves if an abdominal approach is planned.

Vagina

1. Sponge forceps should be included on the preparation table for a vaginal prep because a portion of the prep is done internally. A disposable vaginal prep tray, with sponge sticks included, is available.
2. With the patient in the lithotomy position, a moisture-proof pad is placed under the buttocks and extends to the kick bucket that receives solutions and discarded prep sponges.
3. A towel is folded above the pubis.
4. Urinary catheterization is performed if indicated. Vaginal and anal flora should not be permitted to enter the sterile environment of the urinary bladder.
5. The external area includes the pubis, vulva, labia, perineum, anus, and adjacent area, including inner aspects of the upper third of the thighs (see Fig. 26.36).
6. Begin over the pubic area, scrubbing downward over the vulva and perineum. The inner aspects of the thighs are scrubbed with separate sponges from the labia majora outward.
7. The vagina and cervix are cleansed with sponges on sponge forceps or disposable sponge sticks. The cleansing agent should be applied generously in the vagina because vaginal mucosa has many folds and crevices that are not easily cleansed.
8. After thorough cleansing of the vagina, wipe it out with a dry sponge to prevent the possibility of the fluid entering the peritoneal cavity during the surgical procedure on pelvic organs.
9. The anus is prepped last to prevent intestinal florae from entering the vaginal vault.

Extremities

1. A moisture-proof pad should be placed on the OR bed under an extremity to retain runoff solution. This is removed after the prep so the bed is dry under the surgical site. The extremity is supported by personnel wearing sterile gloves and remains elevated until sterile drapes are applied under and around the prepped area.
2. A full **circumferential** extremity prep may be done in two stages to provide adequate support to joints and to ensure that all areas are scrubbed. It may include the foot for hip, thigh, knee, and lower leg procedures.
3. Caution must be taken to prevent solution from pooling under a tourniquet. The padding absorbs the solution and could cause tissue maceration. If a nonsterile pneumatic tourniquet is used, it is positioned before the prep and protected with a sterile clear plastic drape. A towel tucked around the tourniquet cuff absorbs excess solution. This is removed before the tourniquet is inflated.

Upper Arm

1. A towel is placed under the shoulder and axilla.
2. The arm is held up by grasping the hand and elevating the shoulder slightly from the OR bed.
3. The area includes the entire circumference of the arm to the wrist, the axilla, and over the shoulder and scapula.

Elbow and Forearm

1. A towel is placed under the shoulder and axilla.
2. The arm is held up by grasping the hand.
3. The area includes the entire arm from the shoulder and axilla to and including the hand.

Hand

1. Towels may be omitted. The anatomy of the hand furnishes sufficient landmarks to define the area, and towels are apt to slip over the scrubbed area.
2. The arm must be held up by a gloved person supporting it above the elbow so that the entire circumference can be scrubbed.
3. The area includes the hand and arm to 3 inches (7.5 cm) above the elbow.

Hip

1. One towel is placed under the thigh on the OR bed. Another towel is placed on the abdomen and folded under the edge of the gown, just above the umbilicus.
2. The leg on the affected side is held up by supporting it just below the knee.
3. The area includes the abdomen on the affected side, the thigh to the knee, and the buttocks to the table line, the groin, and the pubis (Fig. 26.37).

Thigh

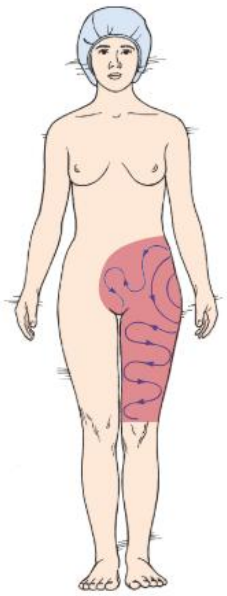
1. One towel is placed under the thigh on the OR bed. Another towel is placed on the abdomen and folded under the edge of the gown, just below the umbilicus.
2. The leg is held up by supporting the foot and ankle.
3. The area includes the entire circumference of the thigh and leg to the ankle, over the hip and buttocks to the table line, the groin, and the pubis. Take care not to allow the solution to pool under the patient's buttocks.

Knee and Lower Leg

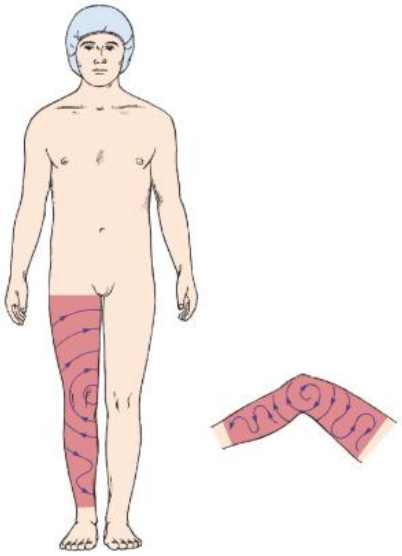
1. A towel is placed over the groin.
2. The leg is held up by supporting it at the foot.
3. The area includes the entire circumference of the leg and extends from the foot to the upper part of the thigh (Fig. 26.38).

Ankle and Foot

1. Towels are omitted.
2. The foot is held up by supporting the leg at the knee. A leg-holder device is useful.
3. The area includes the foot and entire circumference of the lower leg to the knee.



• **Fig. 26.37** Hip antiseptic skin prep. Area includes abdomen on affected side, thigh to knee, buttock to table line, groin, and pubis.



• **Fig. 26.38** Knee and lower leg antiseptic skin prep. Area includes entire circumference of affected leg and extends from foot to upper part of thigh. Upper extremity is prepped in the same manner.

Documentation

Details of the preoperative skin condition and preparation should be documented in the patient's intraoperative record. These should include, but are not limited to, the following:

- The condition of the skin around the surgical site and placement sites of the return electrodes
- Hair removal, if done, including the method and location, and areas for attachment of monitors or electrodes
- Antiseptic solutions, fat solvents, irrigating solutions, and any other agents used
- The skin area prepped and skin reaction, if any
- The name of the person who did the prep

Draping

Draping is the procedure of covering the patient and surrounding areas with a sterile barrier to create and maintain an adequate sterile field. An effective barrier eliminates or minimizes passage of microorganisms between nonsterile and sterile areas. Criteria to be met in establishing an effective barrier are that the material must be:

- Blood and fluid resistant to keep drapes dry and prevent migration of microorganisms. Material should be impermeable to moist microbial penetration (i.e., resistant to strike-through) and resistant to tearing, puncture, or abrasion that causes fiber breakdown and thus permits microbial penetration.
- Lint-free to reduce airborne contaminants and shedding into the surgical site. Cellulose and cotton fibers can cause granulomatous peritonitis or embolize arteries.
- Antistatic to eliminate risk for a spark from static electricity. Material must meet standards of the National Fire Protection Association (NFPA).
- Sufficiently porous to eliminate heat buildup so as to maintain an isothermic environment appropriate for the patient's body temperature.
- Drapable to fit around contours of the patient, furniture, and equipment.
- Dull and nonglaring to minimize color distortion from reflected light.
- Free of toxic ingredients, such as laundry residues and nonfast dyes.
- Flame resistant to self-extinguish rapidly on removal of an ignition source. This is a concern with use of lasers, ESUs, and other high-energy devices that provide an ignition source at the sterile field. Drapes become fuel for a fire. Some materials are more flammable than others; some are fire-retardant.

Draping Materials

Self-Adhering Sheeting

Sterile, waterproof, antistatic, and transparent or translucent plastic sheeting may be applied to dry skin.

Incise Drape. The entire clear plastic drape has an adhesive backing that is applied to skin. This may be applied separately, or the sheeting may be incorporated into the drape sheet. The skin incision is made through the plastic.

Antimicrobial incise drapes have an antimicrobial agent impregnated in the adhesive or the polymeric film. A film coated with an iodophor-containing adhesive, for example, slowly releases active iodine during the surgical procedure to effectively inhibit proliferation of organisms from the patient's skin. The antimicrobial may be another agent that does not contain iodine. The skin may be prepped with alcohol and allowed to dry before the drape is applied. Time is a factor in microbial accumulation from resident bacteria. Antimicrobial incise drapes are used to sustain suppression, particularly for procedures that last more than 3 hours.

Towel Drape. A nonwoven towel drape has a band of adhesive along one edge. Used as a draping towel, it remains fixed on skin without towel clips. This is advantageous when clips might obscure the view of a part exposed to x-rays during the surgical procedure. It also is used to wall off a contaminated area, such as a stoma, from the clean skin area to prevent spilling contents and causing infection or chemical irritation.

Aperture Drape. Adhesive surrounds a fenestration (opening) in the plastic sheeting. This secures the drape to the skin around the surgical site, such as an eye or ear. Caution is used in applying this type of drape around the face of a patient who is awake. The patient must have breathing space. If oxygen is used during a local procedure, it can build up under the drape creating a fire hazard if cautery is used. Some patients experience claustrophobia. Fabric towels may not feel as confining.

Advantages of Self-Adhering Drape Material

- Resident microbial flora from skin pores, sebaceous glands, and hair follicles cannot migrate laterally to the incision.
- Microorganisms do not penetrate the impermeable material.
- Landmarks and skin tones are visible through the transparent plastic.
- Inert adhesive holds drapes securely, eliminating the need for towel clips and possible puncture of the patient's skin.
- Plastic sheeting conforms to body contours and has elasticity to stretch without breaking its adhesion to skin.

Some self-adhering drapes have sufficient moisture-vapor permeability to reduce excessive moisture buildup that could macerate the skin or loosen adhesive. A nonporous material should not cover more than 10% of the body surface because it may interfere with the patient's thermal regulatory mechanism of perspiration evaporation. The heat-retaining property of plastic causes the patient to perspire excessively, but its nonporous nature prevents evaporation.

This material is used in the following manner:

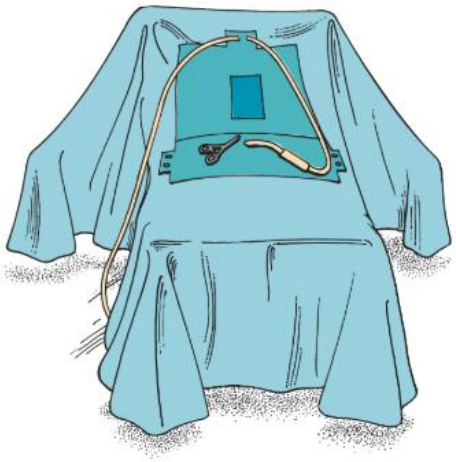
1. The usual skin prep is done.
2. The scrubbed area must be dry. It may dry by evaporation, or excess solution may be blotted with a towel.
3. Transparent plastic material is applied firmly to the skin, with the initial contact along the proposed line of incision. The drape is smoothed away from the incision area.
4. Regular fabric drapes are applied over the plastic sheeting unless plastic is incorporated into the fenestrated area of the drape.

Nonwoven Disposable Drapes

Most nonwoven disposable materials are compressed layers of synthetic fibers (i.e., rayon, nylon, or polyester) combined with cellulose (wood pulp) and bonded together chemically or mechanically without knitting, tufting, or weaving. This material may be either nonabsorbent or absorbent. Polypropylene and foil also are used in some types. Those fabrics that comply with criteria for establishing an effective barrier have the following advantages as disposable drapes:

- They are moisture-repellant; they retard blood and aqueous fluid moisture strike-through to prevent contamination. Not all nonwoven fabrics have this characteristic; only nonabsorbent materials or those laminated with plastic are impermeable to moisture.
- They are lightweight, yet strong enough to resist tears.
- They are lint-free unless cellulose fibers are torn or cut.
- Contaminants are disposed of along with drapes.
- They are antistatic and flame-retardant for OR use.
- They are prepackaged and sterilized by the manufacturer, which eliminates washing, mending, folding, and sterilizing processes.

Some drapes have a reinforced area of multiple layers that surrounds the fenestration. The outer layer absorbs fluids, but the underneath layer is impermeable to strike-through. An antimicrobial may be incorporated into this reinforced area. Other drapes have an impermeable layer around the fenestration. Drapes that are completely laminated with a plastic layer may be used for an extremity or for instrument table covers. They are not used over the entire body of the patient because of their heat retention property.



• **Fig. 26.39** Fenestrated laparotomy drape sheet with reinforcement around fenestration.

Many nonwoven drapes have pouches or troughs incorporated close to the fenestration or along the sides of the drape to collect fluids, such as amniotic fluid. The pouch may have drainage ports, or fluid may be suctioned out. Some drapes also have pockets, skid-resistant instrument pads, or devices for holding cords incorporated in them (Fig. 26.39).

Laser-Resistant Drape. Nonwoven drapes that contain cellulose ignite and burn easily. Polypropylene drapes do not ignite, but they can melt. An aluminum-coated drape may be safest for use with lasers, especially around the oxygen-enriched environment of the head and neck area.

Thermal Drape. An aluminum-coated plastic body cover reflects radiant body heat back to the patient to reduce intraoperative heat loss. A sterile, nonconductive, radiolucent thermal drape may be used as the final drape. The patient may be wrapped in nonsterile reflective covers (thermal drape) in the preoperative holding area. These may remain in place through the surgical procedure under standard sterile drapes and during postoperative recovery in the postanesthesia care unit (PACU). A reflective blanket or thermal drape is recommended when more than 60% of the body surface can be covered and when the surgical procedure will last more than 2 hours.

Nonwoven, disposable drapes are supplied prepackaged and presterilized by the manufacturer. A sterile package may contain a single drape, or it may have all of the drapes needed for a procedure, including towels, a Mayo stand and instrument table covers, and gowns. Unused disposable drapes and gowns should not be resterilized.

Woven Textile Fabrics

The thread count and finish of woven natural fibers determine the integrity and porosity of reusable fabrics. Tightly woven textile fabrics may inhibit migration of microorganisms. Cotton fibers swell when they become wet. This swelling action closes pores or interstices so that liquid cannot diffuse through tightly woven fibers. The fabric can be treated to further repel fluids (i.e., be impermeable to moisture strike-through).

Reusable drapes may be made of Pima cotton of 270 or 280 thread count with a Quarpel finish. This fluorochemical finish combined with phenazopyridine or a melanin hydrophobe produces a durable water-resistant fabric. However, this fabric has essentially the same heat-retaining qualities as plastic lamination, so it cannot be used for complete patient draping. This treated material can be used as reinforcement around fenestrations in otherwise untreated drapes.

Tightly woven 100% polyester reusable fabrics are hydrophobic (repel water droplets) but allow vapor permeation. Other reusable fabrics with different construction but similar barrier properties may be used.

The following points about reusable woven textile drapes should be considered:

- Material must be steam-penetrable and must withstand multiple sterilization cycles.
- When packaged for sterilization, drapes must be properly folded and arranged in sequence of use. Drapes may be fan-folded or rolled.
- Material must be free from holes and tears. The person who folds the drape is responsible for inspecting it for holes. Those detected may be covered with heat-seal patches. Tears or punctures (e.g., from towel clips or sharp instruments) compromise the barrier qualities of drapes.
- Drapes should be sufficiently impermeable to prevent moisture from soaking through them. Moisture has a wicking action that can cause migration of microorganisms.
- Reusable fabrics must maintain barrier qualities through multiple launderings. Densely woven, treated cotton becomes moisture permeable after about 75 washings; untreated cotton becomes moisture permeable after as few as 30 washings. Repeated drying, ironing, and steam sterilizing also alter fabric structure. The number of uses, washings, and sterilizing cycles should be recorded, and drapes that are no longer effective as barriers should be taken out of use.

Styles/Types of Drapes

Towels

Disposable or reusable sterile towels may be used to outline, or square off, the surgical site after prepping the skin. The folded edge of each towel is placed toward the line of incision to square it off. Towels are usually packaged in groups of four by the in-house laundry and can be secured with nonperforating towel clips or may be sutured or stapled to skin.

Radiopaque towels in counted packages are commercially available. Some disposable types have adhesive strips to hold them in place.

Surgical towels are traditionally used as draping material; however, in some facilities they are considered counted items. If a surgical draping towel is placed in the surgical incision, it becomes an item that must be accounted for and is listed using the same mechanism that is in place to track any other counted items.

The scrub person reports to the circulating nurse that a towel has been placed in the incision. The circulating nurse writes down the number of towels placed inside the patient on the count tally sheet or wipe-off board. At the conclusion of the surgical procedure, the scrub person reports how many towels have been removed and the number is validated by the circulating nurse during the final count. Counts are documented as correct or incorrect per facility policy.

The literature is replete with horror stories about surgical towels that carelessly become retained foreign objects when the team fails to account for them. Anything that becomes part of the incisional packing is considered a counted item.

Fenestrated Sheets

The drape sheet has an opening (fenestration) that is placed to expose the anatomic area where the incision will be made. Many styles

of disposable nonwoven or reusable woven fabrics are available for specific uses. The size, direction, and shape of the fenestration vary to give adequate exposure of the surgical site. The sheet is long enough to cover the anesthesia screen at the head and extend down over the foot of the OR bed. Fenestrated sheets are usually marked to indicate the direction in which they should be unfolded. This may be an arrow or label designating the top or head, bottom or foot. It is wide enough to cover one or two armboards.

Reinforcement around the fenestration (see Fig. 26.39) for both nonwoven and woven fabrics provides an extra thickness to minimize the passage of microorganisms by capillary action to the sterile field. The reinforced area is usually 24 inches (60 cm) wide.

The drapes described are basic styles of fenestrated sheets.

Laparotomy Sheet. The laparotomy sheet is often referred to as a lap sheet; the longitudinal fenestration is placed over the surgical site on the abdomen, back, or comparable area (see Fig. 26.37). The opening is large enough to give adequate exposure in the usual laparotomy. The sheet is at least 108 × 72 inches (274 × 183 cm). Pediatric sizes are available. Lap sheets with a vertical fenestration can be used in some spinal procedures. Specialty lap sheets for cesarean sections may have an oval fenestration.

Thyroid Sheet. The thyroid sheet is the same size as a laparotomy sheet. The fenestration is transverse or diamond shaped and is positioned closer to the top of the patient over the neck area.

Chest Sheet. The chest sheet is similar to a laparotomy sheet except that the fenestration provides for a larger exposure. It is used for chest and breast procedures. Some chest sheets have a horizontal fenestration.

Hip Sheet. The hip sheet is similar to the laparotomy sheet but somewhat longer to completely cover the orthopedic fracture table. The fenestration may be oval and used in conjunction with an impervious stockinette.

Perineal Sheet. The perineal sheet is of adequate size to create a sterile field with the patient in the lithotomy position. Some styles have large leggings incorporated into it to cover the legs in stirrups. It may have one or two openings to accommodate the perineum or rectum.

Laparoscopy Sheet. A laparoscopy sheet is a combination laparotomy and perineal sheet. It is used for gynecologic laparoscopy in lithotomy or combined abdominoperineal resection with the patient in the lithotomy position. The fenestrations are located on the abdominal portion and the perineum. Some styles have built in leggings.

Separate Sheets

Although fenestrated sheets are used for most surgical procedures, they are not always practical. The openings may be much too large for small incisions, such as specimens for biopsies or procedures on the hands or feet. Smaller separate sheets may be used for these purposes to leave exposed only the small surgical area or to provide additional drapes on the surgical field. Many of these are disposable.

Split Sheet. The split sheet is the same size as a laparotomy sheet. Rather than the sheet being fenestrated, one end is cut longitudinally up the middle at least one-third the length of the sheet to form two free ends (tails). The upper end of this split may be in the shape of a U. Adhesive strips on each tail approximately 8 inches (20 cm) from the end of the split adhere together to snug the drape around an extremity or head. Shorter styles have adhesive strips the full length of the inner aspect of the tails for circumferential wrapping.

Minor Sheet. The minor sheet is 36 × 45 inches (91 × 114 cm). It has many uses. Wrapped around an extremity, it permits the extremity to remain on the sterile field for manipulation during the surgical procedure. It is used under an arm to cover an armboard for shoulder, axillary, arm, and hand procedures.

Medium Sheet. The medium sheet is about 36 × 72 inches (91 × 183 cm). It is used to drape under legs, as an added protection above or below the surgical area, and for draping areas in which a fenestrated sheet cannot be used.

Single Sheet. The single sheet is 108 × 72 inches (274 × 183 cm). Folded lengthwise, it is placed above the sterile field to shield off the anesthesia provider and anesthesia machine or other equipment near the patient's head or sterile field. A single sheet also is used to cover the patient and OR bed below the surgical area around the face.

Leggings. Leg drapes are supplied in pairs to cover the legs of a patient in the lithotomy position. A rectangle, approximately 36 × 72 inches (91 × 183 cm), is closed on two sides to form a tentlike pocket. One open edge is folded into a cuff to protect gloves from contamination during application.

Stockinette. Stockinette is a tubular drape used to cover an extremity. This seamless tubing of stretchable woven material contours snugly to the skin. The material is porous and absorbent, so it is not a microbial barrier. Therefore, when used as a drape, it may be covered with a layer of plastic.

A two-ply tubular disposable drape is available that has an inner layer of stockinette and an outer layer of vinyl to make it impervious. An opening is cut through the material over the line of incision. Edges may be secured with a plastic incise drape before the incision is made, or it may be clipped to the wound edges after the incision. Rolled elastic ACE or Coban bandage is sometimes used for this purpose. Care is taken to use nonlatex materials for patients sensitive to latex.

Principles of Draping

The entire team should be familiar with the draping procedure because draping is an important step in the preparation of the patient for a surgical procedure. The scrub person should be knowledgeable and ready to assist with draping. The scrub person is responsible for seeing that necessary articles are arranged in proper sequence on the instrument table. Once a drape is placed it cannot be moved without contamination.

The person responsible for draping the patient may vary, as do materials and styles of drapes used to create a sterile field. The surgeon or assistant usually places the self-adhering incise drape or towels and towel clips to outline the surgical site. The scrub person assists with placing the remainder of the drapes.

During any draping procedure, the circulating nurse should stand by to direct the scrub person as necessary and watch carefully for breaks in technique. A contaminated drape or exposure of a nonsterile area is a potential source of infection for the patient.

Basic principles regarding draping are as follows:

1. Place drapes on a dry area. The area around or under the patient may become damp from solutions used for skin preparation. The circulating nurse removes damp items or covers the area to provide a dry field on which to lay sterile drapes.
2. Allow sufficient time to permit careful application.
3. Allow sufficient space to observe sterile technique. Do not reach across a nonsterile surface.
4. Handle drapes as little as possible.
5. Never reach across the OR bed to drape the opposite side; go around it.

6. Take towels and towel clips, if used, to the side of the OR bed from which the surgeon is going to apply them before handing them up.
7. Carry folded drapes to the OR bed. Watch the front of the sterile gown; it may bulge and touch the nonsterile OR bed or blanket on the patient. Stand well back from the nonsterile OR bed.
   a. Hold drapes high enough to avoid touching nonsterile areas, but avoid touching the overhead operating light.
   b. Hold a drape high until it is directly over the proper area, and then lay it down where it is to remain. Once a sheet is placed, do not adjust it. Be careful not to slide the sheet out of place when opening the folds.
   c. Protect gloved hands by cuffing the end of the sheet over them. Do not let gloved hands touch the skin of the patient or other nearby items, such as the IV.
8. In unfolding a sheet from the prepped area toward the foot or head of the OR bed, protect the gloved hand by enclosing it in a turned-back cuff of sheet provided for this purpose. Keep hands at table level.
9. If a drape becomes contaminated, do not handle it further. Discard it without contaminating gloves or other items.
   a. If the end of a sheet falls below waist level, do not handle it further. Drop it, and use another.
   b. If in doubt as to its sterility, consider a drape contaminated.
   c. If a drape is incorrectly placed, discard it. The circulating nurse peels it from the OR bed without contaminating other drapes or the prepped area.
10. A piercing towel clip that has been fastened through a drape has its points contaminated. Remove it only if absolutely necessary, and then discard it from the sterile setup without touching the points. Cover the area from which it was removed with another piece of sterile draping material.

Unusual Circumstances Considered Potentially Contaminated

1. If a hole is found in a drape after it is laid down, the hole must be covered with another piece of draping material (or OpSite) or the entire drape discarded. Use judgment concerning whether covering or discarding the drape is appropriate. Discarding the drape is the ideal if at all possible.
2. A hair found on a drape during a procedure in process must be removed, and the area covered immediately. Ideally the drape should be discarded and replaced if possible. The source of a hair is usually unknown and would cause a foreign body tissue reaction or infection in a patient if it got into the wound. If the drape cannot be removed, remove the hair with a hemostat, and hand the instrument off the sterile field; cover the area with a towel or another piece of draping material.

Procedures for Draping the Patient

Draping procedures establish the sterile field. Standardized methods of application should be practiced using adequate draping materials. The most common procedures are discussed here merely to elaborate the principles. The following section details procedures that use only absorbent woven draping materials because establishing a microbial barrier with them is more complex. The draping procedure is simplified when single-thickness impermeable materials are used. A procedure book should be consulted for specific draping procedures.

Laparotomy

The term *laparotomy* refers to an incision through the abdominal wall into the abdominal cavity. All flat, smooth areas are draped in the same manner as the abdomen. These areas include the neck, chest, flank, and back. The draping procedure is as follows:

1. Hand up four towels and towel clips (if the surgeon uses them). With practice, these can be held in the hands at the same time and separated one by one as the surgeon takes them. Go to the side of the OR bed on which the surgeon is draping to avoid reaching over the nonsterile table. The surgeon places these towels within the prepped area, leaving only the surgical area exposed.
2. Hand one end of a fan-folded medium sheet across the OR bed to the assistant, supporting the folds, keeping the sheet high, and holding it taut until it is opened; then lay it down. Place this medium sheet below the surgical site with the edge of it at the skin edge, covering the draping towel.

   This sheet provides an extra thickness of material under the area from the Mayo stand to the incision, where instruments and sponges are placed, and closes some of the opening in the laparotomy sheet if necessary. This sheet may be eliminated if a self-adhering incise drape or impermeable drapes are used.
3. Place a laparotomy sheet with the opening directly over the prepped area outlined by the towels, in the direction indicated for the foot or head of the OR bed (Fig. 26.40). Drop the folds over the sides of the table. However, if an armboard is in place, hold the folds at table level until the sheet is opened all the way. Open it downward over the patient's feet first and then upward over the anesthesia screen (Fig. 26.41). Sheets with appropriate fenestrations are used to expose the surgical site.
   a. For the neck, use a thyroid sheet.
   b. For the chest, with the patient in either the supine or lateral position, use a breast sheet.
   c. For the flank, with the patient in the kidney position for transverse incision, use a kidney sheet.
   d. For the back, use a laparotomy sheet, the same as for the abdomen.
4. Place a large single sheet crosswise on the OR bed above the fenestrated site. This sheet provides an extra thickness above the area and closes some of the opening in the laparotomy sheet if necessary. It also covers the armboard if one is in use.

• **Fig. 26.40** Draping with sterile laparotomy sheet. Scrub person carries folded sheet to table. Standing far back from OR bed, with one hand, scrub person places the fenestration of the sheet on patient so that opening in sheet is directly over prepped skin area. A second sterile team member helps complete the opening of the drape over the body from the opposite side of the table.

• **Fig. 26.41** Unfolding upper end of laparotomy sheet over anesthesia screen. Note that hands approaching unsterile area are protected in cuff of drape and that sheet is stabilized with other hand.

A single sheet may be needed for this latter purpose even if an impermeable laparotomy sheet is used.

Head

An overhead instrument table may be positioned over the patient for neurologic procedures. The table drape is extended down over the patient's shoulders to create a continuous sterile field between the instrument table and the surgical site. The draping procedure is as follows:

1. The surgeon places four towels around the head and secures them with towel clips or affixes them in place with sutures or skin staples. Towel clips and staples are not used if x-rays will be taken during the surgical procedure.
2. Hand one end of a fan-folded medium sheet to the assistant. Holding it taut, unfold and secure it over the head end of the OR bed below the surgical site at the skin edge of the draping towel.
3. Place a fenestrated sheet with the opening over the exposed skin area of the head. Unfold the sheet across the front edge of the overhead table, and secure it before allowing the remainder of the drape to drop over the head of the OR bed toward the floor. Some disposable fenestrated head sheets have transparent plastic adhesive incise sheeting to cover the incisional site. The incise sheet may be impregnated with iodophor for additional wound protection during the procedure.

Face

Even if the surgical site is unilateral, the surgeon may want the entire face exposed for comparison of skin lines. The draping procedure is as follows:

1. The surgeon places a drape under the head while the circulating nurse or assistant elevates the head. This drape consists of an open towel placed on a medium sheet. The center of the towel edge is 2 inches (5 cm) in from the center of the sheet edge. The towel is drawn up on each side of the face, over the forehead or at the hairline, and fastened with a small nonperforating towel clip. This leaves the desired amount of the face exposed.
2. Hand up three additional towels and four towel clips. These towels frame the surgical site.
3. Place a medium sheet just below the site. This sheet must overlap the one under the head.
4. A fenestrated drape may be placed to complete draping.
5. Cover the remainder of the foot of the OR bed, as necessary, with a single sheet.

If the patient is receiving inhalation anesthesia, use a minor sheet instead of a towel on a medium sheet for the first drape under the head. A minor sheet is large enough to draw up on each side of the face and to enclose the endotracheal tube and oropharyngeal monitoring probes from the anesthesia machine for a considerable distance, thus keeping them from contaminating the sterile field.

If the surgical procedure on the face is unilateral, the anesthesia provider may sit along the unaffected side, near the patient's head, with the anesthesia screen placed on the same side of the OR bed.

Skin staples or sutures may be used to affix towels around the contours of the face and neck of the patient under general anesthesia. Each staple or stitch overlaps the skin and edge of the drape.

Eye

After skin preparation, the unaffected eye is protected by covering it with a sterile eye pad before draping the patient. The draping procedure is as follows:

1. The surgeon places two towels and a medium sheet under the head while the circulating nurse holds the head up, as described for a face drape. One towel is drawn up around the head, exposing only the eyebrow and affected eye, and fastened with a clip without pressure on the eyes.
2. Hand up four towels and towel clips to isolate the affected eye. Some surgeons prefer a self-adhering aperture drape.
3. Cover the patient and remainder of the OR bed below the surgical area with a single sheet.

If local anesthetic will be administered, the drapes are raised off of the patient's nose and mouth to permit free breathing. A Mayo stand or anesthesia screen positioned over the lower face before the draping is one method to elevate the drapes. Oxygen, 6 to 8 L/min, can be supplied under the drapes via tube or nasal cannula. If the patient has chronic obstructive pulmonary disease (COPD), the oxygen level should not exceed 3 L/min. Take extreme caution that oxygen does not build up under the drapes. An ignition source such as a cautery or laser could spark a fire beneath the drapes.

For a microsurgical procedure, a sterile, padded, U-shaped steel wrist rest for the surgeon and assistant is fastened to the head of the OR bed. Towels are put around the patient's head before the rest of the facial and body draping is completed.

If irrigation will be used, a plastic fenestrated drape is placed over the four towels to keep them dry if an aperture drape is not preferred.

Ear

The basic draping procedure is the same as for draping a face or eye, except that only the affected ear is exposed. The head is turned toward the unaffected side. Oxygen can be supplied under the drapes, as previously described. The anesthesia provider is usually positioned at the side of the OR bed near the patient's face.

Chest and Breast

While the arm is still being held up by the assistant after skin preparation:

1. Place a minor sheet on an armboard, under the patient's arm, extending the sheet under the side of the chest and shoulder. The prepped arm is lowered to the sterile draped armboard. The distal portion of the arm may be encased in sterile stockinette so that the arm can be manipulated during the surgical procedure.
2. The patient's body is draped with a sterile medium sheet.
3. Hand up towels and towel clips; five or six are necessary.

4. Apply a breast sheet so that the axilla is exposed for anticipated axillary dissection. Many breast procedures require both breasts to be prepped and exposed for comparison during the procedure.

Shoulder

While the arm is still being held up by the assistant after skin preparation:

1. Place medium sheets over the chest and under the arm.
2. Place a minor sheet under the shoulder and side of the chest.
3. The surgeon outlines the surgical site with towels and secures them with clips.
4. Place a minor sheet over the patient's chest, covering the neck. Keep this sheet even with the edge of the towel that borders the surgical site laterally.
5. Wrap the arm in a minor sheet or encase it in a sterile stockinette, and secure it with a sterile gauze or elastic bandage.[8] At this point, a sterile team member relieves the unsterile person who has been holding the arm.
6. Place a medium sheet above the area, and secure these sheets together with towel clips.
7. A laparotomy or breast sheet may be used. Pull the arm through the opening. Or a single sheet may be placed above the area, and the foot of the OR bed is covered with a medium sheet.
8. If irrigation will be used, an arthroscopy drape with a large packet for fluid collection and a connection for suction tubing is available.

Elbow

While the arm is still being held up by the unsterile assistant after skin preparation:

1. Place a sterile medium sheet across the chest and under the arm, up to the axilla.
2. The surgeon defines the surgical area on the upper (**proximal**) arm by placing a towel around the upper arm and securing it with a towel clip.
3. Wrap the hand in a sterile towel. At this point, a sterile team member relieves the unsterile person who has been holding the arm by grasping the wrapped hand, maintaining the arm in an elevated position.[8]
4. The hand is grasped with a sterile stockinette, which is pulled down over the entire arm toward the axilla, over the surgical site.[8] An elastic bandage is wrapped around the arm starting at the distal end (hand) to the proximal area (axilla).
5. Place a medium sheet across the chest, on top of the arm, even with the towel on the upper arm and covering it. Secure this sheet around the arm with a towel clip.
6. An extremity sheet is drawn over the hand and the arm. The extremity sheet is opened in its entirety across the patient's body.

Hand

While the arm and hand are still being held up after skin preparation:

1. Place an impervious minor sheet, folded in half, on the extremity table.
2. The surgeon places a towel around the lower arm, limiting the exposed area to the affected hand, and secures it with a towel clip.
3. Pull a stockinette over the hand and up over the length of the arm. At this stage in draping, the unsterile person is relieved of holding the arm. The draped arm is laid on the draped extremity table.
4. Place a minor sheet across the extremity table just above the surgical site.
5. Place an extremity sheet over the hand. Do not drop folds below the level of the armboard. Open the sheet across the patient's body toward the feet first. Attach the top end to the IV poles at the head of the bed.

Perineum

With the patient in the lithotomy position for a genital, vaginal, or rectal procedure:

1. Place a medium sheet under the buttocks. The circulating nurse can grasp the underside and assist in placement. With the patient's legs elevated in stirrups, this drape hangs below the level of the OR bed and covers the lowered section of the OR bed.
2. Slide leggings over each leg, protecting the gloved hands in the folded cuffs.
3. The anus is covered if it is not part of the surgical site. An adhesive towel drape may be used for this purpose.
4. Place a medium sheet across the abdomen, from the level of the pubis, extending over the anesthesia screen or attached to IV poles at the head of the bed.
5. A fenestrated perineal sheet may be used rather than a medium sheet over the abdomen. To use a perineal sheet with built-in leggings, hand one end of the sheet to the assistant, opening out folds, and draw the leggings over the feet and legs simultaneously. The hands are kept on the outside of the sheet to avoid contaminating the gloves and gown.

Hip

The patient is in a lateral position. If the leg will be manipulated during the surgical procedure, while the leg is still being held up after skin preparation:

1. Place a medium sheet on the OR bed under the leg, up to the buttock.
2. Place another medium sheet on the OR bed, overlapping the first one, to cover the unaffected leg. Some surgeons prefer to use an incise sheet or a lower extremity stockinette.
3. The surgeon wraps the foot and leg with an elastic bandage, covering the stockinette. The leg, held up to this point, is laid on the OR bed.
4. Place a minor sheet lengthwise of the OR bed on each side of the exposed area, even with the skin. The sheets under the leg and above the site do not overlap. Some surgeons prefer to draw the leg through the opening of a hip sheet or place a split sheet under the leg with the tails crossed over it toward the patient's head.
5. Place a medium sheet above the exposed area. Secure these last three sheets with towel clips.
6. Place a single sheet above the surgical area and over the anesthesia screen.

If manipulation of the leg is not necessary during the surgical procedure, drape the same as for a laparotomy, using a hip sheet instead of a laparotomy sheet.

Knee

While the leg is still being held up after skin preparation:

1. Place a medium sheet lengthwise on the OR bed, under the leg, up to the buttock. Take care not to contaminate sterile gloves on the unsterile tourniquet if used.
2. Place another medium sheet on the OR bed, overlapping the first sheet, to cover the unaffected leg.
3. The surgeon limits the sterile field above the knee by placing a towel around the leg and securing it with a towel clip.

4. Lay a minor sheet on the sterile sheets under the leg. The person who has been holding the leg lays it on this minor sheet. The surgeon wraps the leg in the minor sheet and secures it with a sterile bandage. Stockinette may be preferred for this step.
5. Place a medium sheet above the exposed area, at the skin edge, over the draping towel, and fasten it with a towel clip.
6. Place a laparotomy or extremity sheet, with the opening on the foot and the longer part of the sheet toward the head of the OR bed. Open it, and draw the leg through the opening. A split sheet may be used instead. If water will be used for arthroscopy, a drape with a fluid collection pocket should be opened according to the diagram so the pocket is in the correct position.

Lower Leg and Ankle

While the leg is still being held up after skin preparation:

1. Place a medium sheet under the leg and over the unaffected leg to above the knees.
2. The surgeon limits the sterile field by placing a towel around the leg above the area of the intended surgical site and securing it with a towel clip.
3. Put a stockinette over the foot and draw it up over the leg to above the skin edge of the towel. The person who has been holding the leg is relieved, and the leg is held by a sterile team member.
4. Place a medium sheet above the surgical area, and secure it around the leg with a towel clip.
5. Place a laparotomy, extremity, or split sheet with the leg drawn through the opening.
6. Cover the remainder of the OR bed over the anesthesia screen with a single sheet as necessary.

Foot

The general method of draping a foot is the same as that for the hand. While the foot is still being held up after skin preparation:

1. Place a medium sheet on the OR bed under the foot.
2. The surgeon limits the exposed area to the foot by placing a towel around the ankle and securing it with a towel clip.
3. Enclose the foot in a stockinette. A sterile team member relieves the unsterile person who has been holding the leg.
4. Place a medium sheet above the foot, and secure it around the ankle with a towel clip.
5. Place a laparotomy or extremity sheet with the opening over the foot and longer part of the sheet toward the head of the OR bed.

Draping of Equipment

A pneumatic tourniquet frequently is used to control bleeding during surgical procedures on the upper and lower extremities. A nonsterile tourniquet cuff is placed around the extremity before skin preparation and is covered with the draping material. An impervious towel that delineates the upper limit of the surgical area is placed around the extremity below the tourniquet cuff.

Equipment that is brought into the sterile field but cannot be sterilized must be draped before it is handled by sterile team members. The following applies to draping of equipment:

1. Tailored, disposable, clear plastic drapes are available to cover equipment, such as the operating microscope and the C-arm, so that they can be manipulated in the sterile field by the sterile team.
2. If x-rays are to be taken during the surgical procedure, a cassette holder may be placed on the OR bed, under the mattress, before the patient is positioned, prepped, and draped. The circulating nurse raises the edge of the sterile drape for the radiology technician to place and remove the x-ray cassette. The cassette may be covered with a sterile Mayo stand cover or specially designed disposable cover and placed on sterile drapes when a lateral view is needed.
3. Cords, cables, attachments, and tubing that are not sterile are inserted into sterile plastic sleeves before they are placed on the sterile field.

Nonsterile equipment that must stand near the sterile field is isolated from the sterile area with a barrier drape. IV poles frequently are used to attach drapes to shield off power-generating sources of mechanical and electrical equipment, such as electrosurgical and cryosurgical units, fiberoptic lighting units, and air-powered or electrical instruments. The drape over the patient or a separate single sheet is extended from the OR bed upward in front of or over the nonsterile equipment. The circulating nurse fastens the drape to IV poles on each side of the equipment that stands above the level of the sterile field or near it.

Heat-generating equipment must have adequate ventilation to dissipate heat. Impermeable, heat-retaining materials cannot completely encase these units. Ends of fiberoptic light cables should not make prolonged contact with drapes, or a fire may result.

Some nonsterile equipment, of necessity, is moved over the sterile field. The sterile field is protected using additional draping material as follows:

1. Sterile disposable drapes are available to cover x-ray equipment and image intensifiers.
2. When ready to move an x-ray tube or image intensifier over the sterile field, cover the field with a sterile minor sheet. The circulating nurse discards this sheet after use because it is considered contaminated.
3. Photographic equipment and video cameras should be draped as much as feasible when used over the sterile field. Some video cameras fit directly into the headlamp of the surgeon or in the overhead spotlight and require no special draping.

Plastic Isolator

A patient isolation drape may be used in conjunction with a fracture table. The isolation drape literally divides the room in half vertically. It isolates the sterile field from equipment, such as the C-arm image intensifier used for hip procedures. The drape is suspended from a steel frame on one side of the special orthopedic table but does not enclose the patient. The drape may have an incise portion that may be impregnated with a timed-release iodophor. Storage holsters and irrigation pouches are commonly incorporated into the side. Care is taken not to perforate the plastic surface when placing items in the pouches.

Physiologic Maintenance and Monitoring of the Perioperative Patient

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify pertinent body systems that should be monitored during a surgical procedure.
- Discuss the differences between invasive and noninvasive means of patient monitoring.
- Discuss why personnel monitoring a patient should be knowledgeable about the monitoring devices used.
- Describe how monitoring parameters provide information about interrelated body systems.

KEY TERMS AND DEFINITIONS

Core temperature Temperature inside the body.
Expiration Exit of waste gases from the body through the mouth and nose.
External respiration Exchange of gases between the lungs and blood at the alveolar level.
Hemodynamics Study of blood circulation, blood pressure, peripheral vascular physiology, and cardiac function.
Internal respiration Exchange of gases between the blood and cells at the capillary/tissue level.
Monitoring Observing, evaluating, and reporting physiologic function.
Pulse Palpable sensation of blood passing through an artery.
Respiration Exchange of oxygen (O_2)and carbon dioxide (CO_2) at the molecular level.
Sinus rhythm Electrical impulse in the heart that originates at the sinoatrial node of the right atrium of the heart, passes through the atrioventricular node at the atrial-septal junction, and continues down the length of the Purkinje fibers in the ventricular septum, causing contraction of the ventricles.
Ventilation/inspiration Bringing air into the lungs through the mouth, nose, or tracheal stoma.

The development of successful controllable anesthesia has made modern surgery possible. Because anesthesia is an adjunct to most surgical procedures, familiarity with various anesthetic agents, their interaction with certain drugs, and their potential hazards is a necessity. The perioperative nurse responsible for patient monitoring may detect the onset of complications and help avert an undesired outcome.

Working with anesthesia providers in the perioperative environment gives the learner an unparalleled opportunity to master immediate resuscitative measures and their effectiveness, and an understanding of the care of unconscious and critically ill patients. For example, the learner daily observes endotracheal intubation, ventilatory control, insertion of arterial and venous cannulas, fluid replacement, and sophisticated hemodynamic monitoring.

No surgical procedure is minor. Surgery and anesthesia impose certain inescapable risks, even in supposedly ideal circumstances. Overall, however, the anesthetic-related surgical mortality rate is relatively low. Preexisting patient factors, such as age and medical condition, and those related to the circumstances of the surgical procedure, such as type, duration, and elective versus emergency procedure, are more significant in determining surgical mortality.

The American Society of Anesthesiologists (ASA) has established standards for basic perioperative monitoring. Specialization in monitoring equipment and the use of computers to record monitoring data are facets of contemporary anesthesia practice.

Monitoring Physiologic Functions

Preoperative patient assessment establishes a baseline and provides valuable information with which intraoperative and postoperative patient care is planned and evaluated. Establishing a preoperative baseline enables the caregiver to be alerted to changes in the patient's physiologic condition that may require prompt attention.[1]

Surgical and anesthetic techniques have become increasingly complex, which allows many critically ill patients of all ages to

undergo surgical procedures. The anesthesia provider carefully monitors the patient's condition through the entire perioperative process and keeps the surgeon informed of important changes.

Monitoring implies keeping track of vital functions. During extensive surgery with the patient under anesthesia, the body is subjected to physiologic stress. Bleeding, tissue trauma, potent drugs, large extravascular fluid shifts, multiple transfusions, and a surgical position that may inhibit breathing and circulation all contribute to altered physiology. These factors can induce significant cardiopulmonary dysfunction.

Patients under local anesthesia are frequently monitored with electrocardiographs (ECG). If the patient has a known cardiac condition, such as atrial fibrillation (AF), the atrial dysrhythmia is felt by the patient and demonstrated on the ECG machine. If the patient has had atrial ablation treatments, an AF rhythm may be measured by the ECG monitor and not felt by the patient.[2] It is important to use subjective and objective measures to evaluate the patient's condition.[1,2]

Evaluation of the patient's responses to surgical stressors includes observation, auscultation, and palpation. The assessment is enhanced with the use of electronic or mechanical devices that reveal physiologic trends and subtle changes and indicate responses to therapy. Most of this equipment is expensive and is incorporated into the anesthesia machine. Compact precise devices with miniaturized circuitry, better visibility, and easier maintenance are incorporated into portable models that allow for continued monitoring after the patient leaves the operating room (OR).

Computers improve and expedite analysis of data. They are sophisticated data collection and management tools that assist in physiologic assessment, diagnosis, and therapy. Clinical computers vary from single-function devices to complex, multifunction, real-time systems that acquire, store, and display data; organize information; display trends; and perform calculations.

Personnel who use electronic and computerized monitoring equipment must understand its use and function, be experienced in its interpretation, and be able to determine equipment malfunction easily. Instrumentation should augment, not replace, careful observation of the patient. Monitoring equipment can be inaccurate. Information from monitors should be compared with physical assessment data.[1]

Perioperative nurses involved with patient monitoring should remain current in the knowledge of physical assessment and the use of the equipment. Periodic competency testing should be performed. Written policies, procedures, and guidelines should be available for reference.[1]

The spectrum of monitoring devices is broad. It ranges from noninvasive to invasive. Noninvasive monitors do not penetrate the body or a body orifice. Conversely, invasive monitors penetrate skin or mucosa, or they enter a body cavity. Some parameters can be measured with both noninvasive and invasive methods. Perioperative nursing responsibilities may include assisting with sophisticated hemodynamic monitoring to evaluate the interrelationship of blood pressure (BP), blood flow, vascular volumes, and physical properties of blood, heart rate, and ventricular function.

Detection of early changes in hemodynamics allows prompt action to maintain cardiac function and adequate cardiac output (CO). Monitoring facilitates rapid, accurate determination of decreased perfusion. It reflects immediate response to therapeutic measures and stress.

Invasive Hemodynamic Monitoring

Hemodynamics is the study of the movement of blood. Measurements of CO and intracardiac pressures provide information related to functions of the heart and other major organ systems.

Invasive hemodynamic monitoring uses basic physiologic principles to detect and treat a wide variety of abnormalities. Its purpose is to avoid problems in high-risk patients and accurately diagnose and treat patients with established life-threatening disorders. Hemodynamic monitoring involves direct intravascular measurements and assessments by means of indwelling catheters connected to transducers and monitors.[3]

Pressures and forces within arteries and veins are converted to electrical signals by the transducer, a device that transfers energy from one system to another. These electrical signals are then processed and amplified by the monitor into a continuous waveform displayed on an oscilloscope or monitoring screen that reproduces images received via the transducer; or the monitor may digitally display the values.

These measurements yield specific information that is otherwise not usually attainable or as accurate. Although these measurements may be pertinent in guiding patient care, they present additional risks because obtaining them requires invasion of the great vessels or heart. The benefits of invasive monitoring must be balanced against the risks.

Various types of equipment, monitors, and catheters are in use. Everyone caring for patients with invasive monitors must have knowledge of anatomy and physiology and an understanding of the entire monitoring circuit. Every precaution must be taken to ensure patient safety. Strict adherence to policies and procedures, manufacturer instructions for use, and sterile technique is absolutely essential to minimize complications and misinterpretation of data that could lead to errors in therapy.

Indwelling arterial, venous, and intracardiac catheters permit rapid accurate assessment of physiologic alterations in high-risk patients. Intravascular access is justified because of the high yield of information with minimal discomfort to patients. But hemodynamic monitoring techniques must not be abused.

Cardiac dysrhythmias, thrombosis, embolism, and infection are serious, sometimes fatal, complications of intravascular cannulation. Some facilities require the patient to sign a consent form before insertion of an invasive catheter.

Intravascular Cannulation

Intravascular catheters usually are inserted before induction of anesthesia by the anesthesia provider. They may be inserted percutaneously or by cutdown, depending on the type of catheter, intended purpose, and location of the vessel to be cannulated. Intracardiac catheters may be placed under fluoroscopic control, or their position may be verified on a chest x-ray after insertion. In addition to their use in hemodynamic monitoring, intravenous (IV) catheters can be used to administer blood, drugs, and nutrients. Catheters may be inserted into the right atrium or pulmonary artery via the vena cava through a subclavian, jugular, brachial, or femoral vein.

Intraarterial catheters are inserted for direct pressure measurements and to obtain blood for arterial blood gas (ABG) analyses.[1] Potential sites for cannulation include the radial, ulnar, axillary, brachial, femoral, and dorsalis pedis arteries. The radial artery is most commonly used if ulnar circulation to the hand is adequate. A Doppler ultrasound device may be used to determine a dominant artery and locate a weakly palpable one. When radial artery dominance exists, the ulnar, brachial, or other artery is used.

As a precaution, adequacy of perfusion to the extremity below the catheter should be established before insertion, in case thrombosis or occlusion occurs. A radial artery distal to a brachial artery previously used for cardiac catheterization is avoided because of the possibility of distorted pressures or occlusion. Some physicians cannulate the femoral artery if the catheter is to remain in place for more than 24 hours. The incidence of thrombosis is lower when a large vessel is used.

Thrombosis may result from irritation of the vessel wall or hypercoagulation or inadequate flushing of the catheter and line. The larger the catheter in relation to the arterial lumen, the greater the incidence of thrombosis. Other complications of arterial cannulation include embolic phenomena, blood loss from a dislodged catheter or disconnected line, bruise or hematoma formation, arteriovenous fistula or aneurysm formation, systemic infection, and ischemic fingers from arterial spasm.

Intravascular Catheters

Most catheters are radiopaque and have centimeter calibrations. They are flexible. They may be made of silicone, polyethylene, polyvinyl chloride, polytetrafluoroethylene (Teflon), or polyurethane. Those with soft pliable tips are safer than are stiff catheters. Shearing of a vessel with extravascular migration of the catheter has occurred from stiffness and sharpness of the catheter and movement of the patient. Soft catheters are introduced over a guidewire or with flow-directed balloons. The catheter and related introducer, guidewire, and caps may be supplied as a prepackaged sterile kit.

Many catheters have a heparin coating to prevent clot formation. Polyurethane or other uncoated catheters are available for the patient who is allergic to heparin. The catheter is kept open with a slow continuous infusion. Routine flushing of the catheter is necessary. Normal saline solution may be used if heparin is unnecessary or contraindicated. Continuous-flush devices with fast-flush valves release small amounts of solution. Limited pressure diminishes the possibility of ejecting a large clot. The catheter usually is fast-flushed both hourly and after blood samples are withdrawn. Air bubbles in the line must be avoided. After flushing, the drip rate in the drip chamber is checked.

A catheter may have a single lumen or two or three lumens. The catheters discussed are used for hemodynamic monitoring of the following:

- ABGs and pressure via a single-lumen intraarterial catheter
- Central venous pressure (CVP) via a central venous, Hickman, or Broviac catheter
- Pulmonary artery pressures (PAPs) via a pulmonary artery or Swan-Ganz catheter

Catheter Insertion

Catheter insertion is a sterile procedure. The necessary sterile supplies should be collected before the patient arrives. Although catheters are different, the technique for insertion is basically the same for all types. Insertion is a team effort. The circulating nurse's responsibilities may vary but usually include the following:

1. Explain the procedure and reassure the patient. If the patient will be awake, sedation may be ordered.
2. Document the patient's vital signs and **pulse** distal to the selected insertion site if the arm is the insertion site. If the pulse weakens after cannulation, circulation may be inadequate in an extremity and the catheter may need to be removed.
3. Position the patient as appropriate.
   a. For radial artery cannulation, affix the forearm to an armboard with the hand supinated and wrist dorsiflexed to an angle of 50 to 60 degrees over a towel. Avoid extreme dorsiflexion; this can obliterate the pulse. Tape the thumb to the armboard to stabilize the artery at the wrist.
   b. For subclavian or jugular vein insertion, place the patient in a 25 to 30-degree Trendelenburg's position to reduce the potential for air embolism. Elevate the right scapular area with padding or a rolled towel underneath the shoulders to allow the physician to identify anatomic landmarks and locate the vein more easily. Turn the patient's head away from the insertion site.[4]
4. Prepare the skin per routine procedure. Wearing sterile gloves, the anesthesia provider then drapes the area. Warn patients if their face will be covered.
5. Inform patients, if awake, that they may have a burning sensation for a few seconds when the local anesthetic is injected before the area becomes numb. Explain that pressure, but not pain, may be felt during insertion. The skin and subcutaneous tissues are infiltrated with a local anesthetic because the skin is incised to facilitate entrance of the catheter. A cutdown, or opening of the skin and tissues to access a vein, may be necessary.
6. Assist the anesthesia provider as appropriate. Be familiar with and follow manufacturer directions for the brand of catheter and monitoring equipment used.
7. Make sure the connections between the catheter and infusion line are secure after the catheter has been inserted and properly placed. The catheter is sutured in place with a synthetic monofilament suture to prevent inadvertent advancement or removal and is taped to the skin. Lumens on the three-way stopcock and catheter may be capped to prevent fibrin deposits and retrograde contamination.
8. Connect the catheter line to the transducer or monitor, and take baseline pressure readings.
9. Dress the puncture site. An antibacterial ointment may be put around the site. Tape must not apply pressure directly over the insertion site or catheter. A transparent dressing is preferable. The catheter beneath it must not be bent or curled.
10. Take the patient's vital signs. Use a sphygmomanometer with the BP cuff on the arm opposite from the insertion site, and check the BP to compare with the monitor's pressure reading to verify the monitor's accuracy. The monitor may read higher systolic and lower diastolic pressures than the BP cuff readings.
11. Document the procedure and initial readings. Include the insertion site; type and gauge of catheter; type of infusion solution and amount of heparin, if added; flow rate and pressure; pulse before and after insertion; tolerance of the procedure; color, sensation, and warmth of the area distal to the insertion site; time of insertion; and names of insertion team members.

Frequent checks of circuitry and calibrations are necessary to validate the recorded data. Conscientious attention to every detail is mandatory during catheter insertion and monitoring. An ultrasound can be used to check for the tip placement of the central venous catheter to ensure there has been no perforation or other catheter misplacement.[4] Ultrasound is a quick method that does not expose the patient to unnecessary x-ray exposure.

Drawing Blood Samples

When the arterial or venous catheters are in place, the perioperative nurse may be asked to collect blood samples for analysis or to

take measurements, although this is not universal practice. These procedures require special training, skill, and knowledge of equipment and hazards involved.

Samples for ABG measurements are sometimes drawn from an indwelling catheter line kept open with a continuously running infusion. The tubing incorporates a plastic three-way stopcock, usually close to the catheter insertion site. One lumen of the stopcock goes to the infusion solution, one to the cannulated vessel, and one to outside air. The lumen to outside air is normally closed or covered with a sterile cap, or a sterile syringe is kept inserted in the lumen to prevent bacteria and air from entering. With a three-way stopcock, two of the three lumens are always open.

In drawing blood samples from an indwelling catheter, always use strict sterile technique. Blood may be drawn through a stopcock on a single-lumen catheter or from one lumen of a multilumen catheter. A sterile ABG monitoring kit with administration tubing and pressure transducers may be used for intraarterial pressure monitoring. Manufacturer instructions should be followed for turning the stopcock to draw blood samples and to flush lines. Drawing blood from a multilumen catheter is simplified when an injection port can be used. Many styles do not use needles, but use a double Luer-Lok tip to connect. The basic procedure is similar to the following, using a stopcock (always wipe the stopcock or end of the catheter with alcohol before entering the system):

1. Wear sterile gloves. A sterile heparinized syringe is used to prevent the blood samples from clotting. To heparinize, draw 1 mL of aqueous heparin 1:1000 into a 10-mL syringe. While rotating the barrel, pull the plunger back beyond the 7-mL calibration. With the syringe in an upright position, slowly eject the heparin and air bubbles while rotating the barrel.
2. Attach a sterile 5-mL syringe to the stopcock lumen going to outside air. Turn off (close) the infusion lumen. This automatically opens the line between the patient and the syringe. Aspirate to clear the line of fluid, and close the lumen to the patient. Discard this diluted sample.
3. Quickly attach the sterile heparinized syringe to a lumen to outside air, and open the lumen to the patient. This closes the lumen to the infusion, permitting aspiration of undiluted blood for analysis. Arterial pressure forces blood into the syringe. Withdraw 3 to 5 mL of blood. Hold the barrel and the plunger of the syringe to avoid their separation. Cap the syringe for placement in a properly labeled specimen bag.
4. Close the lumen to the patient, and flush the line and stopcock by letting the infusion solution run through them to prevent clot formation inside the catheter wall or stopcock, which could result in arterial embolization.
5. Close and recap the lumen to outside air (being careful not to contaminate the cap), thereby restarting the infusion to the patient. Regulate the infusion rate with the clamp on the infusion tubing.
6. If air bubbles are in the syringe, remove them. Send the samples immediately to the laboratory. If more than 10 minutes elapses between blood drawing and analysis, the analysis cannot be considered accurate. In the event of delay, the syringe with blood should be immersed in ice immediately and refrigerated at near-freezing temperature. Iced specimen bags may be used.
7. Attach the appropriate laboratory slips that include information such as the patient's name and location, the time and date, and whether the patient is receiving supplemental oxygen or breathing room air.

Physiologic Parameters Monitored

Noninvasive methods can be used to monitor some cardiopulmonary and neural functions and determine body temperature and urinary output (Box 27.1). Both noninvasive and invasive techniques are used for monitoring hemodynamic parameters to show minute-to-minute changes in physiologic variables. Normal ranges of hemodynamic parameters are given in Table 27.1.

Electrocardiogram

Every heartbeat depends on the electrical process of polarization. Muscles in the heart wall are alternately stimulated and relaxed. An ECG is a recording of electrical forces produced by the heart and translated as waveforms (Fig. 27.1). It shows changes in rhythm, rate, and conduction, such as dysrhythmias, appearance of premature beats, and block of impulses. An ECG does not provide an index of CO. Cardiac monitoring has become standard procedure in the OR and postanesthesia care unit (PACU).

Cardiac monitoring systems generally consist of a monitor screen; a cathode ray oscilloscope, on which the ECG is continuously visualized; and a printout system, which transcribes the rhythm strip to paper to permit comparison of tracings and

• BOX 27.1 Noninvasive Methods of Monitoring Vital Functions

Cardiopulmonary Functions

- *Blood pressure (BP):* Measurement of pressure exerted against arterial vessel walls to force blood through circulation.
- *Capnometry:* Measurement of end-tidal concentration of carbon dioxide, by exposing expired air to infrared light.
- *Cardiac index (CI):* Measurement of cardiac output in relation to body surface, with use of ultrasound.
- *Chest x-ray study:* Determination via radiology of the position of intravascular catheters and endotracheal or chest tubes.
- *Echocardiogram:* Assessment of intraventricular blood volume by observing two-dimensional color images of the beating heart produced by an ultrasonic probe placed in the esophagus.
- *Electrocardiogram (ECG):* Recording of electrical forces produced by the heart to evaluate changes in rhythm, rate, or conduction.
- *Near-infrared reflectance:* Determination of the amount of oxygen in hemoglobin being delivered to the brain, with use of a niroscope (near-infrared reflectance scope [NIRS]).
- *Pulse oximetry:* Determination of arterial hemoglobin oxygen saturation with measurement of the optical density of light passing through tissues.
- *Respiratory tidal volume (V_T):* With use of a respirometer, measurement of the volume of air moved with each respiration.
- *Stethoscopy:* Detection of cardiac rate and rhythm and pulmonary sounds, with auscultation.
- *Total blood volume (TBV):* Measurement of plasma and red blood cell volumes, with use of an electronic device.

Neural Functions

- *Electroencephalogram (EEG):* Recording of electrical activity in the brain.
- *Evoked potentials:* Recording of electrical responses from the cerebral cortex after stimulation of a peripheral sensory organ.

Other Functions

- *Temperature:* Measurement of core body temperature, with use of a thermometer probe.
- *Urinary output:* Measurement of urine to assess renal perfusion, with use of an indwelling catheter attached to a calibrated collection device.

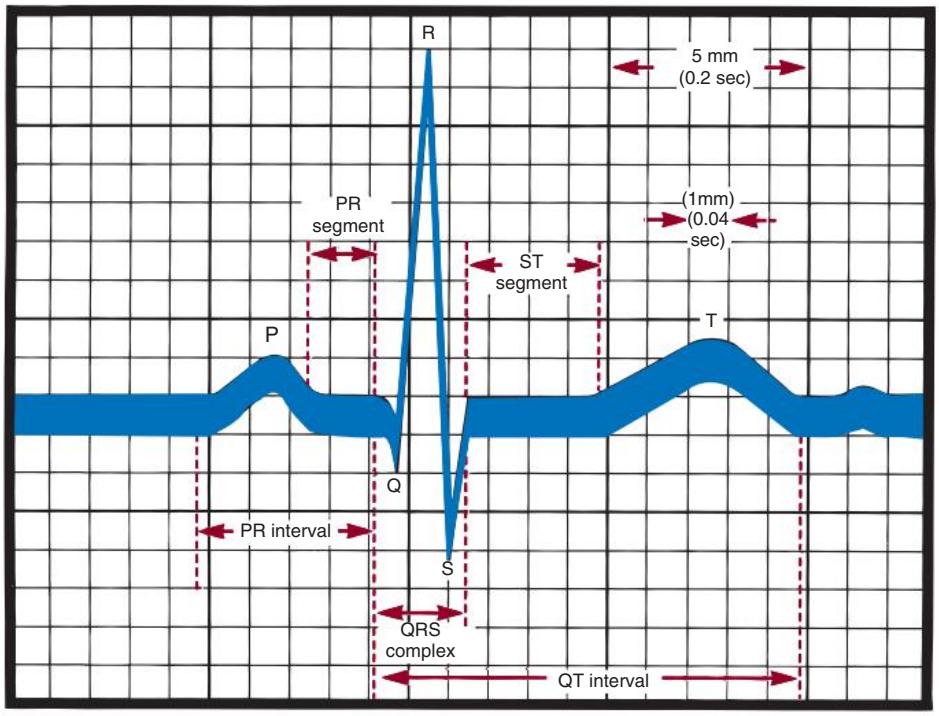
TABLE 27.1 Hemodynamic Monitoring Parameters

Parameter	Abbreviation	Normal Range for Adults
Arterial oxygen content	Ca_{O_2}	17-20 mL/dL blood
Blood pressure	BP	Systolic 90-130 mm Hg Diastolic 60-85 mm Hg
Cardiac index	CI	2.8-4.2 L/min/m^2
Cardiac output	CO	4-8 L/min
Central venous pressure	CVP	2-8 mm Hg, 3-10 cm H_2O
Cerebral perfusion pressure	CPP	80-100 mm Hg
Coronary perfusion pressure	CPP	60-80 mm Hg
Ejection fraction	EF	60%-70%
Glomerular filtration rate	GFR	80-120 mL/min
Heart rate	HR	60-100 beats/min
Intracranial pressure	ICP	0-15 mm Hg
Left ventricular end-diastolic pressure	LVEDP	8-12 mm Hg
Mean arterial pressure	MAP	70-105 mm Hg
Mean pulmonary artery pressure	MPAP	9-19 mm Hg
Oxygen saturation in arterial blood	Sa_{O_2}	95%-97.5%
Oxygen saturation in mixed venous blood	Sv_{O_2}	75%
Partial pressure of carbon dioxide in arterial blood	Pac_{O_2}	34-45 mm Hg (torr)
Partial pressure of oxygen in arterial blood	Pa_{O_2}	80-100 mm Hg (torr)
Partial pressure of oxygen in venous blood	Pv_{O_2}	40 mm Hg (torr)
Pulmonary artery pressure	PAP	Systolic: 15-25 mm Hg Diastolic: 8-15 mm Hg
Pulmonary capillary wedge pressure	PCWP	6-12 mm Hg
Right atrial pressure	RAP	3-6 mm Hg
Right ventricular pressure	RVP	Systolic: 15-25 mm Hg Diastolic: 0-5 mm Hg
Stroke volume	SV	60-130 mL/beat
Systemic vascular resistance	SVR	800-1600 dyne/sec/cm
Total blood volume	TBV	8.5%-9% of body weight in kg
Venous oxygen content	Cv_{O_2}	15 mL/dL blood

provide a permanent record. The printout may be controlled or automatic. A heart rate meter may be set to print out a rhythm strip and sound an alarm if the rate goes above or below a preset figure. Lights and beeps may provide appropriate visual and audible signals of the heart rate.

Monitor leads or electrodes are attached to the chest or extremities. These electrodes detect electrical impulses that the heart generates. Connecting lead wires and cables transmit them to the cardiac monitor. A complete cardiogram includes 12 different leads, but usually only two or three electrodes are used. Careful placement of leads is important to show waves and complexes on the ECG rhythm strip. Leads to the anterior, lateral, or inferior cardiac surfaces, where ischemia most often occurs, provide myocardial ischemia monitoring. Use of multiple leads allows better definition of dysrhythmia and ischemia—the main reason for cardiac monitoring in the OR.[5] The choice of leads is made by the anesthesia provider or by the surgeon in unattended local anesthesia.

When placing disc electrodes, the underlying skin must be clean and dry for adequate adherence. The sites are shaved, if necessary, because hair can interfere with adherence. The skin is abraded slightly with a gauze pad or rough material to facilitate conduction. The paper backing is peeled off the disc being careful to not touch the adhesive. The conductive gel within the gauze



• **Fig. 27.1** Electrocardiogram complex. P wave before each QRS complex represents atrial depolarization. PR interval of sinus rhythm occurs between each P wave and R wave. PR segment represents conduction of impulse through atrioventricular (AV) node, bundle of His, bundle branches, and Purkinje fibers. QRS complex after each P wave represents ventricular depolarization and occurs at regular intervals, but rate can vary. T wave represents ventricular repolarization.

pad at the center of the disc is checked. If it is not moist, another is used. The electrode is placed on the desired site, adhesive side down, and secured tightly by applying pressure. Begin at the center and move outward to avoid expressing gel from beneath the electrode. Placing gel over a bony area is avoided because bone interferes with conduction.

One ECG tracing is taken as a baseline before induction of anesthesia. An ECG is especially valuable during induction and intubation, when dysrhythmias are prone to occur. Early detection and rapid identification of abnormal rhythms and irregularities of the heart's actions permit treatment to be more specific.[5] Tracings may show changes related to the anesthetic itself or to oxygenation, coronary blood flow, hypercapnia (increased $Paco_2$), or alterations in electrolyte balance or body temperature.

The ECG tracing becomes a flat line when heart action ceases, but preceding tracings may define the type of cardiac arrest, which is of value in treatment. It is beyond the scope of this text to describe normal and abnormal cardiac rhythms interpreted by the ECG. However, perioperative nurses who monitor patients under local anesthesia should become familiar with them. Box 27.2 shows the characteristics of **sinus rhythm**, and Fig. 27.2 shows an example of sinus rhythm in each of 12 leads.

The ECG monitors should be insensitive to electrical interference. Occasionally, recordings may be affected by a high-frequency electrosurgical unit. If a tracing problem occurs, lead contacts, the integrity of the leads, and the choice of monitoring axis are checked.

The ECG monitor may be connected to a computer for analysis and storage of data. From the ECG readings, a device within the computer may be able to measure the amount of blood being pumped by the heart. This gives a continuous assessment of

• BOX 27.2 Characteristics of Sinus Rhythm

- P wave is present before each QRS complex.
- Equal space exists between P wave and R wave (PR interval) in each complex.
- QRS complex follows each P wave (ratio 1:1).
- P wave and QRS complex occur at regular intervals (rate can vary).

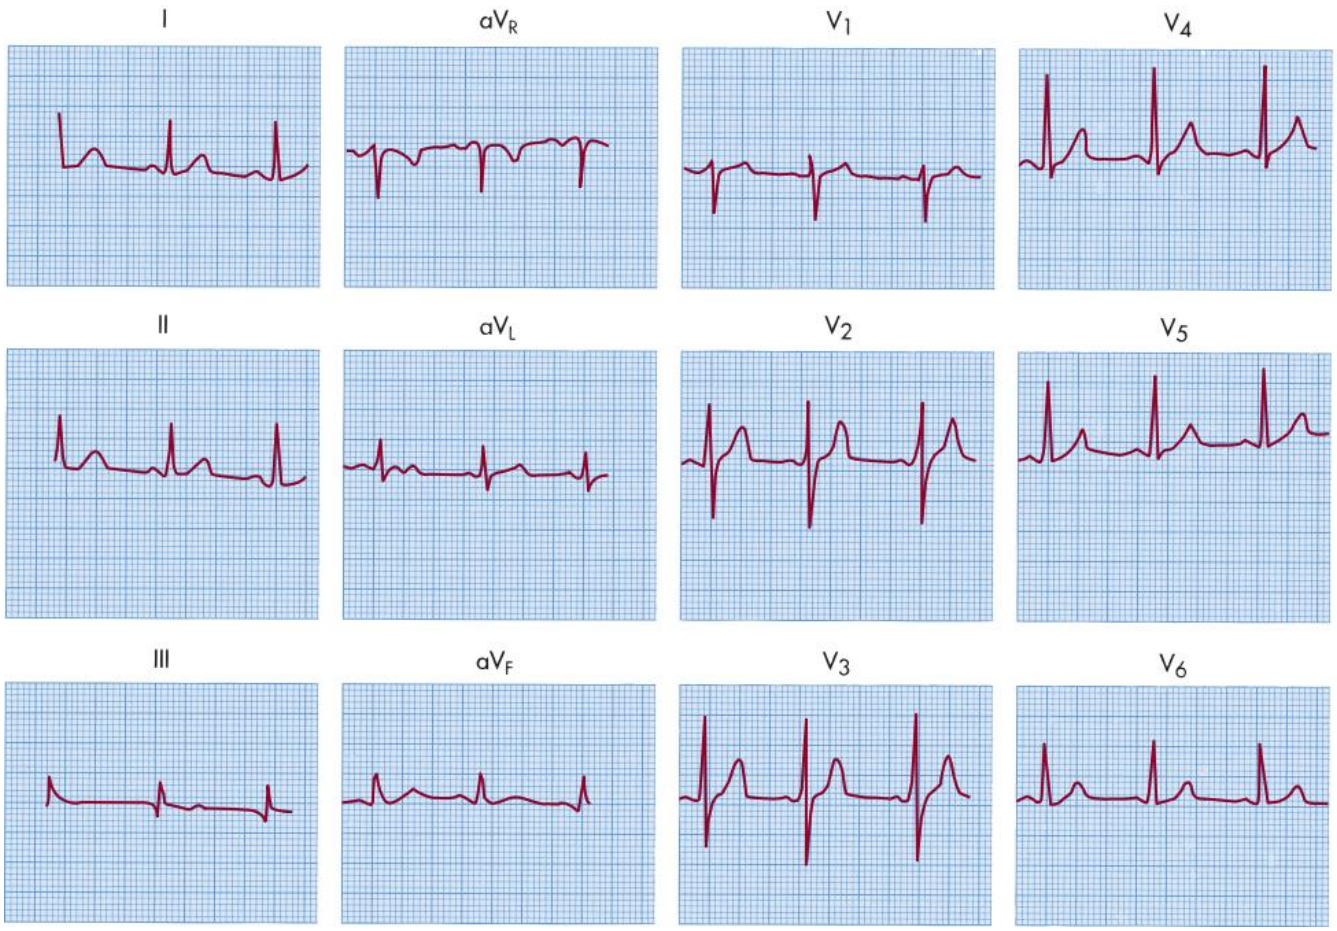
pumping capacity and CO. Impedance cardiography also provides data based on the mechanical activity of the heart. This is also a noninvasive computer-assisted measurement of CO, an alternative to the thermodilution technique.

Echocardiogram

Sound waves from a sonar-like device provide two-dimensional color images of the beating heart. An ultrasonic probe on the end of a small gastroscope is placed in the esophagus during the surgical procedure. Also referred to as transesophageal echocardiography, this form of echocardiogram can help the anesthesia provider immediately assess intraventricular blood volume, which can be useful information for the surgeon during cardiac surgery.

Stethoscopy

Auscultation of the chest (listening to the chest) is used to detect both cardiac rate and rhythm and pulmonary sounds. A stethoscope is taped over the precordium (the region over the heart and stomach at the level of the diaphragm), or a pressure-sensitive detector may be placed within the patient's esophagus. With the trachea protected by a cuffed endotracheal tube to prevent



• **Fig. 27.2** Example of normal sinus rhythms as they appear in each of 12 leads. (From Kinney MR, Packa D: *Andreoli's comprehensive cardiac care,* ed 8, St. Louis, 1996, Mosby.)

aspiration, the stethoscope is inserted into the esophagus to the level of the heart. Esophageal stethoscopy is especially valuable during thoracic and abdominal procedures, when auscultatory monitoring is ineffective because of tissue manipulation or movements of the members of the operating team.

Arterial Blood Pressure

BP signifies the pressure exerted against vessel walls to force blood through the circulation. Evaluation of BP during anesthesia requires consideration of blood volume, CO, and the state of the sympathetic tone of the vessels. Tissue perfusion is dependent on these factors. Arterial BP is used to assess hemodynamic and respiratory status during every surgical procedure, with very few exceptions.

The BP measures contraction of the heart (systolic pressure) and relaxation of the heart between contractions (diastolic pressure). Blood is forced through the arteries between contractions. Pressure is higher during systole and lower during diastole. Many factors can cause BP to vary. It is measured in millimeters of mercury (mm Hg). Normal range is 90 to 130 mm Hg systolic and 60 to 85 mm Hg diastolic.

The arm used for measurements should be opposite the one cannulated for IV fluid therapy or invasive monitoring and should be protected from contact with team members standing beside the OR bed. BP readings can be obtained using indirect or direct methods, either intermittently or continuously.

Sphygmomanometer

A pneumatic cuff is wrapped around the circumference of the upper arm. When the cuff is inflated, measurements are obtained on the sphygmomanometer as the cuff deflates. Through a stethoscope placed over the brachial artery distal to the cuff, the systolic pressure is heard when blood begins to flow through the artery. The diastolic pressure is noted by a change in sound. This is an indirect noninvasive method for intermittent monitoring of BP.

Doppler Ultrasound Flowmeter

With ultrasound, BP can be monitored automatically at preset intervals. The Doppler ultrasound flowmeter monitor automatically inflates the cuff, takes a reading, and deflates the cuff. It can be programmed to sound an alarm if systolic pressure reaches a preset high or low level. The readings are more accurate than with sphygmomanometer pressure cuff monitoring because the ultrasonic transducer amplifies blood flow sounds. Automated noninvasive BP monitors function well in a noisy environment. However, they do not provide continuous BP measurement or detect extremely low pressures. Frequent inflations of the cuff can bruise the skin, especially of geriatric patients.

Infrared Beams

Noninvasive infrared beams (Finapres technique) may be used to indirectly monitor BP. A small cuff fits on a finger. The beams

from the cuff shine through tissue. They continuously measure arterial pressure from one heartbeat to the next.

Direct Arterial Pressure

From an invasive modality, beat-to-beat direct pressures are obtained through an artery, usually the radial or femoral, via an indwelling catheter inserted percutaneously. A very slow drip of slightly heparinized sterile saline solution keeps the catheter open. The fluid-filled tubing from the catheter is connected to a mechanical electric transducer. The transducer is attached to an amplifier. A waveform of the amplified pulse, which represents force imposed on the transducer, is displayed. The monitor also converts waveforms into numeric measurements of systolic and diastolic rates. An alarm sounds if deviations are significant.

Arterial lines can be used to measure arterial pressure curves that in turn provide information about cardiac output. Studies are in process to determine if an arterial line provides the same information as pulmonary artery catheters.

Mean Arterial Pressure

Mean arterial pressure (MAP), calculated by most monitors and shown on digital display, portrays perfusion pressure of the body. This is significant in the evaluation of myocardial perfusion. Normal MAP is between 70 and 105 mm Hg. Direct intraarterial pressure monitoring is valuable in patients with major multiple trauma or burns, inaccessibility of an extremity, unstable vital signs, or inaudible BP. Other indications are complex extensive procedures, such as a cardiopulmonary bypass with an open chest; major vascular surgery with large potential fluid shifts or blood loss; total hip replacement; and major neurosurgery with the patient in the sitting position. Also included are patients in shock or with preexisting cardiac or pulmonary disease who must undergo major surgery.

Direct pressure monitoring is necessary in deliberate hypotensive anesthesia, and in treatment of hypotensive or hypertensive crisis with continuous infusion of vasopressor or hypertensive drugs.

Blood Gases, Oxygenation, and pH

Monitoring of tissue perfusion is indispensable in the evaluation of pulmonary gas exchange and acid-base balance. Measurements are considered in relation to other parameters, such as vital signs, venous pressure, and left atrial pressure. Oxygen (O_2) and carbon dioxide (CO_2) in blood exert their own partial pressures (P). Measurements are expressed in millimeters of mercury or torr. They may be differentiated as arterial (Pa) or venous (Pv). The gas being measured is identified. The partial pressure of oxygen is expressed as Po_2, or specifically in arterial blood as Pao_2 and in venous blood as Pvo_2. Oxygen saturation (So_2) in arterial blood (Sao_2) is expressed in percentages. The partial pressure of carbon dioxide is specified as $Paco_2$ or $Pvco_2$ (see Table 27.1 for normal ranges). Monitoring techniques can be either noninvasive or invasive.

Pulse Oximetry

A pulse oximeter measures arterial oxyhemoglobin saturation (Sao_2). It provides a reading within seconds by measuring the optical density of light passing through tissues. A sensor probe is clipped on each side of a pulsating vascular bed. Fingers, toes, earlobes, and the bridge of the nose are suitable sites. The patient's skin should be clean and dry. An area with fingernail polish should be avoided or the polish removed. Skin integrity under the sensor must be intact.

The sensor must be maintained flush with the skin surface and positioned so that the light source and photodetector are in direct alignment. The sensor is attached to an oximeter, which is plugged into a power source. Some power sources are battery powered. The oximeter may have an earphone adapter and an alarm system. The alarm is usually set for audible alert within 10 seconds if the oxygen saturation falls below the preset range.

Wavelengths of red (660 nm) and infrared (940 nm) light pass through tissues from the light source side of the probe. Light is picked up by a receptor in the sensor on the opposite side of the tissue. The oximeter continuously calculates the amount of oxygen present in the blood by processing the ratio of red to infrared light absorbed. The presence of oxygen in hemoglobin influences this absorption (oxyhemoglobin).

The oximeter reading should remain above 95%. A reading less than 90% probably signifies developing hypoxia. Some patients have significant respiratory disease and prolonged trends of low readings. Oximeters give no information about the retention of carbon dioxide and are not indicators of respiratory failure caused by carbon dioxide retention. In some circumstances, the readings that indicate gas exchange can be altered with the administration of supplemental oxygen.

Falsely high readings may occur in cigarette smokers because carbon monoxide (CO) (carboxyhemoglobin) can prevent red blood cells from picking up oxygen. Carboxyhemoglobin closely resembles oxyhemoglobin and is perceived by the sensor to be oxygenated. These cells may absorb light from the oximeter, however, so the reading may be higher than the actual Sao_2. Other factors may influence reliability, such as shielding of the sensor, excessive ambient light, patient movement, and intravascular dyes (methylene blue). Patients undergoing a surgical procedure with local anesthesia may exhibit an average consistent with 2% of baseline oxygenation.

Oximeter readings always should be compared with patient assessment. (Information about competency testing for the use of pulse oximetry can be found at the National Institutes of Health [NIH] website: www.nih.gov.)

Niroscope

Oxygen reserves in the brain can be assessed with a near-infrared reflectance scope (NIRS), which is a noninvasive technique. A specific form of infrared light passes through the skull. The portion of light reflected back to sensors outside the skull is measured to determine the amount of oxygen in the hemoglobin being delivered to the brain. The niroscope provides a continuous reading of the brain's oxygen reserves.

Capnometry

Changes in exhaled carbon dioxide reflect changes in **internal respiration**, circulation, and metabolism. Capnometry measures end-tidal concentration of carbon dioxide. Normal concentration is 38 torr (5%). Carbon dioxide production is in direct relationship to cellular metabolism. Monitoring **external respiration** of carbon dioxide can detect the onset of inadvertent hypothermia or malignant hyperthermia. Capnometry, a noninvasive technique, also can be used to detect anesthesia equipment problems, inadvertent esophageal intubation, inadequate neuromuscular blockage, air embolus, and a ventilation-perfusion problem.

A mainstream or sidestream adapter is placed in the breathing circuit as close to the facemask as possible so that expired carbon dioxide approximates alveolar concentration. The analyzer, attached to the adapter, exposes expired air to infrared light.

The amount of light absorbed by carbon dioxide determines the end-tidal concentration. A sidestream analyzer can be used to monitor patients receiving local or regional anesthesia by placing the sampling end of the tubing in the patient's nostril or mouth.

A capnographic waveform printout provides data to evaluate respiratory rate and rhythm. Some gas monitors continuously measure carbon dioxide, oxygen, and nitrous oxide parameters of the patient's airway. Digital values are displayed on the monitor.

Optode

An optode is an optical fiber inserted through an 18 or 20-gauge radial artery cannula. The tip contains chemicals that react to oxygen, carbon dioxide, and acidity of the blood. The optode is connected to a monitor that generates light through the fiber. The chemicals produce luminosities that vary in intensity for oxygen and carbon dioxide. These are measured. Readings are instantaneously and continuously shown on a digital display. Precautions must be taken to maintain sterile technique with this equipment as with other methods of percutaneous radial artery cannulation.

Direct Arterial Blood Gas Analysis

Blood samples may be drawn intermittently from arterial or venous indwelling catheters. ABG determinations of Pa_{O_2}, Pc_{O_2}, and S_{O_2} are used to monitor adequacy of oxygenation and carbon dioxide elimination. This is especially important in patients who need mechanical **ventilation**. The tidal volume, respiratory rate, and concentration of oxygen can be appropriately adjusted. ABG monitoring also permits laboratory analyses of pH, base excess, bicarbonate, and electrolytes to evaluate metabolic processes and acid-base status. Differentiation of respiratory or metabolic acidosis or alkalosis is a guide to appropriate treatment. Samples may be taken for other analyses (e.g., glucose or coagulation factors).

Hypoventilation, uneven ventilation in relation to blood flow, impairment of diffusion, and venous-to-arterial shunting lead to anoxemia unless oxygen in inspired air is increased. Hypoventilation of the whole lung or a major portion leads to retention of carbon dioxide and predisposes the patient to cardiac dysrhythmias. Disturbances of acid-base balance have many serious consequences in many organs. They must be corrected to achieve normal physiologic functioning.

Central Venous Pressure

Because it accurately measures right atrial BP, which in turn images right ventricular BP, central venous pressure (CVP) monitoring assesses function of the heart's right side. It measures the pressure under which blood returns to the right atrium and reflects pressure in the venous system as blood returns to the heart. In other words, CVP represents the amount of venous return and filling pressure of the right ventricle. This information helps determine the patient's circulatory status.

CVP monitoring also aids in the evaluation of blood volume and the relationship between circulating blood volume and the pumping action of the heart (i.e., adequacy of volume presented to the heart for pumping). Therefore CVP monitoring is a useful guide in blood or fluid administration to avoid circulatory overload in patients with limited cardiopulmonary reserve. Too great or too rapid replacement can cause pulmonary edema. Generally, a low CVP indicates that additional fluid can be given safely. CVP monitoring may be used during shock or hypotension to judge the adequacy of blood replacement. However, CVP is not a measure of blood volume per se or of CO.

Indications for CVP monitoring include major surgical procedures in patients with preexisting cardiovascular disease, in surgical procedures in which large-volume shifts are anticipated (e.g., open heart surgery), in critically ill patients (e.g., massive trauma, malignant hyperthermia), in surgical procedures in which venous air emboli are a risk (e.g., craniotomy in a sitting position), and in rapid administration of blood or fluid.

Although CVP monitoring provides valuable data for assessment of the adequacy of vascular volume, it only indirectly reflects the function of the left side of the heart. There is no direct relationship between right and left ventricular filling pressures. Because of the distensibility (compliancy) of the pulmonary blood vessels, the lungs can accept a marked increase in blood flow before significant congestion appears. Backup of blood caused by impaired function of the left ventricle and a subsequent increase in pulmonary vascular resistance (PVR) may occur before this increased pressure affects the right side of the heart, as exhibited by CVP values. CVP does not correlate with left-sided heart performance in patients with left ventricular dysfunction or pulmonary congestion.

Central Venous Cannulation

CVP may be monitored with a single-lumen or multilumen radiopaque catheter. A double-lumen or triple-lumen Hickman or Broviac catheter is used most commonly. The right atrial lumen of a Swan-Ganz pulmonary artery catheter also can be used to obtain CVP readings. The lumens are labeled and color-coded on multilumen catheters.

The catheter is inserted, preferably percutaneously through a subclavian vein. A brachial, external or internal jugular, or femoral vein may be used or, via cutdown, the antecubital vein. If patients are awake, they are asked to bear down (Valsalva's maneuver) as the vein is punctured. This increases intrathoracic pressure and counteracts negative pressure from the vein, thus reducing the possibility of air embolism.

The catheter is threaded through the vein and advanced into the superior vena cava or right atrium. This may be done by fluoroscopy, or a chest x-ray may be taken to verify accurate placement of the catheter tip.

The catheter may be attached to a transducer and monitor. Pressure readings are expressed in millimeters of mercury. The catheter can be attached to a fluid-filled manometer that measures pressure in centimeters of water (cm H_2O).

To set up this line, the IV solution bag is connected to the tubing, the manometer is inserted into the line by attaching it to the stopcock between the IV tubing and the extension tubing, air is expelled from the line, the line is clamped, and the manometer is secured upright to an IV pole. The hub of the catheter lumen is connected to the stopcock. Connections to the three-way stopcock should be taped to prevent inadvertent disconnection and air leaks. Cyclic variations in intracaval venous pressure occur; pressure becomes negative during atrial filling and respiratory **inspiration**. Sucking of air into the system during negative venous pressure can result in an air embolus.

Baseline measurement is taken as soon as the catheter is in place and attached to the monitor. This is also a presumptive check for proper placement of the cannula tip. Because expansion of the lungs increases intrathoracic pressure and deflation decreases it, fluid in the manometer should fluctuate with each breath.

To obtain a CVP reading on the manometer, adjust the scale to zero level with the patient's right atrium. The lumen of the

stopcock to the catheter is shut off, which allows the IV fluid to run into the manometer to the desired level. The infusion is shut off, and the catheter is opened. After the reading is obtained, the infusion lumen to the catheter is opened to keep the line open.

Electronic transducer systems provide continuous monitoring of venous pressure. Continuous monitoring supplies good measurement of the right side of the heart and portrays the trend of heart function that is more valuable than are isolated readings obtained with a manometer. CVP values may vary somewhat, but normal readings range from 2 to 8 mm Hg, or 3 to 10 cm H_2O.[4]

Multilumen central venous catheters provide access for administration of drugs, blood, fluids, and hyperalimentation. Blood can be removed for blood gas analyses or autotransfusion. These catheters also provide access for removal of air emboli.

Pulmonary Artery Pressure Monitoring

Because a pulmonary artery catheter measures function of both the right and the left sides of the heart, it provides faster, more accurate indication of impending left ventricular failure than does CVP alone.[6] Pressures of the left side of the heart are reflected in pulmonary artery and pulmonary capillary wedge pressures, measured with the pulmonary artery catheter. This is more sensitive to rapid changes in the cardiovascular system than is CVP and is more sensitive to the ability of the heart to accommodate fluid loads.

Measurement of pulmonary pressures enables precise rapid assessment of the left ventricle's ability to eject adequate CO. Continuous evaluation of left ventricular function is extremely important in patients whose left-sided heart dysfunction has a greater direct effect on CO, circulating volume, and respiratory function than does impaired right-sided heart function. Data procured include pulmonary artery pressure (PAP), pulmonary capillary wedge pressure (PCWP), right atrial pressure (RAP), and CO computation. These pressures reveal the hemodynamic status of cardiovascular and pulmonary functions. They also serve as guidelines for administration of fluids, diuretics, and cardiotonic drugs to obtain optimal CO.[6]

Indications for pulmonary artery monitoring include preexisting cardiac or pulmonary disease in a patient undergoing a major vascular, intraabdominal, or neurosurgical procedure and a potential risk for development of cardiopulmonary instability from the stress of the surgical procedure. Other conditions may include shock, burns with large fluid shifts, renal failure with low CO, and pulmonary emboli. Pulmonary artery catheters may be used in patients who need long-term monitoring.

Some multipurpose catheters may be used with ventricular and atrial pacing wires in patients with heart block or severe bradycardia. These catheters may be used to measure CO in patients with intracardiac shunts or during titrated drug administration.

Contraindications to invasive pulmonary catheter monitoring are abnormal cardiac anatomy in the patient, inadequate monitors, and lack of personnel trained in the use of the monitors.

Pulmonary Artery Cannulation

Various pulmonary artery catheters are available. The number of lumens varies from two to five, depending on the range of functions desired. These catheters are used with transducers for monitoring. The type of transducer varies according to the balloon flotation device in the catheter.

In setting up the monitoring system, manufacturer instructions must be followed explicitly. All equipment, including the oscilloscope, should be checked. The stopcocks and flush devices in the lines to the transducer heads need to be attached. Preassembled tubing systems and disposable transducer domes are commercially available. If the patient also will have a peripheral arterial line, two transducers and a triple stopcock manifold are needed. Simultaneous monitoring of PAP and RAP is thus possible. The transducer dome is back-flushed. The monitor should be balanced and calibrated according to manufacturer directions. There must be no air bubbles remaining in the lines or system.

Before the catheter is inserted, the physician inspects it for defects and tests the balloon for leakage by inflating it, submerging it in sterile saline solution, and watching for air bubbles. The balloon must then be deflated. Moistening the catheter tip with saline solution or lidocaine reduces the possibility of venospasm at insertion.

Vital signs are taken before insertion of the catheter. ECG readings should be monitored for dysrhythmias during insertion. With the introducer set, the catheter is inserted and advanced rapidly to prevent kinking or knotting. It is advanced through the vein into the inferior or superior vena cava and on into the right atrium.

Continued manipulation irritates or damages vessel walls. Watching the increment markings on the side helps determine how far the catheter has advanced. It is possible to keep pushing the catheter while it is not going into the right place. It can coil up and knot in the ventricle.

When the catheter tip reaches the right atrium and a right atrial waveform appears on the oscilloscope screen or readout strip, the balloon is inflated slowly with air with a tuberculin syringe to enable it to float with the flow of blood. The balloon is never inflated without a visible oscilloscope trace. If the patient is awake, a voluntary cough confirms the position of the catheter in the thoracic cavity if the right atrial wave fluctuates. The amount of air is specified by the manufacturer (usually about 1.3 to 1.5 mL). Overinflation could rupture the balloon.

Carbon dioxide (CO_2) is used for balloon inflation in patients with intracardiac shunts. If the balloon ruptures in arterial circulation, carbon dioxide is more soluble than ambient (room) air in blood. A feeling of resistance should accompany inflation. Absence of resistance is a sign of a ruptured balloon; inflation should be stopped immediately. Fluid is never used for inflation because it prevents proper catheter flotation and complete deflation.

Passing through the tricuspid valve, the catheter enters the right ventricle. A typical right ventricular waveform should appear. If dysrhythmia develops or is persistent, a bolus of lidocaine may be injected. Then, after the catheter floats through the pulmonary semilunar valve into the pulmonary artery, a pulmonary artery tracing should appear on the monitor. This waveform has a steep upstroke at the beginning from right ventricular ejection and opening of the pulmonic valve, followed by a dicrotic notch on the downstroke at the closing of the pulmonic valve.

Pulmonary artery blood flow carries the balloon into one of the artery's smaller branches. When the vessel diameter becomes too narrow for it to pass, the balloon wedges in the vessel and occludes it. A PCWP waveform should appear. After recording of this wedge pressure, the physician permits the balloon to deflate passively; air is not aspirated with the syringe.

The catheter then slips back into the main branch of the pulmonary artery. A PAP waveform should reappear on the monitor. The physician depends on these sequential characteristic pressure waveforms to reveal the catheter tip's location at all times. The circulating nurse records pressure at each location. The catheter remains in the pulmonary artery with the balloon deflated,

continuously recording the PAP, except when a PCWP reading is desired. The balloon may be ruptured if a PAP waveform persists and a PCWP reading is unobtainable or if resistance is not felt with an attempt to inflate the balloon.

An x-ray is taken to confirm the catheter position. In the case of rupture, the catheter may be left in place to record the PAP, provided it has not slipped back to the right ventricle. The physician may also elect to remove it. The balloon is always inflated during catheter advancement and deflated during catheter withdrawal.

For prevention of an air embolus after catheter insertion, the catheter must not be attached to the monitoring system until all air has been expelled. All lines and transducers should be checked for secure connections and patency. Each transducer's balancing port must be leveled with the patient's right atrium. RAP, PAP, and PCWP waveforms and the patient's response to the procedure must be documented.

Swan-Ganz Thermodilution Catheter

The no. 7 Swan-Ganz thermodilution catheter has four separate lumens or passages within its outside wall. It is versatile and widely used to measure right-sided heart pressure and CO. Critical conditions such as heart failure, cardiac tamponade, pulmonary hypertension, and other causes of shock can be diagnosed and monitored with a Swan-Ganz catheter.

The catheter is 43¼ inches (110 cm) long, with 10-cm increments marked on the side to permit observation of how far the catheter has advanced during insertion. Like all pulmonary artery catheters, it is a balloon-tipped flotation catheter that is inserted into a major vein and advanced to the inferior or superior vena cava.

When inflated, the thin latex balloon at the tip permits the catheter to float with the flow of blood through the right atrium, tricuspid valve, right ventricle, pulmonary semilunar valve, and pulmonary artery and to wedge in a small pulmonary artery branch (arteriole) for recording of the PCWP during occlusion of the vessel. When the balloon is not inflated, the catheter lies in the pulmonary artery to record the PAP. Proper catheter placement is essential to minimize the risk for vessel damage and complications and to validate pressure readings.

The end of the catheter inserted in the patient is referred to as the distal end; the opposite one is the proximal end. The proximal end has several external ports that provide access to the lumens used in patient monitoring. The pulmonary artery port is used for monitoring PAP and PCWP. A syringe is connected to the balloon port for the desired balloon inflation. The thermistor port is used for CO calculation. The right atrial port is used for measurement of RAP. This port also can be used to administer fluids or can be connected to a flush system for maintenance of catheter patency. For CO measurement, normal saline or dextrose solution is injected into the cardiovascular system via the proximal lumen. The pulmonary artery and right atrial ports should be labeled.

The catheter has four separate lumens or passages. The pulmonary artery lumen, the largest and most distal, terminates in the opening at the catheter's tip. With proper catheter positioning, this opening lies in the pulmonary artery. In this position, with the balloon deflated, pulmonary artery systolic, diastolic, and mean pressures are recorded on the monitor. These are indicative of pulmonary function. When the balloon is inflated and the catheter migrates to a pulmonary artery branch to wedge, the PCWP is recorded. PCWP is sometimes referred to as pulmonary artery wedge pressure (PAWP) or pulmonary artery occlusion pressure (PAOP).

Occlusion of a pulmonary artery branch creates a no-flow system, thereby blocking blood flow from the right side of the heart to the lungs and permitting pressure equilibration in the pulmonary vascular bed distal to the catheter. Occlusion of an arteriole and low resistance of the pulmonary systems give a pressure measurement equal to the left atrial pressure (LAP), which in turn is equal to the left ventricular end-diastolic pressure (LVEDP).

To prevent pulmonary infarction, ischemia, and hemorrhage from prolonged wedging, the balloon is always deflated immediately after a reading is taken. The catheter floats back into the main pulmonary artery. The pulmonary artery lumen can provide blood samples for blood gas measurements and mixed venous blood, which is also of value in evaluating cardiac function.

The balloon lumen opening, which permits inflation and deflation, is about 1 cm from the catheter tip. When inflated, the balloon surrounds, but does not cover, the opening in this tip.

The thermistor lumen opening is about 4 cm from the catheter tip. This lumen contains temperature-sensitive wires that run its length and transmit the temperature of blood flowing over them from the thermistor to the computer for determination of CO using the thermodilution technique.

The proximal right atrial lumen opening is about 30 cm from the catheter's tip. This opening lies in the right atrium to monitor RAP when the catheter is in place.

Interpretation of Pressures

The range of normal pressure values may vary slightly from one authority to another. Characteristic waveforms appear on the oscilloscope or screen, depending on the location of the catheter tip during insertion and continuous monitoring. These waveforms must be watched carefully to ascertain that the catheter is in the desired position. The catheter enters the right atrium via the vena cava.

Right Atrial Pressure. Normal RAP is 3 to 6 mm Hg. RAP reflects right atrial filling diastolic pressure, equivalent to CVP, and right ventricular end-diastolic pressure (RVEDP), pressure at the end of filling just before contraction. A rise in RAP may indicate right or left ventricular failure, volume overload (hypovolemia), or air embolism. A fall in RAP may indicate vasodilation, hypovolemia, or peripheral blood pooling.

Right Ventricular Pressure. Normal right ventricular pressure (RVP) is 15 to 25 mm Hg systolic and 0 to 5 mm Hg diastolic. A rise in RVP may indicate mitral insufficiency, congestive heart failure, hypoxemia, or left ventricular failure.

Pulmonary Artery Pressure. Normal PAP is 15 to 25 mm Hg systolic and 8 to 15 mm Hg diastolic; the mean is 9 to 19 mm Hg. These pressures estimate venous pressure in the lungs, and mean filling pressure of the left atrium and left ventricle. They reflect right ventricular function, unless the patient has pulmonary stenosis, because the pulmonary artery systolic pressure commonly approximates the right ventricular systolic pressure. Changes in pulmonary artery systolic and mean pressures indicate changes in PVR.

Alterations in PVR occur in hypoxemia, respiratory insufficiency, pulmonary edema, pulmonary emboli, shock, and sepsis. Thus these pressures are indices of pulmonary function. A rise in PAP may indicate left ventricular failure; increased pulmonary arteriolar resistance, as in pulmonary hypertension and hypoxia; or fluid overload.

Pulmonary Capillary Wedge Pressure. Normal pressure is 6 to 12 mm Hg. Pulmonary artery diastolic pressure and PCWP are

prime determinants of function of the left side of the heart because they reflect LVEDP just before the left ventricle contracts, except in patients with mitral valve impairment.

Normally, when the mitral valve between the right atrium and right ventricle is open (ventricular diastole), flow of blood from the pulmonary artery to the pulmonary veins and left side of the heart is unimpeded. Then, pressures throughout the pulmonary circulation and left side of the heart are comparable. Because PCWP usually approximates LAP, an indicator of left heart function, it is an important determinant of left ventricular preload.

Intraoperative monitoring of PCWP usually can give early disclosure of left ventricular dysfunction. A rise in PCWP may indicate left ventricular failure, mitral insufficiency, pulmonary hypertension, fluid overload, or pulmonary congestion. A rise also may occur during anesthesia induction. A fall in PCWP may indicate a reduction in LVEDP and CO, or hypovolemia.

Complications of Pulmonary Artery Catheter Monitoring

Invasion of the great vessels and heart carries many inherent perils. Probably the most common during insertion is cardiac dysrhythmia, especially premature contractions. Other problems include local or systemic infection (septicemia, endocarditis), thrombus formation, pulmonary emboli, pulmonary infarction, pneumothorax, hemothorax, major vessel or heart chamber perforation, kinking or knotting of the catheter, balloon rupture, postoperative bleeding, and erroneous diagnosis from misinterpretation of data.

Although rare, pulmonary artery perforation is very serious. Predisposing factors are pulmonary hypertension, anticoagulation therapy, hyperthermia, or an overinflated balloon or catheter. Hemoptysis and sudden hypotension are signs and symptoms of pulmonary artery rupture. Equipment for endobronchial intubation, chest tube insertion, and surgical intervention must be available.

Complications that are potentially life threatening increase markedly after 48 to 72 hours of indwelling catheterization. The physician must be notified of any change in patient status. Catheter withdrawal is performed by and at the discretion of a physician. For prevention of injury to the heart valves, the balloon is slightly inflated until the catheter is withdrawn to the right atrium. Then the balloon is completely deflated for withdrawal. Dysrhythmias may occur.

Pressure is applied to the percutaneous insertion site to prevent bleeding. The pulse and BP are checked before and after withdrawal. A post-withdrawal dressing is applied. The patient is monitored for at least 24 hours.

In addition to patient problems, monitoring problems may arise. Each requires a specific intervention. A major problem is a damped pressure or PAP waveform, which means decreased amplitude in pressure tracings or loss of sharpness in the image that suggests a defect in the circuit.

Common causes are air in the system or blood in the transducer; loose connections; a kinked, overwedged, or malpositioned catheter; falling systolic pressure in the patient; or a clot in the monitor system. If the last-mentioned cause is suspected, gently try to aspirate blood. If no blood can be aspirated, the catheter should not be flushed. Flushing could dislodge a clot. The physician should be notified and may withdraw the catheter.

Another problem involves a sudden change in configuration of a pressure tracing. Potential causes include the following:

- The transducer is not at the right atrial level.
- The transducer is in need of calibration.
- The transducer connection to the catheter is not secure.
- The catheter is no longer in the proper position.
- A loss of pressure in the pressure bag has occurred.

If a PCWP waveform persists after a reading, the balloon may not be completely deflated or the distal catheter tip may be caught in the wedge position, which requires immediate attention. Circulating nurses should be familiar with the appropriate interventions in both patient problems and monitoring problems, in addition to being knowledgeable about the causes and preventive measures. Only in this way can patient safety be maximized in invasive monitoring.

Cardiac Output

Cardiac output (CO) is measured using the thermodilution technique to determine liters of blood pumped per minute by the left ventricle into the aorta. Normal resting value is 4 to 8 L/min. A known amount of fluid at a known temperature is injected into a lumen of an arterial catheter, and a temperature gradient at a point downstream is measured via a second lumen. Iced-cold or room-temperature physiologic saline solution or 5% dextrose in water (10 mL) generally is used.

Blood flow supplies the thermal dilution; for example, saline solution mixes with blood in the superior vena cava or right atrium, depending on the catheter location, which reduces the temperature of blood in the heart. The cooled blood flows past a transistorized intravascular thermistor in the thermodilution catheter that detects changes in blood temperatures that are then used to compute CO. When the solution is injected via the proximal right atrial lumen of a pulmonary artery Swan-Ganz catheter, a digital display of CO is seen within 4 to 5 seconds.

CO reflects the mechanical activity of the heart and represents total blood flow to all tissues and vascular shunts. It depends on the heart rate, the contractile strength of the heart muscle (myocardial contractility), the peripheral resistance of vessels, and venous return. Inotropic agents such as digitalis or epinephrine increase contractility and CO, except in patients with loss of functioning ventricular muscle (e.g., after myocardial infarction or an aneurysm of the left ventricle). Agents such as beta-blockers decrease the work of the heart by reducing contractility and CO. Calculation of the left ventricular stroke work index reflects pumping ability.

During systole, the ventricle does not totally eject the blood received during diastole. The amount of blood ejected with each contraction is referred to as the stroke volume (SV). Normal resting SV is 60 to 130 mL per beat. Determinants of the SV are the LAP, afterload, contractile state of the myocardium, and LVEDP. The ejection fraction (EF), a commonly used indicator of ventricular function, is the percentage value of the SV. Normal EF is 60% to 70%. Major SV determinants of CO are preload, contractility, and afterload. Only in limited circumstances does adjustment of the heart rate therapeutically enhance CO.

Preload, the amount of blood in the ventricle at the end of diastole, may be referred to as left ventricular end-diastolic volume (LVEDV) or filling pressure (LVEDP). Assessment of changes in volume and measurement of changes in filling pressure help describe cardiac function. The Starling principle concerns the relationship between volume, stretch, and contractility. It relates myocardial fiber length to the force of the contraction. The greater the preload and stretch of myocardial fibers, the greater the subsequent contraction, which thereby increases the SV until at some point ventricular failure commences. Fiber overstretch weakens contractions.

As the pumping ability decreases, the left ventricle is unable to empty completely. Residual blood, combined during diastole with

incoming oxygenated blood from the pulmonary veins and left atrium, increases workload and elevates the left ventricular volume and pressure. As ventricular efficiency declines, CO falls. Retained blood in the left ventricle backs up into the left atrium and pulmonary circulation, increasing these pressures. Pulmonary edema and respiratory insufficiency result as fluid is impelled into the alveoli. The CVP catheter measures the right-sided heart preload; the pulmonary artery catheter measures left atrial and left ventricular end-diastolic pressures.

Cardiac function may be classified as normal, compromised, or failing. In healthy hearts, maximum ventricular performance seems to be achieved at filling pressure of 8 to 12 mm Hg. In compromised hearts, this pressure is higher.

A reduced CO results in decreased perfusion of the capillary circulation. During hemorrhage, when circulating blood volume is reduced, the resulting diminished venous return and preload lead to a lowered CO. Atrial fibrillation also can modify the filling of the ventricles. Venous dilation contributes to pooling of blood, with subsequent decreased venous return to the heart. Low CO states result from reduced preload, as in hypovolemia, venous dilation, or cardiac tamponade; reduced contractility, as from anesthetic drugs, ischemia, infarction, or cardiac decompensation; dysrhythmias; or increased afterload, as in hypertension, pulmonary emboli, or an elevated or diminished heart rate.

Body position can influence circulation, as can age, body surface area, oxygen consumption, body temperature, basal metabolic rate, and activity. Thus many factors can affect CO.

Afterload indicates the resistance the heart must overcome to eject blood into the systemic circulation. This impedance to flow is called systemic vascular resistance (SVR). Left ventricular pressure must exceed pressure in the aorta to open the aortic valve and force blood from the heart into the circulation. Afterload, not a direct measure, is deduced by calculating the SVR. An elevated afterload can produce increased left ventricular wall tension in an attempt to generate adequate intracavitary ventricular pressure to overcome resistance and permit systolic ejection. The subsequent increase in myocardial oxygen demand must be met, or ventricular function deteriorates.

Diminution of afterload reduces wall tension, thereby improving ventricular contraction. Improving cardiac function involves cost in myocardial oxygen consumption. Augmenting CO by increasing the heart rate and contractility increases myocardial oxygen consumption. Improving CO by augmenting preload or by reducing afterload results in relatively little oxygen cost to the myocardium.

A comprehensive view of cardiac function can be obtained with measurements of filling pressure, CO, and calculation of peripheral resistance. Repeated measurements offer evaluation of treatment.

Cardiac Index

The cardiac index (CI) is used to assess the heart's ability to meet the body's need for oxygen and other nutrients. With noninvasive ultrasound, the CI measures CO in relation to body surface. A CI less than 2 L of blood per minute per square meter of body surface identifies high risk for untoward cardiovascular events during or after anesthesia. The BP may drop; irregular heartbeats may develop. If these adverse events are anticipated, they can be prevented or treated.

Total Blood Volume

Blood volume is useful in determining the total amount of blood replacement necessary. An accurate method of total blood volume (TBV) measurement involves measuring plasma and red blood cell volumes separately and then adding the results together. For measurement of red blood cell volume, cells are tagged with detectable, nontoxic, radioactive chromium, subsequently injected IV, and counted after an appropriate mixing time. Or radioactive iodinated human serum albumin, in standard-dose packages, can be injected, mixed, and counted. Counting may be done rapidly using an electronic device. This technique may be used in place of estimation of blood loss.

Respiratory Tidal Volume

The respiratory tidal volume (V_T), the volume of air moved with each respiration and **expiration**, may be measured with a respirometer placed on the expiratory limb of the anesthesia machine or mechanical ventilator. Alarms may be incorporated to signal disconnection, failure to cycle, and excessive pressure.

Body Temperature

The body continuously produces heat through metabolic activities and loses heat through convection, evaporation, conduction, and radiation. The production of heat causes increased oxygen consumption by the body's cells. When the rate of heat production is equal to the rate of loss, a heat balance of constant core body temperature is maintained. **Core temperature** is that of the interior of the body as opposed to the body surface temperature. Normal core temperature ranges from 98° F to 100° F (36.8° C to 37.7° C).

Under anesthesia, the average adult loses 0.9° F to 2.7° F (0.5° C to 1.5° C) of body temperature; the greatest loss occurs during the first hour, through convection from exposure to the environment, through evaporation via respiration, through conduction from contact with cool surfaces, and through radiation from tissues. Intraoperative hypothermia, or core temperature less than 96° F (36° C), is a common complication of surgery under general anesthesia, especially in pediatric and geriatric patients.

Some anesthetic agents inhibit heat production: halogenated agents cause vasodilation that contributes to surface cooling, and muscle relaxants prevent shivering, which is a thermoregulatory protective reflex.

Other factors can change core temperature. Hyperthermia (retention of heat) may be caused by premedication, drapes, a closed anesthesia breathing circuit, hypermetabolic crisis, or fever from sepsis. Physical reactions are not seen in the anesthetized patient; therefore the body temperature should be continuously monitored for metabolic changes.

Electronic thermometers with digital readouts measure body and surface temperatures with thermistor or thermocouple probes. A core temperature probe can be inserted into a body orifice (i.e., nasopharynx, esophagus, bladder, rectum). An esophageal probe measures body temperature at the level of the right side of the heart and is responsive to changes in body heat. A rectal probe responds slowly to changes in body temperature and can be inaccurate because of the presence of stool. These probes are available in various sizes and have flexible tips; some are disposable. The sensor of a bladder probe is in the tip of a sterile Foley catheter. A Foley temperature probe can be misread if the bladder is irrigated during the surgical procedure.

A sterile catheter probe may also be inserted into the pulmonary artery. A probe can be placed on the tympanic membrane via the external auditory canal of the ear to measure temperature closest to the hypothalamus, which is the thermoregulatory center in the brain.

Skin surface probes have either small tips or discs that are attached to the skin, often on an extremity, with an adhesive-backed foam pad. Cutaneous liquid crystal thermography, with

temperature-sensitive chemicals laminated within an adhesive plastic strip, may be used for surface monitoring. The strip is usually applied to the forehead; its chemicals visibly change color with a temperature variation. Proximity to major arteries, insulation from the external environment, and the location of an inflammatory process and the surgical site are considerations in the choice of the temperature monitoring site.

Urinary Output

Urinary output can be measured with an indwelling Foley catheter attached to a calibrated collection bag. The sterile disposable collection system must be below the level of the bladder to prevent distention and allow flow without reflux. Output is valuable in assessing effective blood volume and fluid administration, except when a diuretic is given. Volume, electrolytes, osmolarity, and pH are important.

Any change in urine color can signal a change in the patient's condition. Brown urine can mean the presence of hemoglobin or myoglobin caused by rhabdomyolysis in a hypermetabolic crisis, such as malignant hyperthermia. Frank blood or clots may indicate an injury to the kidney, ureter, or bladder from iatrogenic cause or other trauma. IV dye, such as methylene blue, turns the urine green as it perfuses through the renal system. The blue dye is sometimes used during a surgical procedure to demonstrate renal function, but it can be used for chromopertubation of the fallopian tubes and be resorbed into the systemic circulation. Pulse oximeter readings can be altered by the dye.

A reduction in urinary volume may indicate reduced renal perfusion. Oliguria can result from stress of the surgical procedure, antidiuresis from the anesthetic agent, impending renal failure, or reduced volume of circulating blood. Urinary output greater than 30 to 60 mL/hr usually shows adequate intravascular volume and BP.

The collecting system should be able to accurately measure a half-hour output between 1 and 200 mL and provide observation of the urine. Hemoglobinuria can be a manifestation of transfusion of incompatible blood.

An electronic monitoring system is available with digital display of data that can be fed into a computer. The system records output in milliliters for both the present and the immediately past hours. It also shows the number of minutes elapsed in the current hour. Early warning of possible cardiovascular or renal problems is facilitated by visual alert signals if urine flow falls below 15 mL/hr or ceases.

Chest X-Ray

A chest x-ray is essential for checking the position of the pulmonary artery (Swan-Ganz) catheter, CVP line, endotracheal tube, and chest tube and for observing changes in the lungs and heart during the perioperative care period.

Electroencephalogram

Electrical activity of the nervous system reflects neurologic function; therefore electrophysiologic monitoring provides information about the functional integrity of the central nervous system during anesthesia and is especially valuable in patients undergoing high-risk neurosurgical, cardiac, vascular, and orthopedic procedures.

Electrodes placed on the scalp transmit the electrical signals, or alpha rhythms, from brain activity. Alpha rhythms normally occur at a rate of 8 to 13 waves per second. On the electroencephalogram (EEG), these wave patterns vary among individuals in response to anesthetics, drugs, and pathologic and physiologic changes. They reveal the presence of organic brain damage, abnormal physiologic alterations, and actions of drugs.

Regional cerebral blood flow correlates well with EEG activity. Computer analysis offers visual recognition of cerebral hypoperfusion or ischemia. The EEG is used particularly in surgical procedures that involve expected localized brain ischemia caused by intentional surgical occlusion. An EEG also is a means of determining cessation of circulation, an index of expected prognosis, and brain vitality.

Scalp electrodes (cups or discs of silver/silver chloride, gold, or tin) are fixed in place with conductive gel. Subdermal platinum electrodes can be used. Electrodes are placed over areas of cerebral cortex according to a system that uses measurements of head circumference, distance between the ears, and distance from the nasion (point where the sagittal plane intersects the frontonasal suture) to the inion (external protuberance of the occipital bone). The small neurophysiologic signals recorded are amplified for analysis and display. Multiple channels are necessary to detect regional versus global alterations in function. As many as 8 to 32 channels may be recorded simultaneously.

Paper records or strip-charting provides comparisons of EEG activity during crucial periods, with the activity seen before anesthesia induction or surgical manipulation. Methods of EEG analysis that permit automated pattern recognition and alarm generation enhance monitoring in the OR and intensive care unit (ICU). Devices are available that process EEG signals to simplify and facilitate the complex EEG analysis.

Cerebral Function Monitor

The cerebral function monitor provides trend recording of amplitude and amplitude variability for a single channel of the EEG and is useful mainly for detection of marked global alterations in EEG activity during cardiopulmonary bypass, induced hypotension, or metabolic coma. During carotid endarterectomy, paired monitors can detect EEG asymmetries. Although they simplify monitoring, they may be less sensitive to ischemia than the 16-channel strip-chart recording.

Compressed Spectral Array

Compressed spectral array (CSA) programs may give a time-compressed mountain-and-valley representation of brain activity. The mountains move to the left with slower brain activity and to the right with faster activity. CSA helps determine whether the brain is ischemic because of a lack of contralateral circulation during vascular surgery, such as carotid endarterectomy. This type of computerized EEG can be run on general-purpose minicomputers or microcomputers.

Neurometrics Monitor

A neurometrics monitor is a single-channel device for displaying processed EEG signals. From 4 to 32 minutes of EEG can be seen at one time, but trends are less easily seen.

Bispectral Index Monitoring

Bispectral index (BIS) monitoring is a noninvasive method of monitoring the anesthesia level through processed EEG parameters. Electrodes are placed on the patient's forehead, and the brain signals are relayed to a monitor. Readings are displayed as a single number (100 [wide awake] to 0 [absence of brain electrical activity]) and indicate the level of anesthesia.

The BIS electrodes are placed after the induction of general anesthesia while the patient is in a neutral supine position. The baseline reading is recorded by the anesthesia provider. BIS readings change with positional adjustments, such as Trendelenburg's and reverse Trendelenburg's positions. The reading increases in

Trendelenburg's position and decreases in reverse Trendelenburg's position. The change is generally attributed to increased or decreased intracranial and intraocular pressure caused by position shift.

The results are reduced drug use, faster wake-up time, and decreased risk for patient awareness during the surgical procedure. This potentially translates into faster discharge for ambulatory surgery patients.

Evoked Potentials

Sensory information (sight, sound, smell, taste, touch) evokes an electrical response when it reaches the brain. Evoked potentials are those electrical responses recorded from the cerebral cortex after stimulation of a peripheral sensory organ. A computer is programmed to average the brain's repetitive responses to the stimuli. The computer displays these as waves on a video screen or prints them on a plotter.

Auditory Evoked Potentials

A clicking sound is delivered in the ear to stimulate the auditory nerve. Brain waves are recorded using the evoked potential computer. The evoked potentials can be used to assess function of the auditory nerve (e.g., during removal of acoustic neuroma). Because the auditory nerve enters the brainstem, evoked responses provide an indirect assessment of brainstem activity.

Somatosensory Evoked Potentials

Intraoperative monitoring of somatosensory evoked potentials is used to continuously assess spinal cord function and protect the cord from injury during orthopedic or neurosurgical procedures on the spine or spinal cord. Because hypotension increases the insult of direct pressure on the cord and heightens damage to cord function, the spinal cord is monitored when induced hypotension is used for spinal surgery.

Impulses generated below the site of the surgical procedure travel over lateral afferent neural pathways and through the operative spinal area and are recorded using electrodes at the brain level. Abnormal brain responses are marked by changes in the arrival time of electrical impulses or amplitude of the waves on a graph. Change in latency and amplitude of the recorded signal, which normally averages 30 to 50 evoked responses, alerts the team to the danger of spinal cord compression or ischemia. Corrective measures taken immediately can prevent serious sequelae. Evoked responses then return to normal.

Intracranial Pressure Monitoring

Intracranial pressure (ICP) is the result of cerebral spinal fluid (CSF) production-absorption or arterial blood flow–venous drainage in the cranium. Average ICP in adults is 8 to 15 mm Hg/cm H_2O. ICP is lower when the head is elevated and higher when the head is lowered. Increased pressure within the thoracic cavity causes pressure in the skull to rise. The patient is maintained in 30 to 45-degree semi-Fowler position. The zero reference point of the calibrated fluid tube is mounted level with the outer canthus of the patient's eye, which falls relatively even with the foramen of Monroe.

ICP is measured with a fluid-filled monitoring system and an intraventricular catheter. Placement of and care for the catheter are sterile procedures. Cap, mask, eyewear, and sterile gloves are worn. Only sterile 0.9% preservative-free saline solution is used. Heparinized solution is contraindicated. The tubing has a stopcock to drain CSF and take samples for testing. Only 2 mL is drained at a time to prevent cerebral decompression. Never flush the ICP catheter. The fluid should be clear, with no traces of blood.

Contraindications to ICP monitoring include coagulopathies, anticoagulation therapy, cerebral edema with ventricular collapse or shift, and known scalp infection.

The normal flow of CSF is slow because it is secreted and absorbed at the same constant rate. The average adult has 75 mL of CSF present at any given time. Approximately 500 to 700 mL flows through the dural sheath. The blood flow through the intracranial circulation is influenced by systemic BP in normal circumstances. Pressure in the cranium rises in response to several factors: a rise in CSF production, a decrease in CSF resorption, increased blood flow, and decreased venous drainage. The fluid volume-pressure relationship can fluctuate with cardiac dysrhythmia (bradycardia vs. tachycardia) by increasing and decreasing.

Signs of decompensation include change in the patient's level of consciousness, sudden confusion, seizures, altered breathing, vomiting, and coma. Immediate treatment includes hyperventilating with 100% oxygen and evaluation of the pressure. Complications include infection, hemorrhage, air leak into the ventricle, CSF leak around the catheter, occluded catheter, ventricular collapse, and brain herniation.

A prolonged pressure of 18 to 20 mm Hg is considered elevated. The cerebral perfusion pressure (CPP) is calculated by subtracting the ICP measurement from the MAP. When the CPP falls below 50 mm Hg, the brain is at significant risk for deterioration.

Extremes of pressure cause herniation of the brain into the foramen magnum, which creates an ischemic environment for the brainstem and brain death. Cerebral blood flow is restricted when the pressure rises above normal.

28 Surgical Incisions, Implants, and Wound Closure

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Describe the anatomy of the skin and underlying tissues.
- Discuss the rationale for placement of the surgical incision.
- Identify several surgical incisions and their associated surgical procedure.
- Identify several absorbable sutures and their application.
- Identify several nonabsorbable sutures and their application.
- List several different types of needles and their application.

KEY TERMS AND DEFINITIONS

Allogeneic graft Tissue taken from the same species for implantation into a different individual of the same species.
Approximation Bringing the edges of an incision together.
Autologous graft Tissue taken from one area of a person's body for implantation into another area of the same person's body.
Evert edges Turning the edges of the skin outward with pick-ups for approximation.
Figure of 8 Suturing method used to provide hemostasis of a large vessel.
Free tie Strand of suture without a needle.
Fusiform (elliptical) Oval-shaped incision that follows the natural lines of tension in the integument.
Implantation Process of placing material or tissue into a surgical site.
Ligature Strand of suture material used to tie or bind. Suture ligature is a free tie. Tie on a passer is a tie held in the tip of a clamp.
Prosthesis Artificial part worn on the outside or implanted inside the body.
Purse string Circular suturing method for closure of a round opening.
Stick tie Suture on a needle in a needle holder.
Suture Strand of material used for sewing tissue together or ligating a structure.
Undermine Method of releasing the skin edges by sharp dissection to approximate skin. Care is taken not to interrupt circulation to the tissue.
Xenograft Tissue taken from one species for implantation into another species.

The Surgical Incision

Anatomy and Physiology of the Integument

Tissue structure and function vary according to location in the body. Basic tissue types are described in Table 28.1.

The skin contributes to the health and well-being of the patient. Intact skin is an effective barrier to most harmful elements. Wounded, nonintact skin is an open avenue for microbial entry. Wounds occur intentionally or unintentionally. When treated properly, most wounds heal without incident. Unfavorable outcomes occur when wound healing is disrupted by poor circulation, infection, or immune dysfunction.

Skin is a multifunction body cover, and skin assessment is an important measurement of generalized wellness. Skin color, texture,

TABLE 28.1 Four Basic Histologic Tissue Types

Histologic Tissue Type	Description	Implications to Surgical Team
Epithelial Tissue		
A. Types		
1. Simple	Single layer of cells (endothelium) that lines the blood vessels, heart, and lymphatics	Delicate tissue that is easily damaged by rough handling
2. Stratified	Several layers of cells that form the skin, gastrointestinal tract, genitourinary (GU) tract, reproductive tract, and oropharynx; lines area that serves as a passage; reduces friction with mucus; can convert into keratin	Superficial layer of body cover; surface modifications are performed here; forms hair and nails
3. Transitional	Combination of simple and stratified layers found in ureters and bladder	Encountered during GU reconstruction and neoconstruction
B. Cellular surface structure		
1. Squamous	Flat	
2. Columnar	Tall, cylindric	
3. Cuboidal	Square	
Connective Tissue		
A. Fluid	Blood, lymph, chyle, cerebrospinal fluid, synovium vitreous and aqueous, and mucinous material	Care with body substance isolation and provision of hemostasis
B. Fibrous		
1. Areolar	Loose network forming the frame for subcuticular tissue	Reorganized during liposuction and fat transplantation procedures
2. Adipose	Fat that fills the loose network; visible in fetus at 14 weeks' gestation; not found in eyelid, penis, scrotum, labia minora, cranium, and lung tissue	
3. Reticular	Forms firmer framework for organs and vessels	
C. Supportive		
1. Cartilage	Avascular, no lymphatics or nerves	Structural integrity is altered during rhinoplasty and otoplasty; cartilage may be used as graft material; radical neck reconstruction may involve tracheal rings or laryngectomy for multidisciplinary treatment
a. Hyaline	Translucent, articular, and rubs against other articular surface; forms the epiphyseal line in long bone, portions of the nose, and tracheal rings	
b. Costal elastic	Becomes fibrous with age; found in ribs, nose, trachea, and larynx	
c. White fibrocartilage	Forms circular menisci in joints and between vertebrae	
d. Yellow elastic	Found in auricle of ear, eustachian tubes, and epiglottis	
2. Erectile	Found in corpus cavernosa, clitoris, and nose	
D. Hard	Bony surfaces covered with periosteum except at articulations and cartilaginous areas of circulating nurse insertion points	Reconstruction requires framework of underlying bone or graft material; autologous bone may be harvested from graft site for neoconstruction; donor bone may be used as transplant material
1. Cancellous bone	Spaces are filled with red marrow; erythroblasts and smaller vessels	
2. Compact bone	Hollow center filled with yellow marrow (higher fat content) and larger vessels	
Muscle Tissue		
A. Visceral	Smooth, involuntary muscle; hollow organs, vessels, glands, areola, scrotum, iris of eye	Skeletal muscle may be used to replace bulk lost to debridement; vascularized flaps replace radical tissue excisions

TABLE 28.1 Four Basic Histologic Tissue Types—cont'd

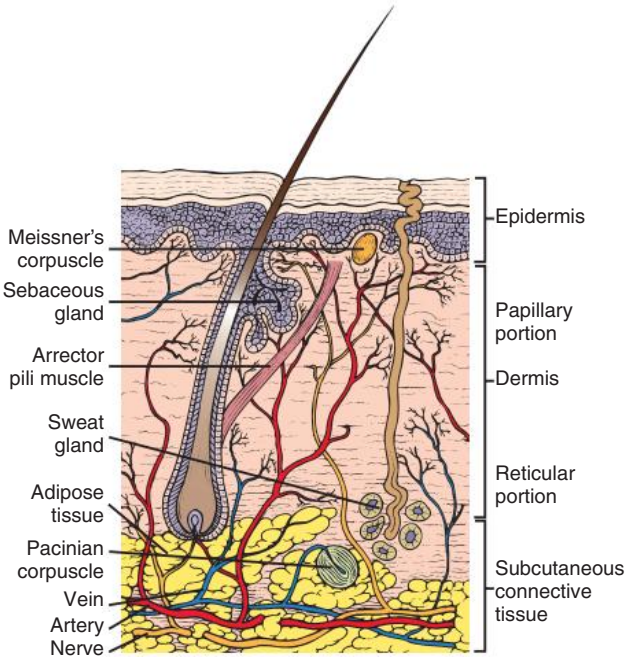
Histologic Tissue Type	Description	Implications to Surgical Team
B. Skeletal	Cylindric, striated, voluntary cells	
C. Cardiac	Branching cells, nonnucleated, less fibrous connective tissue	
Nerve Tissue		
A. Types		
1. Neuron	Cells generate and conduct nerve impulses; has multiple cytoplasmic fibers on one side (dendrites) and a single myelinated extension from the other side (axon)	Nerves may be injured during any procedure
2. Neuroglia	Insulate and support neurons in central nervous system	
B. Classification by activity type		
1. Afferent	Sensory	
2. Efferent	Motor	

From Fortunato NM, McCullough SM: *Plastic and reconstructive surgery,* St. Louis, 1998, Mosby.

and condition can be the best predictors of how well a surgical site will heal. The most intricate procedure can be done in deep tissue layers, but the superficial layers are what the patient sees and measures the outcome against. Durability and viability of the skin of the perioperative patient are influenced by many factors. Within reasonable limits, in the absence of hemorrhage and sepsis, wound healing is predictable. Disregard for the principles of tissue handling and wound management can lead to complications. The intent of this chapter is to provide an overview of body tissues, surgical incisions, and surgical site closure.

The skin is the largest and heaviest organ of the body. The two main layers that compose the integument are the *epidermis* and the *dermis.* The thickness of the skin and its layers is determined by its location. The combined thickness of the epidermis and dermis ranges from 4 mm on the back to 1.5 mm on the scalp. Fig. 28.1 shows a cross-section of the integument (skin) and its layers. Areas involving bone will incorporate vascularized periosteum over the bone.

There are two basic skin types: glabrous and hairy. Glabrous, smooth skin is very thick and is found on the palms and soles. The surface is marked by ridges and sulci arranged in unique configurations referred to as *dermatographics,* or fingerprints. These ridges first appear in the fingertips during the thirteenth week of fetal life. A marked absence of hair follicles and oil glands is characteristic of this tissue. Hairy, thin skin has hair follicles, sweat glands, and oil glands.



• **Fig. 28.1** Anatomy of the skin.

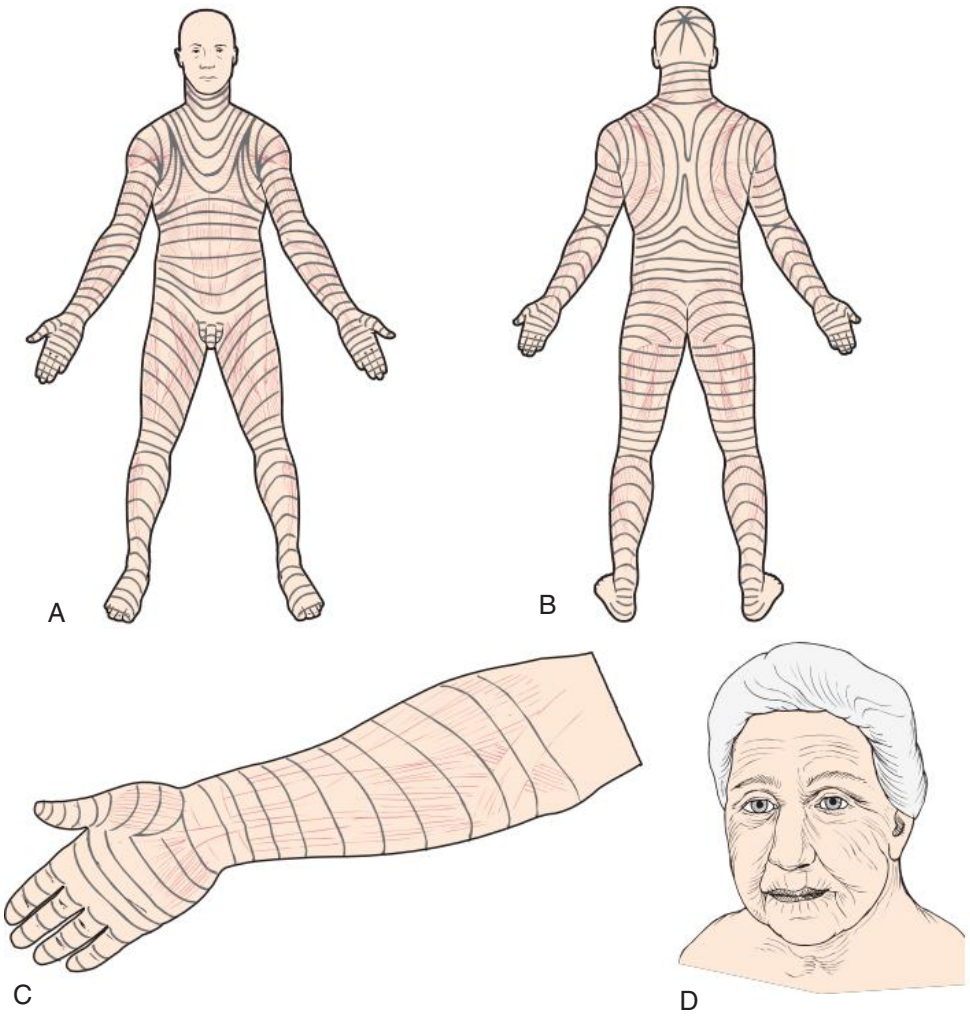
Langer's Lines

Natural lines of tension are formed by the relationship of the skin to the underlying musculature (Fig. 28.2). Austrian anatomist Karl Langer (1819–1887) described how incisions could be more cosmetic if natural cleavage lines were followed when planning the surgical incision. The collagen fibers in the epidermis and dermis form an elliptical shape when the skin is incised in **fusiform** fashion along the natural lines. The angle of the incision should be no more than 30 degrees at each margin. The surgeon may **undermine** the tissue to minimize the distance between the skin edges. Closure is better when the edges meet during **approximation**. As the incision heals, tension of the skin is relaxed, causing minimal pulling and widening of the bridge of scar tissue.

Epidermis

The epidermis is the outermost layer of skin. It is organized into five levels of stratified squamous epithelium and contains no organs, glands, nerve endings, or blood vessels. This layer renews itself every 15 to 30 days, depending on the body surface area, the age of the individual, and the individual's generalized condition. The basic anatomy and physiology of epidermal layers are as follows:

- *Stratum corneum:* Keratinized cells make up 75% of the epidermal thickness. Cells are shed from this level, which



• **Fig. 28.2** Langer's lines. **A,** Anterior view. **B,** Posterior view. **C,** Forearm. **D,** Relaxed skin tension lines of face. (From Fortunato NM, McCullough SM: *Plastic and reconstructive surgery,* St. Louis, 1998, Mosby.)

is referred to as the *horny layer.* It is thinner in hairy, thin-skinned areas.

- *Stratum lucidum:* Cells are flattened. Organelles and nuclei are absent.
- *Stratum granulosum:* This level is arranged in three to five layers. Mitotic activity creates cells for renewal of epidermal layers.
- *Stratum spinosum:* This layer creates cells for renewal of epidermal layers.
- *Stratum basale:* A single cell layer that lies between the junction of the epidermis and the dermis. Intense mitosis in this layer in combination with the basal layer and the spinosum causes epidermal regeneration. As cells are generated they migrate upward, toward the surface. Melanocytes, located between basal cells and in hair follicles, create melanin, which causes skin pigmentation. Melanin enters and accumulates in keratocytes, causing superficial skin tone and providing ultraviolet protection. Exposure to sunlight causes darkening of existing melanin and accelerated generation of new melanin.

Each epithelial layer consists of keratin-producing cells (keratinocytes). Keratin is modified into functional components such as hair and fingernails on select body surfaces. Overactivity of the spinosum and basal levels can increase epidermal thickness in normally thin areas, causing psoriasis.

Dermis

The dermis is composed of papillary and reticular layers of flexible connective tissue. Superficially, the dermis has an irregular surface of papilla-like fingers that project into the strata basale of the epidermal layers. The dermis, regardless of location, is a loose, areolar connective tissue that contains pain and touch receptors, glands, blood vessels, and lymphatics. It is the key layer in wound repair and tissue healing.

Glandular Structures and Ducts in the Integument

Oil Glands (Sebaceous Glands)

Sebaceous and sudoriferous glands are found within the dermal layers of the skin. Sebaceous glands are referred to as *holocrine glands* because the oily secretion sebum also carries cellular debris. The sebaceous duct empties into a hair follicle or, on nonhairy areas, directly onto the surface of the skin. Sebum is a lubricant with minor antibacterial and antifungal properties. The palms and soles lack sebaceous glands, but these glands are numerous on the scalp and face and around natural body orifices. Oily skin types sometimes have increased scar formation because the oil forms a mechanical barrier to healing.

Sweat Glands (Sudoriferous Glands)

Sudoriferous glands are found on every area of the body except the lips, nipples, and glans penis. Eccrine and apocrine glands are two types of sudoriferous glands. Eccrine glands are widely distributed over the entire surface of the body and are responsible for producing 700 to 900 g of sweat per 24 hours. These simple structures are embedded in the dermis and have a funnel-shaped exit path (pore) leading directly to the skin's surface. Secretions are produced in response to physical activity and cool the body by evaporation. These glands are most numerous on the palms, soles, and forehead.

Apocrine glands are located only in the axillary, perineal, and areolar areas in combination with eccrine glands. Apocrine glands are larger than eccrine glands and are embedded in subcutaneous tissue. These glands secrete a viscous fluid and have ducts that open into hair follicles. Initially the secretion is odorless, but it quickly develops an odor caused by bacterial decomposition. These glands secrete in response to stress or excitement. In animals, apocrine and sebaceous glands are thought to release pheromones, which are hormones thought to cause sexual attraction. Modified apocrine glands are found in the ear canals and secrete cerumen (earwax).

Blood Supply and Innervation

The dermis contains a rich supply of blood and lymph. In some areas, arterial and venous communication is by direct shunting, without using a capillary mechanism. Arteriovenous shunts allow for thermoregulation and blood pressure control. Capillary networks are located in the papillary layer to nourish the epidermis. *Effector innervation* of the dermis is derived from postganglionic fibers of the sympathetic ganglia. *Affector innervation* is a superficial dermal network of free nerve endings, hair follicles, and encapsulated sensory organs.

Tissue Layers under the Integument

Subcutaneous Adipose Layer

Underneath the dermis is a loose, fatty layer that is referred to as the *subcutaneous layer.* Beneath the subcutaneous tissue is a layer of striated muscle. The looseness of this structure allows for movement of the skin over supporting musculature. In males the distribution is through the nape of the neck, deltoids, triceps, abdomen, lumbosacral region, and buttocks. In females the fatty layer extends through the breasts, abdomen, buttocks, epitrochanteric area, and anterior thighs.

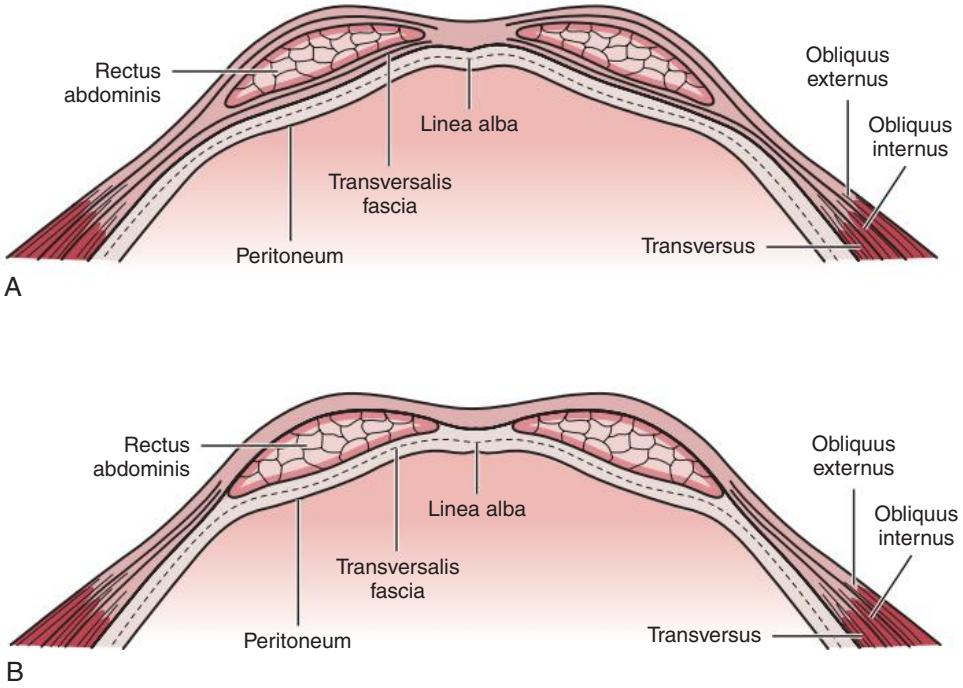
Fascia

The fascia is a fibrous areolar tissue that supports the superficial skin layers and encases the muscle. Fascia throughout the body covers the muscles anteriorly and posteriorly. The superficial fascia is located directly underneath the integument and is the point to which injection of a local anesthetic agent should extend for the best effect. Sensory nerve fibers run through this area, and an anesthetic agent is easily absorbed. Adipose cells occupy areolar spaces, rendering the fascia soft and pliable and permitting vessels, nerves, and lymphatics to pass through the layers.

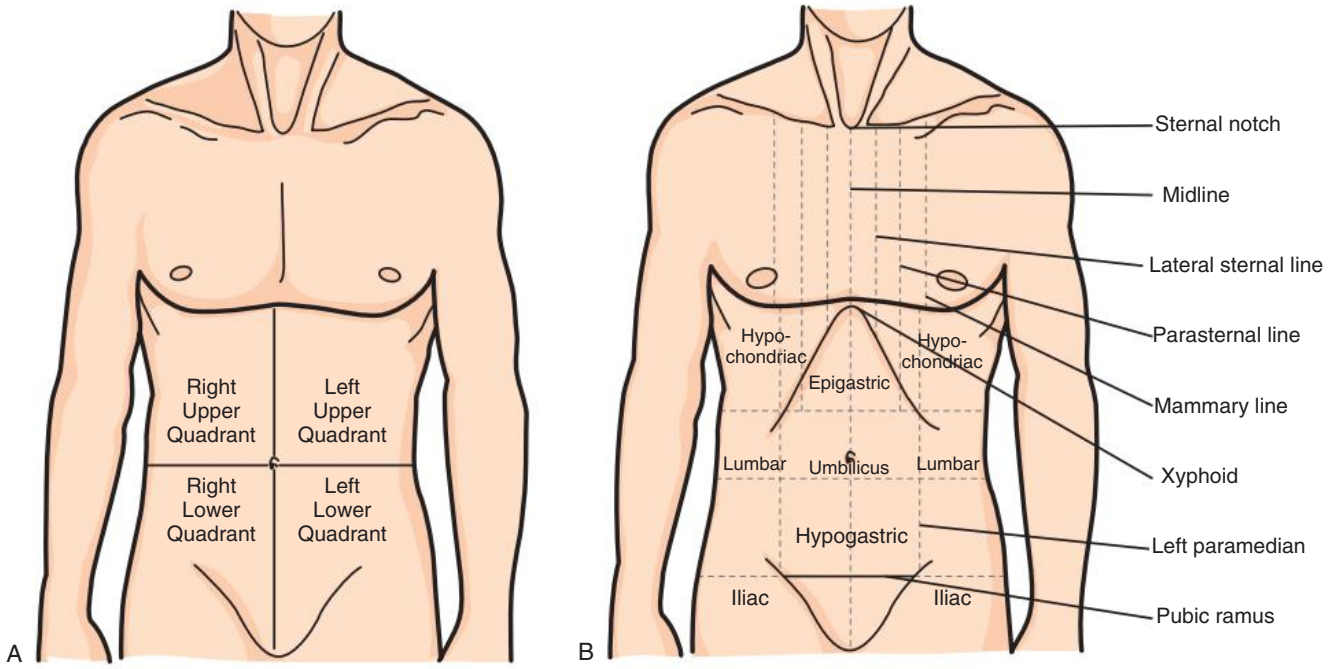
The deep fascia is tough and less pliable. It runs the length of the muscle bundle and terminates in fibrous tendons that attach to bones beneath the periosteum. The anterior fascia of the abdomen is arranged in three layers that merge around the rectus abdominis muscles. The internal and external oblique muscles cover and surround the rectus muscles to the level of the linea circularis, or the landmark known as the *arcuate line,* sometimes called the *semicircular line of Douglas* (Fig. 28.3). The arcuate line is formed by three fascial merges one-third the distance between the umbilicus and the pubis. Below the level of the arcuate line the fascial layers are fully anterior with no posterior fascial component. The rectus abdominis is behind the layered fascia.

Peritoneum

Lying beneath the posterior fascia of the abdomen is the peritoneum—the thin, two-layer serous membrane that lines the interior of the abdominal cavity (parietal peritoneum) and surrounds the organs (visceral peritoneum). The inferior aspect of the peritoneum overlies or is superior to the dome of the urinary bladder. In other words, the bladder is



• **Fig. 28.3** Abdominal tissue layer at the arcuate line. **A,** Above the arcuate line. **B,** Below the arcuate line.



• **Fig. 28.4** Surgical landmarks. **A,** Surgical quadrants. **B,** Surgical topographic landmarks.

infraperitoneal, or below the peritoneal cavity. The stomach is superior to the peritoneal sac with the fundus situated supraperitoneally. The kidneys and the aorta are behind the peritoneum (retroperitoneal).

Accessory Appendages to the Integument

Modifications in the epidermal layer cause varied degrees of keratin deposition. Thickness and durability are functionally related to the location of keratinization. Hair and fingernails are modified keratin.

Other skin appendages include glands, blood vessels, and sensory organs. Glands arise in the dermis, and some exit the body through ducts that penetrate the epidermis. Other glands empty into the superior segment of hair follicles.

Hair Follicles

Hair follicles are keratinized epidermal epithelium that terminates in the dermal layers. The follicle is nourished by a capillary bed. Loss of this blood supply results in death of the follicle. Small bundles of smooth muscle cells, referred to as *arrector pili,* form attachments to the surrounding connective tissue in a diagonal fashion. As arrector pili contract, the shaft of the hair is straightened to an upright position. This contraction causes the superficial skin to dimple and pucker, creating "goose bumps."

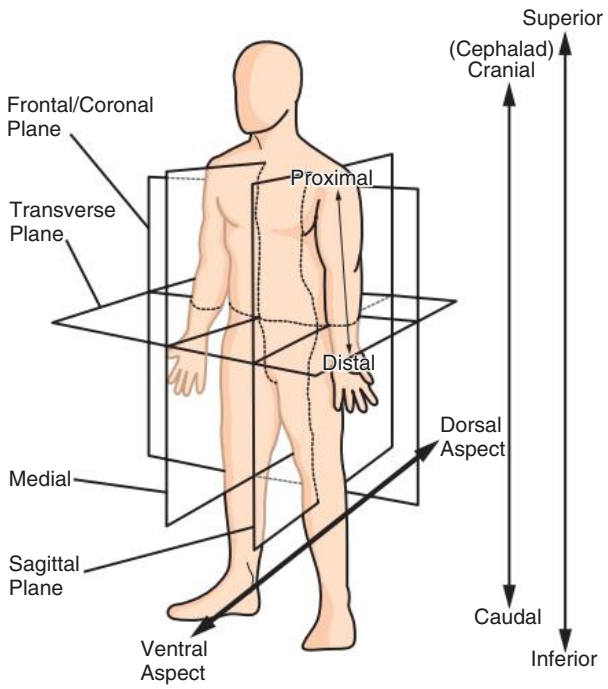
Nails (Ungues)

The dorsal tip of each phalanx is tipped with a plate of specialized keratinized cells. Proximally, the nail root is covered by stratum corneum, which is referred to as the *eponychium,* or cuticle. The nail plate rests on a bed of epidermis (nailbed). Nails are chemically similar to the surface epidermis. Peripheral blood supply may be assessed through the translucent nail plate but should not be the sole determinant of oxygenation and well-being of the patient.

Surgical Landmarks

The primary reference point for abdominal incisions is the umbilicus. Secondary surface landmarks include the xyphoid, the pubis, and the iliac crests. Incisions may be vertical, horizontal, or oblique and may occur in various areas of the torso (Fig. 28.4). Specialty incisions, such as those involving the head, limbs, breast, reconstructive procedures, and other organ systems, are described in their respective chapters.

The direction of the incisional line is determined by the anatomic plane in the body (Fig. 28.5). Some specialty instruments are constructed to dissect, debulk, or separate layers in a specific pattern according to the angle of the natural tissue arrangement. One example is a sagittal saw that is designed to cut bone along the sagittal plane.



• **Fig. 28.5** Surgical lines of direction.

Placement of the Surgical Incision

Before the procedure begins the surgeon chooses the most suitable incision for the procedure being performed. All incisions incorporate, with varying degrees of success, certain characteristics that include the following:

- Condition of the patient
  - Knowledge of previous surgery in the same region and the presence of adhesions
  - Ease and speed of entry into tissues
  - Size of the body habitus and the natural lines of tissue tension (Langer's lines)
- Maximum exposure of intended surgical site and adjacent structures (i.e., muscles, nerves, vessels, lymphatics)
  - Ability to extend the incision if necessary
  - Least amount of disfiguration as possible
- Minimum trauma and scar formation
- Least postoperative discomfort
- Maximum postoperative wound strength

Abdominal Surgery

A laparotomy involves surgically opening the abdominal wall and entering the peritoneal cavity (Fig. 28.6). The skin and subcutaneous tissue are incised, and the blood vessels are ligated or electrocoagulated. Both the posterior fascia and the peritoneum may be cut at the same time, thus exposing the contents of the abdominal cavity. Various types of incisions are used in a laparotomy, but each follows essentially the same technique.

Types of Abdominal Incisions

The incisions discussed in the following sections are applicable to open abdominal or pelvic procedures for specific organs or organ systems. The usual anterior surface incisions are depicted in Fig. 28.7.

Laparoscopy is performed through either one puncture or multiple (usually one to five) incisions that are smaller (usually 5 to 10 mm), separate, and distinct. Endoscopy and laparoscopy are discussed in detail in Chapter 32.

Midline Incision

A midline incision can be upper abdominal, lower abdominal, or a combination of both going around the umbilicus. The patient may have thicker deposits of adipose tissue under the planned incision line. Depending on the intended procedure, a full midline incision can begin in the epigastrium at the level of the xyphoid process and may extend inferiorly to the suprapubic region. The surgeon is careful to avoid cutting bowel that may be close to the surface in the peritoneal cavity. Most surgeons curve the incision around the periphery of the umbilicus to avoid cutting through the structure.

An upper midline incision above the umbilicus offers excellent exposure of and rapid entry into the epigastric region. The upper midline incision is made carefully to accommodate the position of the falciform ligament of the liver. A lower midline incision can begin inferior to the umbilicus and extend to the pubis for lower bowel, gynecologic, or obstetric pelvic procedures. Care is taken at the lower margin to avoid perforating the urinary bladder. An indwelling urinary catheter can help keep the bladder decompressed.

Z. Carotid

• **Fig. 28.7** Anterior surface incisions.

The midline incision enters the body through fascial planes that are relatively avascular. Many vessels and nerve endings are spared. The muscles are easily separated and retracted for visualization and when the procedure is complete it is easy to close. If the incision must be lengthened, the extension is easier to make. When closing, the surgeon may request a visceral retainer to protect the underlying organs and prevent an inadvertent suture from passing through the bowel.

Paramedian Incision

The paramedian incision is a vertical incision made approximately 4 cm (approximately 2 inches) lateral to the midline on either side in the upper or lower abdomen. After the skin and subcutaneous tissue are incised, the rectus sheath is split vertically and the muscle is retracted laterally. This incision allows quick entry into and excellent exposure of the abdominal cavity. It limits trauma, avoids nerve injury, is easily extended, and gives a firm closure. Examples of use include access to the biliary tract or pancreas in the right upper quadrant and access to the left lower quadrant for resection of the sigmoid colon.

Subcostal Upper Quadrant Oblique Incision

A right or left oblique incision begins in the epigastrium and extends laterally and obliquely just below the lower costal margin. One example is the Kocher incision in the right subcostal region, which was developed by Swiss surgeon and Nobel laureate Emil Theodor Kocher (1841–1917). It continues through the rectus muscle, which is either retracted or transversely divided. Although this type of incision affords limited exposure except for upper abdominal viscera, it provides good cosmetic results because it follows skin lines and produces limited nerve damage. Despite being painful, it is a strong incision postoperatively. Examples of use include biliary procedures.

Bilateral subcostal incisions that join in the midline may be preferred for procedures that involve the stomach and/or pancreas. A modified bilateral subcostal incision (chevron incision or rooftop incision) is made for increased visibility during a liver transplantation or resection. The chevron incision can be extended superiorly toward the xyphoid to create the Mercedes incision for greater access to the inferior aspect of the diaphragm.

McBurney's Incision

Charles McBurney (1845–1913) described a method of diagnosing appendicitis in 1889 by pressing on the right lower quadrant, just below the umbilicus and 4 cm (2 inches) medial from the anterior superior iliac spine. This area of the abdomen is referred to as *McBurney's point.*

McBurney's incision involves a muscle-splitting incision that extends through the fibers of the external oblique muscle. The incision is deepened, the internal oblique and transversalis muscles are split and retracted, and the peritoneum is entered. This is a fast and easy incision, but exposure is limited. Its primary use is for appendectomy. Some surgeons modify this incision in a transverse plane

referred to as the *Rockey-Davis* or *Lanz incision* to conceal the scar in a natural skinfold.

Thoracoabdominal Incision

For a thoracoabdominal incision the patient is placed in a lateral position. Either a right or a left incision begins at a point midway between the xyphoid process and umbilicus and extends across the abdomen to the seventh or eighth costal interspace and along the interspace into the thorax. The rectus, oblique, serratus, and intercostal muscles are divided in the line of incision down to the peritoneum and pleura. This converts the pleural and peritoneal cavities into one main cavity, thus allowing excellent exposure for the upper end of the stomach and lower end of the esophagus. Examples of use include esophageal varices and the repair of a hiatal hernia.

Midabdominal Transverse Incision

The midabdominal transverse incision starts on either the right or left side and slightly above or below the umbilicus. It may be carried laterally to the lumbar region between the ribs and crest of the ilium. The intercostal nerves are protected by cutting the posterior rectus sheath and peritoneum in the direction of the divided muscle fibers.

Transverse abdominal incisions are sometimes used for infants because the abdomen is wider than it is long. Better exposure to the intraabdominal cavity is attained. In some cases the same is true for extremely short, stout adults with large abdominal girth.

The advantages are rapid incision, easy extension, a provision for retroperitoneal approach, and a secure postoperative wound. Examples of use include choledochojejunostomy and transverse colostomy.

Pfannenstiel Incision

German gynecologist Herman Johannes Pfannenstiel (1862–1909) developed the Pfannenstiel incision, a curvilinear transverse incision across the lower abdomen and within or superior to the hairline of the pubis. The incision follows the Langer's lines of the natural skinfolds. The rectus fascia is incised transversely below the arcuate line, and the muscles are separated. The peritoneum is incised vertically in the midline. This lower curved incision provides good exposure and strong closure for pelvic procedures. Its primary use is for urologic and gynecologic procedures and cesarean section. One disadvantage is that exposure may be limited. The scar is obscured by the patient's pubic hair.

One modification is the Maylard transverse incision. This incision is not curved but straight. It is made above the level of the curvilinear Pfannenstiel incision for greater access to the pelvic and urologic organs.

Inguinal Incision (Lower Oblique)

An oblique incision of the right or left inguinal region extends from the pubic tubercle to the anterior iliac crest, slightly above and parallel to the inguinal crease. Incision of the external oblique fascia provides access to the cremaster muscle, inguinal canal, and spermatic cord structures. Great care is taken not to entrap ilioinguinal nerves or the spermatic cord. Its primary use is for inguinal herniorrhaphy.

Wound Closure

Closure of a surgical site or other wound is performed after necessary hemostasis has been achieved. Wounds include deep and superficial structures. Methods of wound closure include sutures, staples, clips, tapes, and glues.

Suture Basics

The noun form of **suture** is used for any strand of material used for ligating or approximating tissue; it is also synonymous with stitch. The verb *to suture* denotes the act of sewing by bringing tissues together and holding them in approximation until healing has taken place.

If the material is tied around a blood vessel to occlude the lumen, it is called a **ligature** or *tie.* A suture attached to a needle for a single stitch for hemostasis is referred to as a **stick tie** or *suture ligature.* A **free tie** is a single strand of material handed to the surgeon or first assistant to ligate a vessel. A tie handed to the surgeon in the tip of a forceps or clamp is referred to as a *tie on a passer.*

Suturing Techniques

Halsted Suture Technique

The education a physician receives during postgraduate surgical training exerts a lasting influence on his or her surgical techniques. The classic example of the influence of a professor on his students is that of Dr. William Stewart Halsted (1852–1922).

Halsted, a professor of surgery at Johns Hopkins Hospital in Baltimore from 1893 to 1922, perfected and brought into use the fine-pointed hemostat for occluding vessels, the Penrose drain, and rubber gloves. He is best known for his principles of gentle tissue handling. The silk suture technique he initiated in 1883, or a modification of it, is in use today. Its features are as follows:

1. Interrupted individual sutures are used for greater strength along the wound. Each stitch is taken and tied separately in a **figure of 8** pattern for deeper tissues. If one knot slips, all the others hold. Halsted also believed that interrupted sutures were a barrier to infection, for he thought that if one area of a wound became infected, the microorganisms traveled along a continuous suture to infect the entire wound.
2. Sutures are as fine as is consistent with security. A suture stronger than the tissue it holds is not necessary.
3. Sutures are cut close to the knots. Long ends cause irritation and increase inflammation. Only external stitches have tails for ease of removal after healing.
4. A separate needle is used for each skin stitch.
5. Dead space in the wound is eliminated. Dead space is that space caused by separation of wound edges that have not been closely approximated by sutures. Serum or blood clots may collect in a dead space and prevent healing by keeping the cut edges of tissue separated.
6. Two fine sutures are used in situations usually requiring one large one.
7. Silk is not used in the presence of infection. The interstices (braid pattern) can harbor microorganisms.
8. Tension is not placed on tissue. Approximation versus strangulation preserves the blood supply.

Halsted's principles were based on use of the only suture materials available to him: silk and surgical gut. With the advent of less reactive synthetic materials, wound closure may be safely and more quickly performed with different techniques without complications.

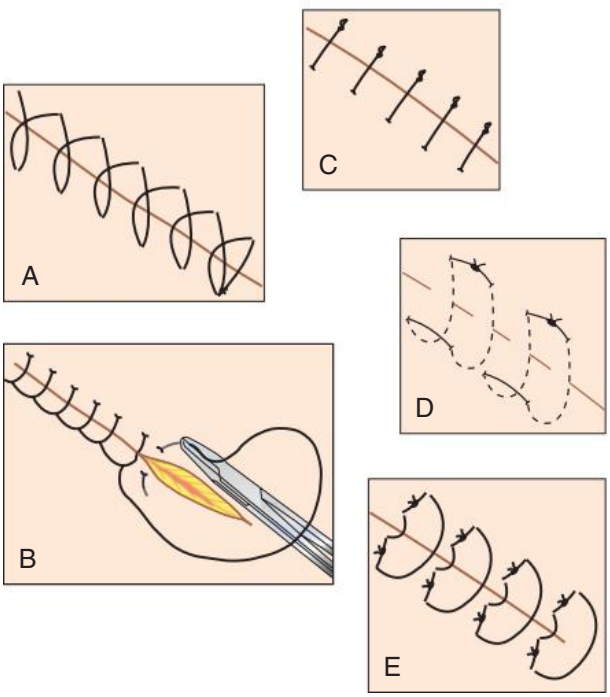
Principles of Suturing

The strength of the wound is related to the condition of the tissue and the number of stitches in the edges. Care is taken not to place more sutures than necessary to approximate the edges. The amount of tissue incorporated into each stitch directly influences the rate of healing.[1] The adequacy of the blood supply to the tissue needs to be preserved for healing to take place.

Methods of Suturing

The edges of the wound are intentionally directed by the placement of sutures during closure. Suturing techniques are depicted in Fig. 28.8. Examples of suturing techniques that direct the wound edges for specific healing mechanisms include, but are not limited to, the following:

1. *Everting sutures:* These interrupted (individual stitches) or continuous (running stitch) sutures are used to **evert edges**.
   a. *Simple continuous (running):* This suture can be used to close multiple layers with one suture. The suture is not cut until the full length is incorporated into the tissue (see Fig. 28.8, *A*).
   b. *Continuous running/locking (blanket stitch):* A single suture is passed in and out of the tissue layers and looped through the free end before the needle is passed through the tissue for another stitch. Each new stitch locks the previous stitch in place (see Fig. 28.8, *B*).
   c. *Simple interrupted:* Each individual stitch is placed, tied, and cut in succession from one suture (see Fig. 28.8, *C*).
   d. *Horizontal mattress:* Stitches are placed parallel to wound edges. Each single bite takes the place of two interrupted stitches (see Fig. 28.8, *D*).
   e. *Vertical mattress:* This suture uses deep and superficial bites, with each stitch crossing the wound at right angles. It works well for deep wounds. Edges approximate well (see Fig. 28.8, *E*).
2. *Inverting sutures:* These sutures are commonly used for two-layer anastomosis of hollow internal organs, such as the bowel and stomach. Placing two layers prevents passing suture through the lumen of the organ and creating a path for infection. A single layer is placed for other structures, such as the trachea, bronchus, and ureter. The edges are turned in toward the lumen to prevent serosal and mucosal adhesions. The number of layers is proportional to the quality of the blood supply. Stitches can be interrupted or continuous.
   a. *Halsted suture:* A two-layer modification of the horizontal mattress suture used for friable tissue.
   b. *Connell suture:* A continuous single-layer suture of gut used for hemostasis in the inner layer of bowel with a separate outer inverting layer of alternating horizontal and vertical mattress sutures.
   c. *Cushing suture:* A continuous vertical mattress suture that unites half of the lumen, followed by a second continuous vertical mattress suture that completes the second half of the circumference.
   d. *Grey-Turner sutures:* A series of inverted interrupted horizontal or vertical mattress stitches.
   e. *Purse string suture:* A continuous stitch that encircles and closes a lumen while inverting the edges.



• **Fig. 28.8** Examples of suturing techniques. **A,** Simple continuous. **B,** Continuous locking. **C,** Simple interrupted. **D,** Horizontal mattress. **E,** Vertical mattress.

Knot Placement

Each suture placed in tissue usually requires the placement of a knot to secure the ends. Interrupted stitches require individual knots, and therefore placement of each knot can influence how well the wound heals and the cosmetic result. The following list of principles concerns knots and knot tying:

1. The knot should be tied away from:
   a. Vital structures, such as the eye
   b. Sources of contamination, such as the mouth
   c. Potential irritants, such as the nares
   d. Potential sources of increased inflammation, such as the incision line
2. The knot should be tied toward:
   a. The better blood supply
   b. The area that provides the best security of the knot
   c. Where the mark would be less noticeable, if possible

Cutting Sutures

Care is taken to prevent excess suture from remaining in the wound. Suture tails are trimmed close to the knot inside the body, but a short tail may be left for external stitches to facilitate removal. Considerations for cutting suture include the following:

1. Scissors are stabilized by the index finger on the screw (tripod stance), the blades are angled slightly and slide down to the area just above the knot, and the suture is cut with the tips of the scissors.
2. The tips of the scissors must be visible to ensure that other structures are not injured by the cutting motion.
3. A hemostat and/or a second suture should be available in the event the knot is inadvertently cut, releasing the sutured tissue.
4. A hemostat may be placed on one of the suture ends to stabilize the suture to be cut.
5. If removing a suture, a forceps is used to grasp the suture at the knot. Cut the suture between the knot and the skin. Extract the cut suture with the forceps.

Retention Sutures

Interrupted nonabsorbable sutures are placed through tissue on each side of the primary suture line, a short distance from it, to relieve tension on it. Heavy strands are used in sizes ranging from 0 through 5. The tissue through which retention sutures are passed includes skin, subcutaneous tissue, and fascia and may include rectus muscle and peritoneum of an abdominal incision.

After abdominal surgical procedures, retention sutures are used frequently in patients in whom slow healing is expected because of malnutrition, obesity, carcinoma, or infection; in geriatric patients; in patients receiving cortisone; and in patients with respiratory problems.[2]

Retention sutures may be used as a precautionary measure to prevent wound disruption when postoperative stress on the primary suture line from distention, vomiting, or coughing is anticipated. Retention sutures should be removed as soon as the danger of sudden increases in intraabdominal pressure is over, usually on the fourth or fifth postoperative day. Retention sutures are also used to support wounds for healing by second intention and for secondary closure after wound disruption for healing by third intention.

Retention Bridges, Bolsters, and Bumpers

To prevent heavy retention suture from cutting into skin, several different types of bridges, bolsters, or bumpers are used:

- Bridges are plastic devices placed on the skin to span the incision. The retention suture is brought through the skin on both sides of the incision and through holes on each side of the bridge and is fastened over the bridge. One type allows adjustment of tension on the edges of the incision during the postoperative healing period.
- Bumpers are segments of plastic or rubber tubing. One end of the suture is threaded through the tubing before the suture is tied. It covers the entire retention suture strand that is on the skin surface to prevent irritation (Fig. 28.9). Compression bolsters are made from polyethylene foam held in place with malleable aluminum buttons to secure and distribute tension of retention sutures.
- Buttons and beads are used as bolsters and bumpers to prevent the suture from retracting or cutting into skin or friable tissue. The suture is pulled through holes and tied over a sterile button (e.g., with pull-out tendon sutures). Beads may be placed on the ends of pull-out subcuticular skin sutures. The devices are used most frequently in plastic and orthopedic surgery.

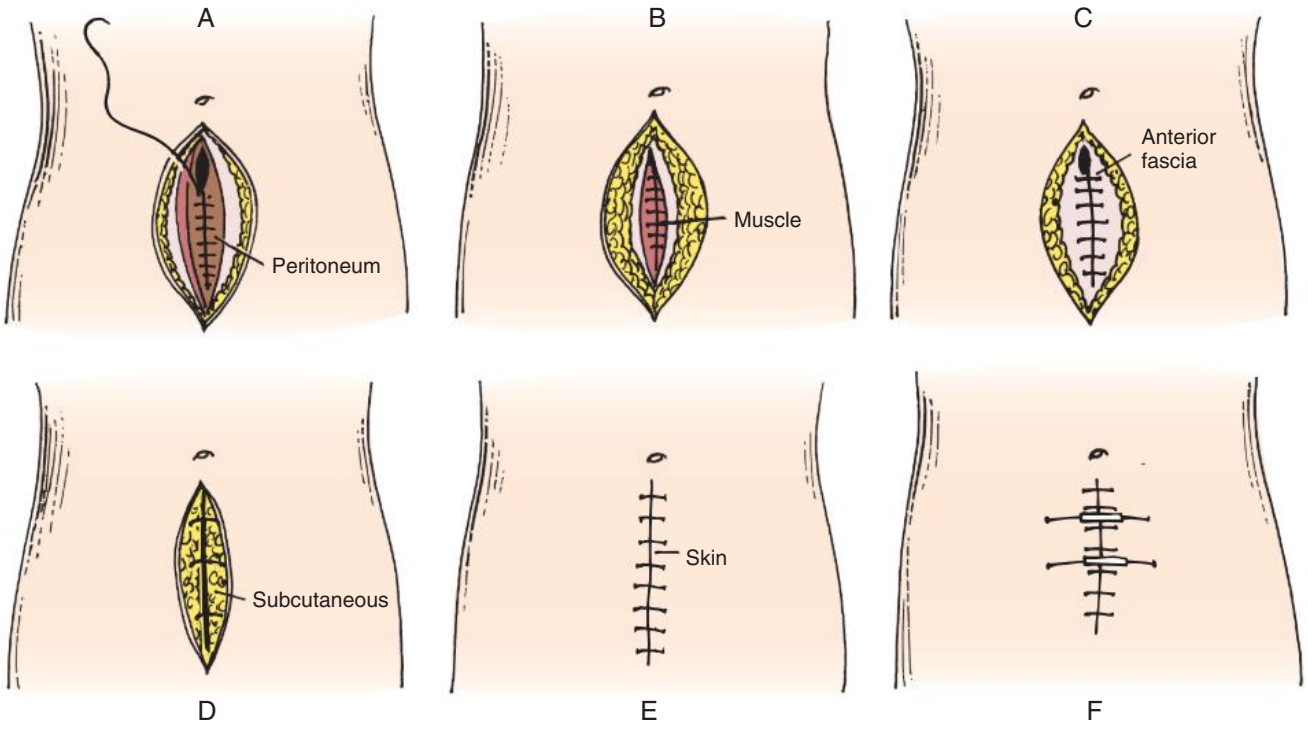
Traction Suture

A traction suture may be used to retract tissue to the side or out of the way, such as the tongue in a surgical procedure in the mouth. Usually a nonabsorbable suture is placed through the part. Other materials that may be used to retract or ligate vessels include the following:

- *Umbilical tape:* Aside from its original use for tying the umbilical cord on a newborn, cotton umbilical tape may be used as a heavy tie or as a traction suture. It may be placed around a portion of bowel or a great vessel to retract it. These should be counted and accounted for at the end of the procedure. Cotton should be moistened with sterile saline before use. Umbilical tapes should not be cut into pieces.
- *Vessel loop:* A length of thin flat silicone can be placed around a vessel, nerve, or other tubular structure for retraction. It can be tightened around a blood vessel for temporary vascular occlusion. These should be counted and accounted for at the end of the procedure. Vessel loops should not be cut into pieces.
- *Aneurysm needle:* An aneurysm needle is an instrument with a blunt needle on the end for passing suture. The eye is on the distal end of the needle. The needle forms a right or oblique angle to the handle, which is one continuous unit with the needle. The needles are made in symmetric pairs, right and left. The surgeon uses them to place a ligature around a deep, large vessel, such as in a thyroidectomy or in thoracic surgery. They can be used to pass a suture tape around an incompetent cervix to perform cerclage. These should be counted and accounted for at the end of the procedure. (Refer to Chapter 34, Fig. 34.19.)

Endoscopic Suturing

Endoscopic sutures are available as ligatures and preknotted loops or with curved or straight, permanently swaged needles for use through



• **Fig. 28.9** Suturing incised abdominal tissue layers. **A,** Peritoneum (continuous stitch, taper-point needle). **B,** Muscle (interrupted stitch). **C,** Anterior fascia (interrupted stitch, cutting needle). **D,** Subcutaneous (not always sutured, taper-point needle). **E,** Skin (interrupted stitch, cutting needle). **F,** Retention sutures. Note bumpers to protect skin.

• BOX 28.1 Suture Gauge Diagram

SMALLER GAUGE					ZERO												LARGER GAUGE			
12-0	11-0	10-0	9-0	8-0	7-0	6-0	5-0	4-0	3-0	2-0	0	1	2	3	4	5	6	7	8	9	10

an endoscope. The ligatures are fashioned into loosely knotted loops before being passed through the endoscope to tie off vessels and tissue pedicles. After the loop is placed around the target site, the knot is slid into position and tightened. The ends are cut with endoscopic scissors and removed through the endoscope. Suture with a permanently swaged needle is placed through either a 3-mm suture introducer for a straight needle or an 8-mm suture introducer for a curved needle. Used to suture vessels, reconstruct organs, approximate opposing tissue surfaces, and anastomose tubular structures, the technique varies according to the method used for knot tying.[3] The methods of endoscopic knot tying are as follows:

- *Extracorporeal method:* The swaged needle and both ends of the suture are brought outside the body through the trocar. The needle is cut off, and the knot is loosely fashioned. The knot is reintroduced into the body through the trocar by means of a knot-sliding cannula. It is snugged into position and tightened against the tissue. The ends of the suture are cut close to the knot with endoscopic scissors. Excess suture ends are removed through the endoscope.
- *Intracorporeal method:* The needle and suture are passed through the tissue with an endoscopic needle holder. Endoscopic instruments are used to tie the knot and cut the suture inside the body.

Specifications for Suture Material

- It must be sterile when placed in tissue. Sterile techniques must be rigidly followed in handling suture material. For example, if the end of a strand drops over the side of any sterile surface, discard the strand. Almost all postoperative wound infections are initiated along or adjacent to suture lines. Affinity for bacterial contamination varies with the physical characteristics of the material.
- It must be predictably uniform in tensile strength by size and material. Tensile strength is the measured pounds of tension or pull that a strand will withstand before it breaks when knotted. Minimum knot-pull strengths are specified for each basic raw material and for each size of that material by the U.S. Pharmacopeia (USP). Tensile strength decreases as the diameter of the strand decreases.
- It must be as small in diameter as is safe to use on each type of tissue. The strength of the suture usually needs to be no greater than the strength of the tissue on which it is used. Smaller sizes are less traumatic during placement in tissue and leave less suture mass to cause tissue reaction. The surgeon ties small-diameter sutures more gently and thus is less apt to strangulate tissue. A small-diameter suture is flexible, easy to manipulate, and leaves minimal scar on skin.
- USP-determined sizes range from heavy 10 (largest) to very fine 12-0 (smallest); ranges vary with materials. Taking size 1 as a starting point, sizes increase with each number above 1 and decrease with each 0 (zero) added. The more zeroes in the number, the smaller the size of the strand. As the number of zeroes increases, the size of the strand decreases. In addition to this system of size designation, the manufacturer's labels on boxes and packets may include metric measures for suture diameters. These metric equivalents vary slightly by types of materials. Box 28.1 shows how suture gauge is measured on a scale in numeric descriptions from smallest to largest.
- It must have knot security, remain tied, and give support to tissue during the healing process. However, sutures in the skin are always removed 3 to 10 days postoperatively, depending on the site of incision and cosmetic result desired. Because they are exposed to the external environment, skin sutures can be a source of microbial contamination of the wound that inhibits healing by first intention.
- It must cause as little foreign body tissue reaction as possible. All suture materials are foreign bodies, but some are more inert (less reactive) than others.

Choice of Suture Material

The surgeon selects the type of suture material best suited to maintain tensile strength and promote healing. Fig. 28.10 shows the labeling of a generic suture packet. When selecting a suture, specific notations about the characteristics of each suture are listed on the box and the packet. Surgical sutures are classified as either absorbable or nonabsorbable:

1. *Absorbable sutures:* Sterile strands prepared from collagen derived from healthy mammals or from a synthetic polymer. They are capable of being absorbed by living mammalian tissue but may be treated or coated to modify resistance to absorption. Some synthetic sutures are coated with a Triclosan or chlorhexidine antimicrobial chemical.[4] They may be colored by a dye approved by the U.S. Food and Drug Administration (FDA).
2. *Nonabsorbable sutures:* Strands of natural or synthetic material that effectively resist enzymatic digestion or absorption in living tissue. During the healing process, suture mass becomes encapsulated and may remain for years in tissues without producing any ill effects.

Sutures may be dyed with a color additive approved by the FDA. They may be modified with respect to body, texture, or capillarity. Capillarity refers to a characteristic of nonabsorbable sutures that allows the passage of tissue fluids along the strand, permitting infection, if present, to be drawn along the suture line. Suture materials may be untreated or may be treated to reduce capillarity. Noncapillarity is the characteristic of some nonabsorbable sutures in which the nature of the raw material or specific processing meets USP tests that establish them as resistant to wicking transfer of body fluids.

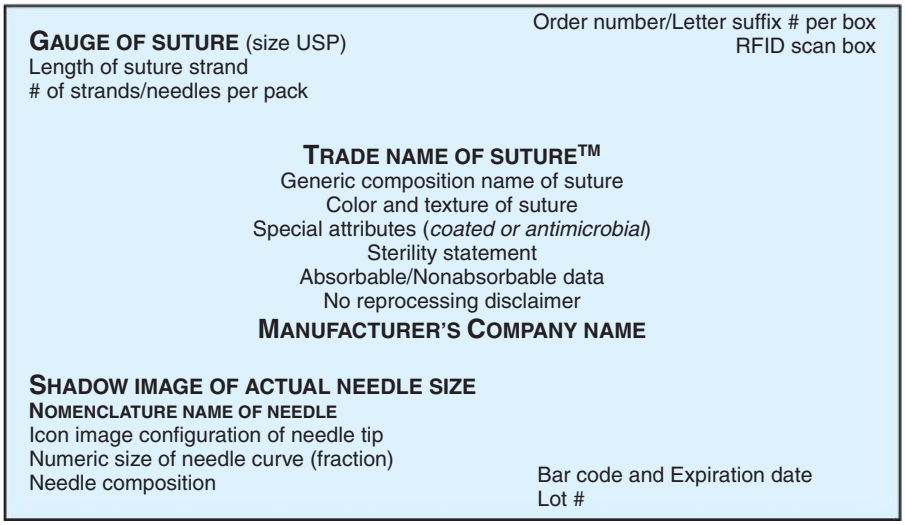
The two classifications of suture materials are subdivided into monofilament and multifilament strands:

1. *Monofilament suture:* A strand consisting of a single threadlike structure that is noncapillary. Monofilament suture is generally less traumatic when pulled through tissue. The smooth surface glides easily without catching on tissue. Some monofilament suture retains its curved shape when removed from the packet. This is referred to as *memory.* Manufacturers recommend that the suture not be tugged on to straighten the strand. It can weaken the integrity.

Each packet is color-coded by type of suture composition for ease of identification when selectiong for a procedure. The package colors are similar between manufacturers for type and chemical makeup of suture.

METHOD TO SELECT A SUTURE FOR A SURGICAL PROCEDURE

1. Identify by color (Trade name)
2. Gauge of suture (more zeros indicate smaller gauge)
3. Size and configuration of needle/tip (actual needle and tip image)
   Double needle image indicates a needle on each end
4. Number of strands/needles per pack (Most packs have one needle/suture combination) (some packs have 3 or 8 swaged-on needles) (Ties can be single, very long, or 12 precut strands)



• **Fig. 28.10** Suture Packet Generic Information.

2. *Multifilament suture:* A strand made of more than one thread-like structure held together by braiding or twisting. This suture strand is capillary unless it is treated to resist capillarity or is absorbable. Multifilament suture has a rougher surface and can be somewhat traumatic as it is pulled through tissue layers. Gut suture has memory and will weaken if stretched for straightening.

The following factors influence suture choice:

- Biologic characteristics of the material in tissue (e.g., absorbable vs. nonabsorbable, capillary vs. noncapillary, or inertness).
- Healing characteristics of tissue. Tissues that normally heal slowly, such as skin, fascia, and tendons, usually are closed with nonabsorbable sutures. Absorbable suture placed through the skin may cause a stitch abscess to develop because it is inclined to act as a culture medium for microorganisms in the pores of the skin. Tissues that heal rapidly, such as stomach, colon, and bladder, may be closed with absorbable sutures. Braided suture can be the nidus for stone formation if placed in moisture reservoirs, such as the urinary bladder.
- Location and length of the incision. Cosmetic results desired may be an influencing factor. The choice of suture is made by determining the best method of closure for minimizing scar formation.
- Presence or absence of infection, contamination, and/or drainage. If infection is present, sutures may be the origin of granuloma formation with subsequent discharge of suture and sinus formation. Foreign bodies in potentially contaminated tissues may convert contamination to infection. Foreign bodies in the presence of some body fluids may cause stone formation, as in the urinary or biliary tract. Braided suture is not used in the presence of infection.
- Patient problems such as obesity, debility, advanced age, and diseases, which influence the rate of healing and time desired for wound support.
- Physical characteristics of the material such as ease of passage through tissue, knot tying, and other personal preferences of the surgeon.

Absorbable Sutures (Table 28.2)

Surgical Gut. Surgical gut is collagen derived from the submucosa of sheep intestine or serosa of beef intestine. Many elaborate mechanical and chemical cleaning processes occur before intestinal ribbons of collagen are spun into strands of various sizes, ranging from the heaviest (size 3) to the finest (size 6-0). Gut is packed in an alcohol solution that is potentially flammable. The manufacturer recommends that gut suture not be rinsed before use. Although the larger sizes are made from two or more ribbons (multifilament), the behavior of surgical gut is that of a monofilament suture. Surgical gut is digested by body enzymes and absorbed by tissue so that no permanent foreign body remains.

Gut is available in plain (untreated) or chromic (treated with chromium salts). Plain surgical gut loses tensile strength relatively quickly. It is used to ligate small vessels and to suture subcutaneous fat. It is not used to suture any layers of tissue likely to be subjected to tension during healing. Fast-absorbing plain surgical gut is specially treated to speed absorption and tensile strength loss. It may be used for epidermal suturing where sutures are needed for no more than a week.

Chromic surgical gut is treated in a chromium salt solution to resist absorption by tissues for varying lengths of time, depending on the strength of the solution and duration and method of the process. Chromic surgical gut is used for ligation of larger vessels

TABLE 28.2 Absorbable Suture

Suture Name	Strand Formation	Sizes Available	Colors	Tensile Strength	Notes
Plain gut	Twisted multifilament	6-0 to 3	Yellow Blue Black	5-10 days	Natural. Duration 70 days. Packed in alcohol solution. Not used in presence of infection.
Chromic gut	Twisted multifilament	7-0 to 3	Brown Blue Black	14-21 days	Natural. Duration 90 days. Packed in alcohol solution. Not used in presence of infection.
Collagen	Twisted multifilament	4-0 to 8-0	Blue		Natural. Available as plain or chromic. Used in eye surgery. Not used in presence of infection.
Maxon[a]	Monofilament	7-0 to 2	Green Clear	60 days	Synthetic. Duration 6 months. Nonantigenic, nonpyogenic. Prolonged approximation without stress. Hydrolytic absorption by tissues. Can be used in presence of infection.
PDS, PDSII[b]	Monofilament	9-0 to 2 10-0 to 7-0	Violet Blue Clear	90 days	Synthetic. Duration 6 months. Nonantigenic, nonpyogenic. Prolonged approximation without stress. Hydrolytic absorption by tissues. Can be used in presence of infection. Antibacterial Irgacare (a form of Triclosan).
Monocryl[b]	Monofilament	6-0 to 2	Golden Clear Undyed Violet	21 days	Synthetic. Duration 91-119 days. Antibacterial Irgacare (a form of Triclosan).
Vicryl[b]	Braided	Coated 9-0 to 2 Undyed 8-0 to 1	Violet Undyed	40 days	Synthetic. Duration 90 days. Coating is a lubricant. Available as 42-day fast absorbing "Vicryl Rapide." Antibacterial Irgacare (a form of Triclosan). Not used in presence of infection.
Velosorb[a]	Braided	6-0 to 1	Violet Undyed	5-10 days	Synthetic. Duration 40-50 days. Not used in presence of infection.
Polysorb[a]	Braided	8-0 to 2	Violet Undyed	21 days	Synthetic. Duration 56-70 days. Not used in presence of infection.
Biosyn[a] Caprosyn[a]	Monofilament	6-0 to 1	Violet Undyed	10 days to 3 weeks	Synthetic. Duration 90-110 days (Biosyn) Duration 56 days (Caprosyn)

[a]Trade name is Covidien.
[b]Trade name is Ethicon.

and for suture of tissues in which nonabsorbable materials are not usually recommended because they may act as a nidus for stone formation, as in the urinary or biliary tracts.

Collagen Sutures. Collagen sutures are extruded from a homogeneous dispersion of pure collagen fibrils from the flexor tendons of beef. Both plain and chromic types are similar in appearance to surgical gut and may be dyed blue. Sizes range from 4-0 through 8-0. These sutures are used primarily in ophthalmic surgery.

Handling Characteristics of Surgical Gut and Collagen.

1. Most surgical gut and collagen sutures are sealed in packets that contain an alcohol solution to keep the material pliable. This solution is mostly alcohol and water but may be irritating to ophthalmic tissues. Hold the packet over a basin and open carefully to avoid spilling fluid on the sterile field or splashing it into your own eyes. Rinsing is necessary only for surgical gut or collagen sutures to be implanted into the eye. Do not soak or the suture will weaken.
2. Surgical gut and collagen sutures should be used immediately after removal from their packets. When the material is removed and not used at once, the alcohol evaporates and the strand loses pliability. Excessive exposure to water or saline will reduce the tensile strength. Before unwinding, the strand can be dipped momentarily in water or saline solution at room temperature; heat will coagulate the protein.
3. Unwind the strand carefully. The suture is stiff and has folded memory. Handle it as little as possible. Never pull or stretch surgical gut; this weakens it. Do not straighten suture by running fingers down the length of the strand; excessive handling with gloves can cause fraying that causes the strand to weaken.

Synthetic Absorbable Polymers. Polymers, either dyed (colored) or undyed (white or clear), are extruded into absorbable suture strands. These synthetic sutures are absorbed by a slow hydrolysis process in the presence of tissue fluids. They are used

for ligating or suturing except when extended approximation of tissues under stress is required. They are inert, nonantigenic, and nonpyrogenic and produce only a mild tissue reaction during absorption. They may be monofilament or multifilament, coated or uncoated.

Handling Characteristics of Synthetic Absorbable Polymers.

- Synthetic absorbable sutures have an expiration date on the package. Therefore rotate stock. "First in, first out" is a good rule to follow.
- Synthetic absorbable sutures are packaged and used dry. Do not soak or dip in water or normal saline solution. The material hydrolyzes in water, so excessive exposure to moisture will reduce the tensile strength. It is smooth and soft and will retain its pliability.

Nonabsorbable Sutures (Table 28.3)

Surgical Silk. Surgical silk is a natural animal product made from the fiber spun by silkworm larvae in making their cocoons.

TABLE 28.3 Nonabsorbable Suture

Suture Name	Strand Formation	Sizes Available	Colors	Tissue Effects	Notes
Silk Sofsilk[a] Perma-hand[b]	Braided	9-0 to 5	Black White	Acute tissue inflammation	Natural fiber coated with silicon or wax. Encapsulates. Not used in presence of infection. Not detectable after 2 years.
Cotton[b]	Twisted strands	Umbilical tape	White	Minimal tissue inflammation	Natural fiber. Moisten before use. Single-strand suture rarely used.
Ethilon[b]	Monofilament	11-0 to 2	Black Green Clear	Minimal tissue inflammation	Synthetic nylon
Nurolon[b]	Braided	6-0 to 1	Black	Minimal tissue inflammation	Synthetic nylon Not used in presence of infection.
Dermalon[a] Monosof[a]	Monofilament	11-0 to 2	Blue Black Clear	Minimal tissue inflammation	Synthetic nylon. Uncoated.
Surgilon[a]	Braided	6-0 to 1	Black White	Minimal tissue inflammation	Synthetic nylon. Silicone coated. Not used in presence of infection.
Prolene[b]	Monofilament	10-0 to 2	Blue Clear	Minimal tissue inflammation	Synthetic. Can be used in a contaminated wound. Available with attached Teflon pledgets.
Pronova[b]	Monofilament	8-0 to 5-0	Blue	Minimal tissue inflammation	Synthetic. Can be used in a contaminated wound.
Surgipro II[a]	Monofilament	8-0 to 2	Blue	Minimal tissue inflammation	Synthetic. Can be used in a contaminated wound.
Vascufil[a]	Monofilament	7-0 to 2-0	Blue	Minimal tissue inflammation	Synthetic. Less memory. Can be used in a contaminated wound.
Novafil[a]	Monofilament	7-0 to 2	Blue Clear	Minimal tissue inflammation	Synthetic. Can be used in a contaminated wound.
Ti-Cron[a]	Braided	7-0 to 5	Blue White	Minimal tissue inflammation	Synthetic. Coated with silicone. Available uncoated. Available with precut pledgets. Not used in presence of infection.
Surgidac[a]	Braided	6-0 to 4-0	White	Minimal tissue inflammation	Synthetic Not used in presence of infection.
Mersilene[b]	Braided Monofilament	10-0 to 5	Green White	Minimal tissue inflammation	Synthetic. Braided form not used in presence of infection.
Ethibond[b]	Braided	7-0 to 5	Green White	Minimal tissue inflammation	Synthetic. Coated with polybutilate. Encapsulates. Available with attached Teflon pledgets. Not used in presence of infection.
Steel	Monofilament Multifilament	6-0 to 7	Silver	Minimal tissue inflammation	Low carbon alloy. Do not handle with serrated instrument. Only use wire scissors to cut. Do not use with metal implant of different alloy.

[a]Trade name is Covidien.
[b]Trade name is Ethicon.

From the raw state, each fiber is processed to remove natural waxes and gums. Fibers are braided or twisted together to form a multifilament suture strand. Braided silk is used more frequently because surgeons prefer its high tensile strength and better handling qualities. Surgical silk is treated to render it noncapillary. The fibers lose tensile strength if wet. Therefore silk sutures should not be moistened before use.

Silk is not a truly nonabsorbable material. It disappears within 2 years. It causes less tissue reaction than does surgical gut, but it is not as inert as most of the other nonabsorbable materials. It is used frequently in the serosa of the gastrointestinal tract and to close fascia in the absence of infection.

Surgical Cotton. Cotton is a natural cellulose fiber. Suture is made from individual, long-staple cotton fibers. Single-strand cotton suture is rarely used because it causes an inflammatory reaction. Cotton umbilical tapes are used to tie umbilical cords or retract tissue structures during a surgical procedure. It should be moistened before it is handed to the surgeon. Moisture prevents clinging to the surgeon's gloves.

Surgical Stainless Steel. Stainless steel sutures are drawn from 316L-SS (L for low carbon) iron alloy wire. This is the same metal formula used in the manufacture of surgical stainless steel implants and prostheses. Two different kinds of metal alloy should not be embedded in the tissues simultaneously. This combination creates an unfavorable electrolytic reaction. Some implants and prostheses are made of Vitallium, titanium, or tantalum. Suture material in the wound must be compatible with these metals.

Before the availability of surgical stainless steel from suture manufacturers, commercial steel was purchased by weight, using the Brown and Sharpe (B&S) scale for diameter variations. Many surgeons still refer to surgical stainless steel size by the B&S gauge, from 18 (the largest diameter) to 40 (the smallest). One manufacturer labels surgical stainless steel with both B&S gauge and equivalent USP diameter classifications. Both monofilament and twisted multifilament stainless steel strands are available.

Surgical stainless steel is inert in tissue and has high tensile strength. It gives the greatest strength of any suture material to a wound before healing begins and supports a wound indefinitely. Some surgeons use stainless steel for abdominal wall or sternal closure or for retention sutures to reduce the danger of wound disruption in the presence of contributing factors. It may be used in the presence of infection or in patients in whom slow healing is expected. It is used for secondary repair or resuturing after wound disruption.

Unlike most other suture materials, steel lacks elasticity. A suture secured too tightly may act as a knife and cut through tissue. Stainless steel sutures are harder to handle than any other suture material. A painstaking knot-tying and twisting technique with a nonserrated instrument is required. The serrations of the instrument will create weak areas along the suture. Wire suture is cut only with wire scissors.

Handling Characteristics of Surgical Stainless Steel Suture.

1. Surgical stainless steel strands are malleable and kink rather easily. Kinks in the strand can make it practically useless. Therefore use care in handling to keep the strand straight.
2. Barbs on the end of a strand can tear gloves, puncture the skin, or traumatize tissue. Sternal wire suture has been known to extrude through the skin if the cut end is not buried deep into the tissue.
3. If surgical stainless steel must be threaded through a needle, some surgeons prefer one or two twists of the end around the strand just below the eye of the needle to prevent unthreading during suturing.

Synthetic Nonabsorbable Polymers. Synthetic nonabsorbable sutures have higher tensile strength and elicit less tissue reaction than does silk. They retain their strength in tissue. Knot tying with most of these materials is more difficult than with silk. Additional throws are required to secure the knot. The surgeon may sacrifice some handling characteristics and ease of knot tying for strength, durability, and nonreactivity of the synthetics. These advantages may outweigh the disadvantages. Synthetic nonabsorbable sutures are available as monofilament or braided strands.

Surgical Nylon. Nylon is a polyamide polymer derived by chemical synthesis from coal, air, and water. It produces minimal tissue reaction. Nylon has high tensile strength, but it degrades by hydrolysis in tissue at a rate of about 15% to 20% per year. It may be used in all tissues where a nonabsorbable suture is acceptable, except when long-term support is critical. It is available in three forms: monofilament, uncoated multifilament, and coated multifilament.

Polyester Fiber. A polymer of terephthalic acid and polyethylene, Dacron polyester fiber is braided into a multifilament suture strand that is available in two forms: uncoated fiber and coated fiber.

1. Uncoated polyester fiber suture is closely braided to provide a flexible, pliable strand that is relatively easy to handle. However, uncoated braided polyester fiber suture has a tendency to drag and exert a sawing or tearing effect when passed through tissue. It may be used in all tissues in which a multifilament nonabsorbable suture is indicated.
2. Coated polyester fiber suture has a lubricated surface for smooth passage through tissue. Sutures are available with different coating materials:
   a. Polybutilate is the only coating developed specifically as a surgical lubricant. This polyester material adheres strongly to the braided polyester fiber. Polyester fiber coated with polybutilate provides a strand superior to any other braided material, coated or uncoated, in decreasing drag through tissue.
   b. Polyfluoroethylene (PTFE), a commercial product known by the name Teflon and manufactured by DuPont, is used as a coating bonded to the surface or impregnated into spaces (interstices) in the braid of the polyester fiber strand. Minute particles of this coating can flake off the strand. Because these particles are insoluble and resistant to enzymes, foreign body granulomas may be produced.
   c. Silicone, a commercial lubricant, provides a slippery coating but does not bond well to polyester fiber. It can become dislodged in tissues as the strand is tied.

Polypropylene Suture. A polymerized propylene is extruded into a monofilament strand. It is the most inert of the synthetic materials and almost as inert as stainless steel. Polypropylene is an acceptable substitute for stainless steel in situations in which strength and nonreactivity are required, and it is easier to handle. The suture may be left in place for prolonged healing. It can be used in the presence of infection.

Handling Characteristics of Synthetic Nonabsorbable Polymers.

1. Physical damage to suture materials can occur from the time the suture is removed from a packet if the strand is mishandled. Handle all sutures and needles as little as possible. Avoid pulling or stretching. Sutures should be handled without using instruments except when grasping the free end during an instrument tie. Clamping instruments—especially needle holders and forceps with serrations—on strands can crush, cut, and weaken them.

TABLE 28.4 Barbed Suture

Barbed Suture	Quill Surgical Specialties Corp	V-Loc Covidien	Stratafix Ethicon
Unidirectional Knotless Loop end	Polypropylene: Clear Nonabsorbable Size 0	V-Loc PBT: Polybutester: Blue Nonabsorbable Size 3-0 to 1 Endo 3-0 to 0	Polypropylene: Undyed Nonabsorbable, Spiral Size 5-0 to 1

	PDO: Violet Absorbable Size 4-0 to 2 180 days	V-Loc 90: Violet or undyed Absorbable Size 4-0 to 2-0 90-110 days	PDO: Violet and Clear Absorbable, Spiral Size 4-0 to 1 120-180 days
Bidirectional Double-armed Knotless	Polypropylene: Clear Nonabsorbable Size 2-0 to 2		Polypropylene: Clear Nonabsorbable, Spiral Size 5-0 to 1
	Nylon: Blue Nonabsorbable Size 1 to 2		
	Monoderm: Violet or Clear Absorbable Size 4-0 to 0 90-120 days		PGA-PCL: Violet or Clear Absorbable, Spiral Size 5-0 to 1
	PDO: Violet Absorbable Size 4-0 to 2 180 days		PDO: Violet and Clear Absorbable, Spiral Size 5-0 to 1 120-180 days

2. All synthetic materials require a specific knot-tying technique. Knot security requires additional flat and square ties. Multifilament materials are generally easier to tie than are monofilament sutures.

Barbed Suture (Table 28.4)

Barbed Suture. This synthetic self-anchoring suture is used for low-tension suturing without the need of knotted ends. Barbed synthetic suture is available in absorbable and nonabsorbable material. Handling barbed suture is done with care. The barbs are tiny but still can snag on sponges or drapes. Use of barbed suture has many applications in several specialties. Barbed suture has two different configurations: unidirectional barbs and bidirectional barbs.

Unidirectional barbed suture has a needle on one end and a loop on the other end. The loop can be used to anchor the suture in place of a knot. The barbs are designed to pull through the tissue in one direction and maintain placement without moving. At the completion of closure the needle can be cut off without losing stability of the wound.

Bidirectional barbed suture is double-armed and has raised barbs that are angled from the center to the ends in both directions. During closure the suture is placed with a slight reverse torque to anchor the barbs into the dermis from the center in one direction, and then the reverse is performed in the opposite direction. The result is a well-approximated incision line.

Surgical Needles

Except for simple ligating with free ties, surgical needles are needed to safely carry suture material through tissue with the least amount of trauma. Each packet is opened and counted during the initial sharps count. The best surgical needles are made of high-quality tempered steel that is:

- Strong enough that it does not break or fracture easily
- Rigid enough to prevent excessive bending, yet flexible enough to prevent breaking if bent
- Sharp enough to penetrate tissue with minimal resistance (yet it need not be stronger than the tissue it penetrates)
- Approximately the same diameter as the suture material it carries to minimize trauma in passage through tissue
- Appropriate in shape and size for the type, condition, and accessibility of the tissue to be sutured
- Free from corrosion and burrs to prevent infection and tissue trauma

Because needles are made of steel, theoretically they are detectable by x-ray if inadvertently lost in tissue. The location in tissue may preclude the needle from appearing on a radiograph. For example, the angle of the needle or its position behind bone may obstruct detection. The smaller the size of the needle, the more likely the image is to be obstructed. All needles should be accounted for in their entirety so that they do not become foreign bodies in tissue. Lost

needles can become embedded in linen or trash, causing harm to unsuspecting support personnel.

Many shapes and sizes of surgical needles are available. Names vary from one manufacturer to another; general classification only, not nomenclature, is standardized. They may be straight like a sewing needle or curved. All surgical needles have three basic components: the point, the body (or shaft), and the eye. They are classified according to these three components.

Point of the Needle

Points of surgical needles are honed to the configuration and sharpness desired for specific types of tissues. The basic shapes are cutting, tapered, and blunt (Fig. 28.11).

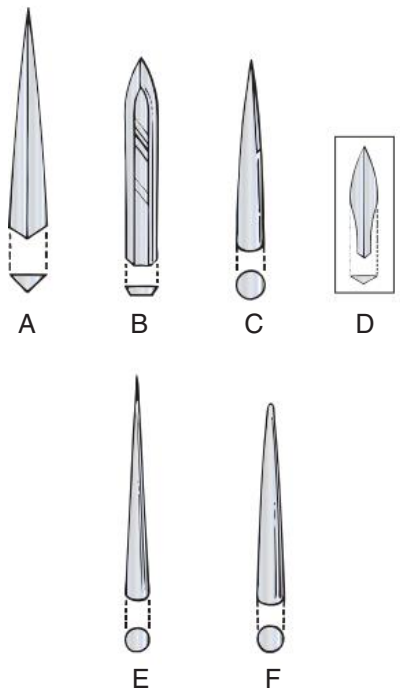
Cutting Point

A razor-sharp, honed cutting point may be preferred when tissue is difficult to penetrate, such as skin, tendon, and tough tissues in the eye. These make a slight cut in tissue as they penetrate. The location and degree of sharpness of cutting edges vary. Cutting needles are less traumatic as they pass through tissues.

Conventional Cutting Needles. Two opposing cutting edges form a triangular configuration with a third edge on the body of the needle. Cutting edges are on the inside curvature of a curved needle. Cutting edges may be honed to precision sharpness to ensure smooth passage through tissue and a minute needle path that heals quickly.

Reverse-Cutting Needles. A triangular configuration extends along the body of the needle. The edges near the point are sharpened or honed to precision points. The two opposing cutting edges are on the outer curvature of a curved needle.

Side-Cutting Needles. Relatively flat on the top and bottom, angulated cutting edges are on the sides. Used primarily in ophthalmic surgery, they will not penetrate underlying tissues. They split through layers of tissue.



• **Fig. 28.11** Configurations of needle points. **A,** Conventional cutting and reverse cutting. **B,** Side cutting. **C,** Cutting edge at end of tapered body with **D,** trocar point, **E,** taper, and **F,** blunt.

Trocar Point

Sharp cutting tips are at the points of tapered needles. All three edges of the tip are sharpened to provide cutting action with the smallest possible hole in tissue as it penetrates.

Taper Point

These needles are used in soft tissues, such as intestine and peritoneum, which offer a small amount of resistance to the needle as it passes through. They tend to push the tissue aside as they go through, rather than cut it. The body tapers to a sharp point at the tip.

Blunt Point

These tapered needles are designed with a rounded blunt point at the tip. They are used primarily for suturing friable tissue, such as liver and kidney. Because the blunt point will not cut through tissue, it is less apt to puncture a vessel in these organs than is a sharp-pointed needle. Blunt needles also may be used in some tissues to reduce the potential for needlesticks, especially in general and gynecologic surgery.

Body of the Needle

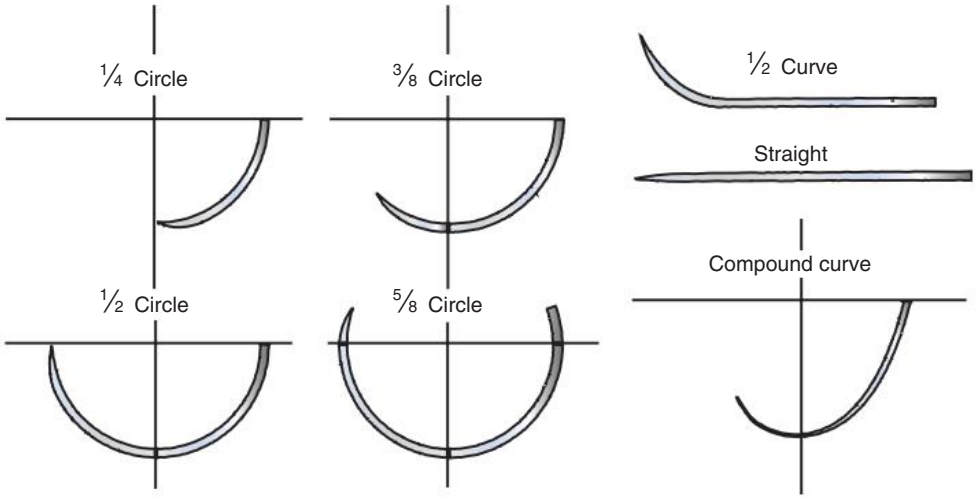
The body, or shaft, varies in wire gauge, length, shape, and finish. The nature and location of tissue to be sutured influence the selection of needles with these variable features. Most manufacturers have designated a specific alphanumeric code to describe each needle they produce. Examples of alphanumeric codes for taper-point needles can be found in Table 28.5.

Considerations relating to the body of the needle are as follows:

1. Tough or fibrosed tissue requires a heavier gauge needle than the fine-gauge diameter needed in microsurgery.
2. The depth of the bite (placement) through tissue determines the appropriate needle length.
3. The body of the needle may be round, oval, flat, or triangular. The point determines the shape: round or oval bodies have trocar, taper, or blunt points; flat or triangular bodies have cutting edges. The shape also may be straight or curved (Fig. 28.12).
   a. Straight needles are used in readily accessible tissue. They have cutting points for use in skin, which is their most frequent use, or tapered points for use in intestinal tissue held by a **purse string** device. They are not used with a needle holder.

TABLE 28.5 Select Examples of Common Taper-Point Needles (Alphanumeric Codes) and Representative Manufacturers

Purpose	Ethicon	Covidien	Configuration
General closure	CT	GS 24	½ circle taper 40 mm
General closure	CT 1	GS 21	37 mm
Cardiovascular	RB	EV 23	17 mm
Gastrointestinal	SH	EV 20	25 mm
Multilayer closure	CTX	GS 25	48 mm
Cardiovascular	BB	CV 15	⅜ circle taper 17 mm
Urologic	UR 6	GU 46	⅜ circle taper 27 mm



• **Fig. 28.12** Shapes of needle bodies.

b. Curved needles are used to approximate most tissues, because quick needle turnout is an advantage. The curvature may be ¼, ⅜, ½, or ⅝ circle; half-curved with only the tip curved; or compound curved. Curved needles always are armed in a needle holder before being handed to the surgeon.
c. J-shaped needles range from 15.5 cm to 17.5 cm in length. The width of the J bend at the tip is available in 7 to 9-mm curvature. They are used for 10 to 14-mm fascial incisions created for trocar use during laparoscopy. They are multiuse needles that can be threaded with the suture of the surgeon's choice at the point of use. Their unique shape enables the surgeon to close the deep layers of the wound without perforation of underlying organs while visualizing closure of the accessory ports with the laparoscopic camera.

4. Curved needles that have longitudinal ribbed depressions or grooves along the body on the inside and outside curvature can be cross-locked in the needle holder. This feature virtually eliminates twisting or turning of the needle in any position in the needle holder.
5. In all needles the body must have a smooth finish. Many needles have a surface coating of microthin plastic or silicone to enhance smooth passage through tissue. Others have a black surface finish to enhance visibility at the surgical site.

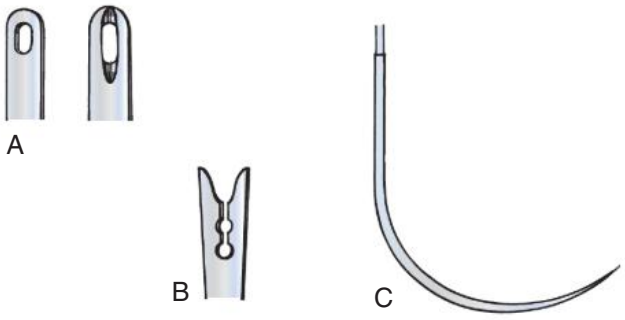
Eye of the Needle

The eye is the segment of the needle where the suture strand is attached. Surgical needles are classified as eyed, French eye, or swaged or atraumatic. Swaged-on suture is inserted directly into the end of the needle by the manufacturer (Fig. 28.13, *C*).

Eyed Free Needle

The closed eye of an eyed surgical needle is like that of any household sewing needle. Needles that are threaded by the scrub person are referred to as *free needles.* The shape of the enclosed eye may be round, oblong, or square. The end of the suture strand is pulled 2 to 4 inches (5 to 10 cm) through the eye so the short end is about one-sixth the length of the long end. Unlike regular sewing thread, there is no knot placed in the end of the suture.

Disposable varieties are preferred. Some specialty needles will be packed in-house on a needle rack. Care is taken when handling these needles. Careful counting and accountability are required. In some cases, if a swaged suture breaks during a procedure, the surgeon may request a free needle to complete the suturing process.



• **Fig. 28.13** Eyes of free needles and swaged-on needles. **A,** Oblong eyes. **B,** French eye. **C,** Swaged.

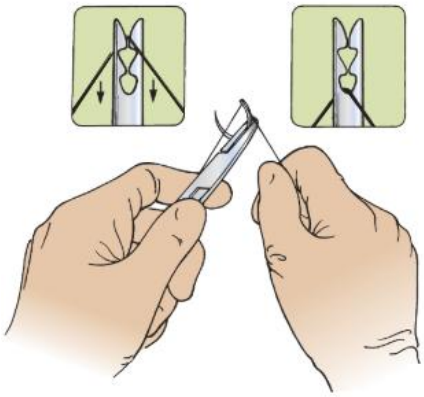
French Eye Needle

Sometimes referred to as *spring eye* or *split eye,* a French eye needle has a slit from the inside of the eye to the end of the needle through which the suture strand is drawn. To thread a French eye after arming the needle in a needle holder, 2 to 3 inches (5 to 7.5 cm) of the strand is secured between the fingers holding the needle holder. The strand is pulled taut across the center of the V-shaped area above the eye and drawn down through the slit into the eye (Fig. 28.13, *B,* and Fig. 28.14).

French eye needles, as a general rule, are used with pliable braided materials, primarily silk and cotton, of medium or fine size. These needles are not practical for surgical gut; the strand may fray, or the eye may break because the diameter is usually too large for the slit.

Handling of Free Needles. Eyed and French eye needles have the following disadvantages for the scrub person, surgeon, and patient:

- Each needle must be carefully inspected by the scrub person before and after use for dull or burred points and defects in the eye.
- Care must be taken to avoid puncturing gloves with the needle point when threading.
- If the scrub person must choose an appropriate needle to thread, the needle should be the same approximate diameter as the suture size requested by the surgeon.



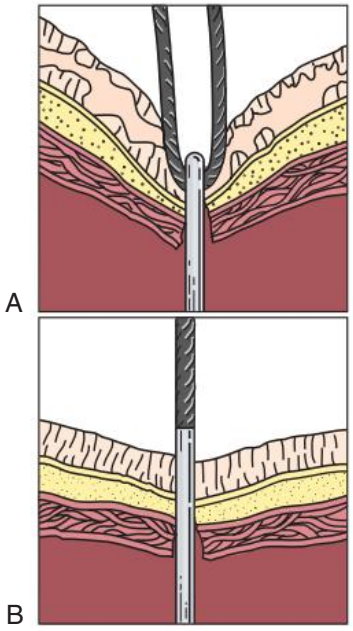
• **Fig. 28.14** To thread French eye needle, pull strand taut across center of V-shaped area and draw down through slit into eye.

- Needles can unthread prematurely. This is an annoyance to the surgeon and prolongs operating time for the patient. To avoid this, the surgeon may prefer the suture strand threaded double with both ends pulled the same length through the eye. The scrub person may lock the suture strand by threading the short end through the eye twice in the same direction.
- Two strands of suture material are pulled through tissue when threaded needles are used. The bulk of the double strand through the eye creates a larger hole than the size of the needle or suture material, causing additional trauma to tissue.

Swaged-on Needle

A swaged-on needle is a continuous unit with the suture strand. The needle is swaged onto the end of the strand in the manufacturing process. This eliminates threading at the operating room (OR) bed and minimizes tissue trauma, because a single strand of material is drawn through tissue (Fig. 28.15). The diameter of the needle matches the size of the strand. The surgeon uses a new sharp needle with every suture strand. Usually referred to as *swaged needles,* three types of swaged-on needle-suture attachments are available.

1. *Single-armed attachment:* One needle is swaged to a suture strand. Some larger closure needles can have the end looped back into the needle. This suture is much longer and can be used to form looped-locking closure.
2. *Double-armed attachment:* A needle is swaged to each end of the suture strand. The two needles are not necessarily the same size and shape. These are used when the surgeon wishes to place a suture and then continue to approximate surrounding tissue on both sides from a midpoint in the strand. Barbed suture is packed this way, for example.
3. *Controlled-release needle attachment:* This attachment is secure, so the suture strand will not separate from the needle inadvertently, but it will release rapidly when pulled off intentionally. It is usually only single-armed. The surgeon grasps the suture strand just below the needle, pulling the strand taut, and releases the needle with a straight tug of the needle holder on the needle. This facilitates fast separation of the needle from the suture when desired. This type of needle is referred to as a *pop-off needle.*



• **Fig. 28.15** Tissue effects of needle penetration. **A,** Threaded. **B,** Swaged atraumatic.

Placement of the Needle in the Needle Holder

Needle holders have specially designed jaws to securely grasp surgical needles without damage if they are used correctly. Care is taken not to use needle holders for anything other than holding needles. The jaw can weaken or spring, causing the needle to twist and turn when suturing. The scrub person should observe the following principles in handling needles and needle holders:

1. Select a needle holder with appropriate-size jaws for the size of the needle to be used. An extremely small needle requires a needle holder with very fine tipped jaws. As the wire gauge of the needle increases, the jaws of the needle holder selected should be proportionately wider and heavier. Curved jaws or angulated handles may be needed for placement of the needle in tissues.
2. Select an appropriate-length needle holder for the area of tissue to be sutured. When the surgeon works deep inside the abdomen, chest, or pelvic cavity, a longer needle holder will be needed than is needed in superficial areas.
3. Clamp the body of the needle in an area one-fourth to half the distance from the eye to the point (Fig. 28.16). Never clamp the needle holder over the swaged area. This is the weakest area of a swaged-on needle because it is hollow before the suture strand is attached. Pressure on or near the needle-suture juncture may break the needle.
4. Place the needle securely in the tip of the needle holder jaws, and close the needle holder in the first or second ratchet. If the needle is held too tightly in the jaws or the needle holder is defective, the needle may be damaged or notched in such a manner that it will have a tendency to bend or break on successive passes through tissue.

• **Fig. 28.16** Correct position of curved needle in needle holder for right-handed surgeon, about one-third down from swage or eye.

If the needle breaks, it must be accounted for in its entirety. All pieces and fragments must be retrieved from the patient's body and the surrounding environment for personnel safety.

5. Pass the needle holder with the needle point up and directed toward the surgeon's thumb when grasped so it is ready for use without readjustment. If a hands-free technique is preferred, place the needle holder on a tray or magnetic mat with the needle point facing down.
6. Hand the needle holder to the surgeon so the suture strand is free and not entangled with the needle holder. Hold the free end of the suture in one hand while passing the loaded needle holder with the other hand. Protect the end of the suture material from dragging across the sterile field. The assistant may take hold of the free end to keep the strand straight for the surgeon and to keep it from falling over the side of the sterile field. This is referred to as *trailing the suture.*
7. Hand the needle holder to an assistant to pull the needle out through tissue. A hemostat or other tissue forceps is not used for this purpose because the instrument may be damaged or may damage the needle. The needle should be grasped as far back as possible to avoid damage to the point or cutting edges.

Considerations in the Choice of Sutures and Needles

The surgeon chooses from available types and sizes of sutures and needles, the ones that best suit each purpose. In general, fine sizes are used for plastic, ophthalmic, pediatric, and vascular surgery; medium sizes are used for all other kinds of surgery; heavy sizes are used for retention and for anchoring bone. In general, cutting needles are used in tough tissue such as skin, fascia, tendon, and mucous membranes, including the cervix, palate, tongue, and nose. Medium tissue calls for round taper-point or cutting needles. Round taper-point needles generally are used for nerve, peritoneum, muscle, and other soft tissue, such as lung and intestine, subcutaneous tissue, and dura.

It is almost impossible to learn the needle-tissue-suture-surgeon combinations by memory alone because of the unlimited number of combinations. Learning the general classification of needles, sutures, and tissues is the first step; practical experience is necessary to remember the combinations. Try to learn the suture and needle combinations most commonly used.

The preference card usually lists the surgeon's usual suture-and-needle routine by tissue layer. Some cards list swaged-on sutures by order number, but this can be confusing. Some of the order numbers include alphanumeric labels that refer to how many sutures are packed in a box. This has nothing to do with the suture itself. Others list sutures by size and materials and needles by size and shape, which is easier to follow. Suture and needle sizes are as variable as patient sizes. Therefore the surgeon may unexpectedly request a smaller or larger size out of routine for a particular patient's situation.

Each manufacturer produces different needle styles. Most types have a comparable counterpart in another brand name. Table 28.5 describes cross-referencing of needle types by alphanumeric codes among different manufacturers.

Packaging and Preparation of Sutures and Needles

Suture material is individually packaged and supplied sterile by the manufacturer. It is sterilized by cobalt-60 irradiation or ethylene oxide gas. Reprocessing of suture material is not recommended. It can be damaged and is not guaranteed to be sterile.

Swaged needles come in sterile packets attached to the suture material. The suture needles are counted as the packet is dispensed to the field and confirmed as they are opened. When the swaged-on suture is opened in the field the contents are verified. Discard the outer sterile packet as soon as the suture is opened. Saving the empty packet on the field is not a reliable way to keep track of the number of suture needles used.

Disposable eyed and French eye needles are individually packaged and sterilized by the manufacturer. Needles are counted when dispensed to the sterile field one at a time and only as needed. Single-use needles ensure a sharper point with less tissue trauma.

Preparation of Reusable Needles

Standard sets of reusable eyed and French eye needles may be prepared for each surgical procedure where they are used. This necessitates preparing more needles in a package than will actually be used. The margin for error in counting increases when too many needles are present on the field. Choose needles for each procedure according to each surgeon's preferences as listed on the preference card.

Packaging of Suture Materials

A strand of sterile suture material is supplied with as many as four coverings.

Box

Each box is sealed in cellophane and contains one, two, or three dozen packets of sterile suture material. The label on the box may be color-coded by suture material (e.g., light blue for silk, tan for chromic gut, yellow for plain surgical gut). Competing manufacturers frequently select similar colors for box labels and suture material identification. Most boxes fit into a suture cabinet rack. Many synthetic sutures have expiration dates because the material degrades with time. Each box is provided with a lot number that corresponds to the lot number on the individual suture packets.

Overwrap

Each individual suture packet has a sealed outer overwrap. The overwrap is peeled back to expose the inner primary sterile packet for aseptic transfer to the sterile table. The circulating nurse must not contaminate the sterile inner primary packet as the overwrap is peeled apart and the packet is transferred onto the sterile table or presented to the scrub person.

Primary Sterile Packet

Suture material, with or without swaged needles, is sealed in a sterile primary inner packet that is to be opened by the scrub person. The primary packet may be made of foil, paper, or plastic, or combinations of these. Labels may be color-coded by material, the same as the box. If a swaged needle is enclosed, a silhouette of the needle is included on the label, along with the size and type of suture material.

A single strand of material or multiple strands may be in the primary packet. The packet may be designed for dispensing individual strands from a multiple suture packet. Packaging configurations and considerations include the following:

1. Suture packets should be opened only as needed, to minimize waste.

2. Custom kits with multiple suture packets within a single package facilitate dispensing sutures to and organizing them on the sterile table. The kit may have appropriate sutures, with or without swaged needles, to meet the requirements of a particular surgeon or procedure. The packets are organized in order of use. The contents are listed on the cover of the package to facilitate counts. Expiration date will be printed on the outer label if synthetic suture is inside.
3. Sterile suture packets are labeled "Do Not Resterilize." Component layers of the packaging materials cannot withstand exposure to the heat of steam sterilization without potential physical damage to the contents and packets. The manufacturer will not guarantee product stability or sterility for packets resterilized in the hospital or in secondary processors, or for strands removed from packets and sterilized.
4. Some suture materials have an expiration date stamped on the box and primary packet to indicate the stability of the material. Oldest sutures should be used first. Sutures should not be used past this expiration date because the chemical composition may have started to degrade, and the safety and stability of the suture is in question.

Inner Dispenser Matrix

Suture material is contained within the primary sterile packet in a manner that facilitates removing or dispensing it. This may be a paper folder, reel, or plastic tray that may or may not be removed with the suture strands. The inner matrix keeps the suture from tangling as it is pulled out for use.

Preparation of Suture Material

The length of each strand of suture material within the primary packet varies; the shortest is 5 inches (approximately 13 cm), and the longest is 60 inches (152 cm). The most commonly used lengths range from 18 to 30 inches (46 to 76 cm). The length the surgeon prefers should be noted on the preference card. The scrub person may have to cut the strands to the desired length, depending on the lengths available.

Standard Length

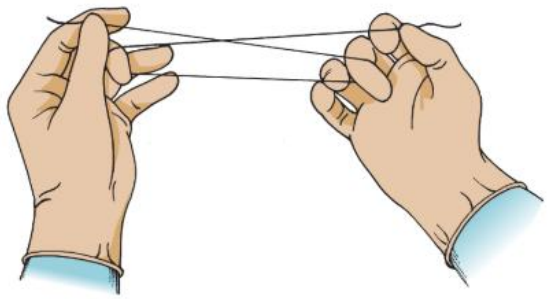
The term *standard length* refers to a 60-inch (152-cm) strand of nonabsorbable material or a 54-inch (137-cm) strand of absorbable material without a swaged needle referred to as a *free tie.* It is not handed to the surgeon in this length. The scrub person may cut it into a half- length, or third length for use as a free tie (suture ligature), or thread it for a stick tie or suture, as shown in Figs. 28.17 and 28.18.

Ligating Reels

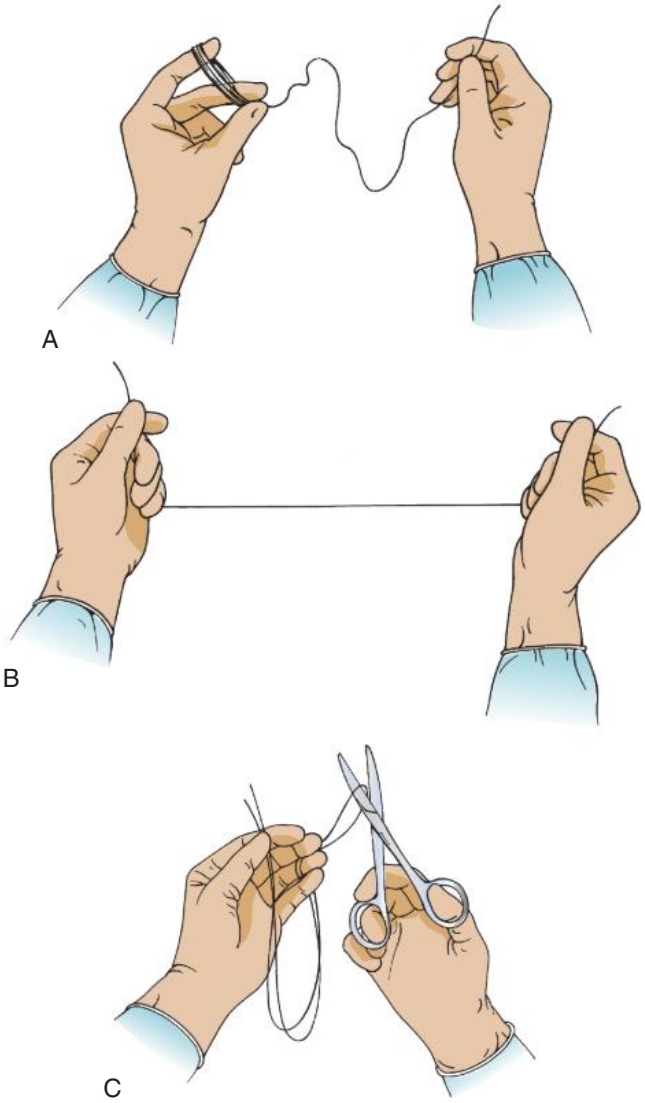
Twelve-foot (approximately 4-m) lengths of nonabsorbable or 54-inch (137-cm) lengths of absorbable suture are wound on disposable plastic reels. These reels are color-coded by material and have size identification. The surgeon keeps the reel in the palm of the hand for a series of free ties. The reel is radiopaque in case it is inadvertently dropped in a body cavity. These are counted items.

Precut Lengths

Most suture materials are supplied in precut lengths of 12 to 18 inches and are ready for use as free ties or for threading. These facilitate handling for the scrub person. They are dispensed individually from some primary packets or may be removed and placed in a fold of a towel near the sterile field. Packets contain from 3 to 17 strands, depending on the material.



• **Fig. 28.17** Scrub person preparing one-third–length sutures. One free end of full-length strand is passed from right to left hand. At the same time, loop is caught around third finger of right hand. Other loop is caught around third finger of left hand while each end is held and suture is adjusted to equal lengths (thirds). Then each loop is cut with scissors.



• **Fig. 28.18** Sequence of scrub person preparing half-lengths. **A,** Suture loops are separated by fingers of left hand while unwinding. **B,** Full length is gently unwound and straightened before cutting. Scrub person does not pull hard or test strand, but keeps firm grasp on both ends to prevent suture from snapping away and possibly becoming contaminated. **C,** Suture is bent in half, and loop is cut.

Swaged Needle-Suture

The manufacturer predetermines lengths of sutures; however, the surgeon has a wide variety of choices to meet all suturing needs. The scrub person must remember that a strand can be shortened but not extended. An appropriate length for location of tissue must be handed to the surgeon. A packet may contain one suture strand armed with a single or double needle(s) or multiple strands with swaged needles.

The sterile package will depict the needle image of a single-armed suture or two needles in a double-armed suture. The package will also indicate how many sutures are enclosed. The number of suture needles recorded on the pack is reported to the circulating nurse during the count.

Surgical Staples

Surgeons can join many tissues with staples. This involves inserting stainless steel or titanium staples through tissues with a stapler—a device specifically designed for this purpose. Some surgical procedures have become simplified or feasible since the advent of surgical stapling techniques. Titanium internal staples are preferred.

As Hümer Hültl recognized in 1908, for internal stapling to be successful, fine wire as the basic material must form a B shape when stapled into tissue. This shape allows blood to flow through tissues, preventing necrosis secondary to devascularization beyond the staple line. Sufficient pressure must be exerted, however, to provide hemostasis of cut tissues.

Skin staples form a D shape when placed with the stapler. The box shape of the staple allows for adequate blood flow through the dermal layers. The length and width of the staples must accommodate tissue being approximated or transected. The number of staples varies with the length of the staple line.

Individual titanium ligation clips used for hemostasis form a completely occlusive, flat closure. Unlike the protection of blood flow in the shape of internal staples and skin staples, complete closure of the clipped structure is critical to prevent blood loss.

Advantages of Using Staples

Staples can be used safely in many types of tissues and have a wide range of applications.

- Stapling is a rapid method of ligating, anastomosing, and approximating tissues. The time saved, compared with suturing techniques, reduces blood loss and total operating and anesthesia time for the patient.
- Wound healing may be accelerated because of minimal trauma and the nonreactive nature of metallic staples.
- Staples produce an even surface and an airtight, leakproof closure.
- Staples can be placed through an endoscopic trocar.

Stapling Instruments

Each stapler is designed for stapling specific tissues (i.e., skin, fascia, bronchus, gastrointestinal tract, vessels). The surgeon selects the correct instrument for the desired application. The consequences of an erroneous staple application, however, are much more difficult to correct than those of manually placed sutures. The surgeon must learn when and how to use each instrument. Whether the stapler is reusable or a single-use disposable, the basic technical mechanics of stapling are the same.

Staplers either fire a single staple or simultaneously fire straight or circular rows of staples. The rows can be double or triple-staggered staple lines. A different instrument must be used for each type of staple cartridge.

Skin Stapler

To approximate skin edges, the stapler fires a single staple with each squeeze of the trigger. Edges of both cuticular and subcuticular layers are aligned, with the edges slightly raised in an everted direction with Adson pick-ups with teeth, as close to their original configuration on the horizontal plane as possible. Care is taken not to perforate the skin with the tips of the pick-ups. The stapler is positioned over the line of incision so that the staple will be placed evenly on each side. The staple forms a rectangular D shape over the incision. As many staples as needed are placed to close the incision.

Skin staplers are supplied preloaded with different quantities of staples in varying widths (i.e., crown span). The most appropriate stapler should be chosen for the selected use. For example, an average range of 28 to 35 staples is needed to close most abdominal incisions. More may be needed to close the chest; fewer may be needed for an inguinal herniorrhaphy.

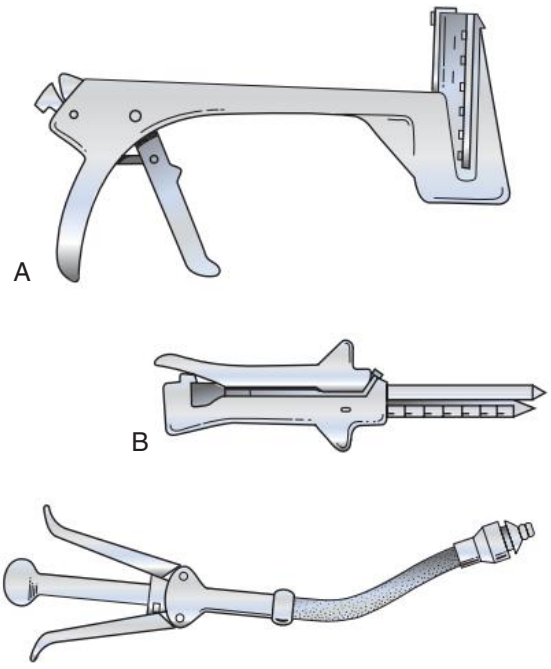
Skin staples are removed 5 to 7 days postoperatively. Extractors are used for this purpose. As it heals, the skin flattens out to form an even surface with excellent cosmetic results if the staples have been properly placed lightly over the skin. Embedded staples are difficult to remove, and results may be less than desired.

Internal Staplers

Internal staplers are used to separate, anastomose, or occlude vessels and internal organs. They are manufactured as reusable stainless steel instruments with cartridges, single-use instruments with cartridges, or single-use single-fire disposable instruments.

Several internal staplers used for separation and anastomosis have self-contained knives. Some occlusion models do not have knives. They only create a reinforced staple line. The surgeon can trim away excess tissue along the staple line with a scalpel.

Staplers with cartridges and knives can be used on the same patient throughout the entire procedure. As the staples are fired and the knife used, the scrub person carefully changes the cartridge without disturbing the next load of staples. Fig. 28.19



• **Fig. 28.19** Internal staplers. **A,** Terminal end stapler. **B,** Internal anastomosis stapler with linear knife. **C,** End-to-end stapler with circular knife.

shows the three most common styles of internal staplers that can be reloaded or purchased as single-fire instruments.

To avoid unnecessary contamination of a sterile instrument, the package should not be opened until the surgeon determines the correct size for the intended use of the stapler. Staplers should never be flipped or dumped onto the field. The impact can cause misalignment of the staples or internal knife and result in misfire. This could cause problems during the procedure and possibly cause an anastomotic leak postoperatively. The circulating nurse should open the package aseptically, and the scrub person should lift the instrument out of the sterile pack. A misfired stapler and its packaging should be given to the supervisor in charge for inspection by the manufacturer.

The numbers and sizes of staples in cartridges vary; the length of the linear jaws or the diameter of the circular head varies for internal use. Internal staplers are available with either stainless steel or titanium staples. The surgeon may prefer titanium, because it creates less distortion when CT scans are used. Titanium staples are safer for use in MRI because they are nonmagnetic. Care is taken to discard any used staple device in the designated container at the end of the surgical procedure for the safety of the surgical services personnel.

Linear Stapler

Two staggered or side-by-side straight double or triple rows of staples are placed simultaneously in tissue with a linear stapler. This stapler is used throughout the alimentary tract and in thoracic surgery for transection and resection of internal tissues. The tissue is positioned in the straight jaws of the stapler. The gap between the jaws must be adequate for the thickness of tissues. Terminal anastomosis (thoracoabdominal [TA]) staplers have no built-in knife. Excess tissue is trimmed away after firing with a scalpel before the instrument is removed. TA is commonly used to close a side or end of a structure such as a segment of bowel or the lobe of a lung.

Gastrointestinal anastomosis (GIA) staplers have a knife that is run between the two staple lines to separate tissue after firing. GIA staplers are commonly used to join two tubular segments side-by-side to form a pouch. They also can be used to close a terminal end of an organ. GIA is commercially available without a knife, referred to as *SGIA.*

The number of staples that will be fired depends on the length of the stapler jaws. The TA and GIA instruments can be reloaded with a second staple cartridge for use on the same patient. The instrument is discarded at the end of the surgical procedure. Single-use disposable models are available.

Intraluminal Circular Stapler

With the circular stapler a double row of staggered staples is placed in a circle for intraluminal end-to-end anastomosis (EEA) of tubular hollow organs in the gastrointestinal tract. Because the diameter of the lumen of organs in the alimentary tract varies, the surgeon must choose a stapler with an appropriate head circumference size. The number of staples the instrument fires depends on its head size. The instrument can be reloaded with a new staple-cutting head for second use on the same patient. Single-fire models are available. The EEA stapler is available curved or straight.

A circular knife within the head of the EEA stapler trims tissue to produce a round lumen as the stapler is fired. The result is a circular anastomosis and two distinct tissue rings, intact circles of tissue from the anastomosed region referred to as *doughnuts.* These are sent as two separate specimens to be examined for intactness. Care is taken to keep the distal and proximal tissue circles separate, so if cancerous margins are present, they will be correctly identified if a second resection is required.

Ligating and Dividing Stapler

A double row of two staples each ligates tissue and vessels that are then divided simultaneously between the staple lines with a cutting knife incorporated into the stapler. The staple configuration after firing is flat like a ligating clip. Hemostasis is attained. This disposable stapler is used primarily to ligate and divide omental vessels or other small, soft tubular structures. The working end is curved to encircle the vessel as it is ligated and cut. Some types have built-in carbon dioxide (CO_2) cartridges referred to as *powered LDS* (ligate-divide-staple).

Endoscopic Stapler

Endoscopic staplers are available for ligating and dividing and for linear stapling. The stapling device is passed through an 11 or 12-gauge laparoscopic trocar. It may be reloaded several times with staple cartridges for multiple firings. The stapler is discarded in the sharps container after single-patient use.

Clips

Multiload or single-load ligating clips are used to completely occlude vessels as needed. Titanium is the usual composition. Clips are applied to individual vessels with a clip application instrument and are designed to close flat. They do not cut tissue. The purpose is to permanently occlude the vessel. The instrument can be a reusable ring-handled stainless instrument or a disposable preloaded plastic applicator. Care is taken not to prematurely squeeze the handles as the instrument is passed to the surgeon. Squeezing will cause the clip to fall from the jaws of the instrument before it can be applied to the vessels.

Tissue Adhesives

Conventional suturing and stapling materials hold tissues in apposition during the healing process. Sutures and staples will not fuse or bond tissues. Ancient Egyptians used resins and gums to hold tissue surfaces together. Research is ongoing for an ideal tissue adhesive that will bond tissue, effect hemostasis, promote regeneration of cells, and serve as a barrier to microbes, fluid, and air. Biologic and synthetic tissue adhesives have extensive potential applications for wound closure and reconstruction.

Biologic Adhesives

Fibrin sealants, most commonly called *fibrin glue,* act as biologic adhesives and hemostatic agents. The components are fibrinogen, cryoprecipitate from human plasma; calcium chloride; and reconstituted thrombin of bovine origin. When applied directly to tissues, thrombin converts fibrinogen to fibrin to produce a clot. Fibrin sealants can be applied to deeper tissues as a liquid, gel, or aerosol spray to control bleeding and approximate tissues technically difficult to approximate by suturing, especially after resections or traumatic injuries of friable or highly vascular tissues, such as liver, spleen, and lung. Each component is applied simultaneously with separate syringes to prevent congealing before application to the tissue site. It is not mixed ahead of use or it will congeal and be useless. A sample formula and supplies for fibrin glue compound are found in Box 28.2.

• BOX 28.2 Sample Fibrin Glue Compound and Supplies

Sterile specimen cup
Two 2-mL disposable syringes
Two 14-gauge intravenous (IV) catheters
6 units thawed cryoprecipitate
1 ampule calcium chloride (CaCl) (10%, 1 g)
50,000 units thrombin

Instructions

Mix CaCl and thrombin in the specimen cup. Draw into the 20-mL syringe, and attach a 14-gauge IV catheter. Draw cryoprecipitate into the second syringe with a 14-gauge IV catheter on the end. Both syringes are discharged over the wound at the same time. The fibrin glue will form a clot over the wound. This method can be used if commercial fibrin glue is unavailable.

Fibrin glue may be used for microsurgical anastomoses of blood vessels, nerves, and other structures such as fallopian tubes; for reconstruction of the middle ear; to fix ocular implants; to close superficial lacerations and fistula tracts; and to secure some skin grafts. It may be used as a carrier for demineralized bone powder to promote osteoregeneration.

Tisseel is a topical fibrin sealant produced by Baxter Healthcare Corporation that can be applied by a duo syringe or a spray. Tisseel is derived from the human blood proteins fibrin and thrombin and is applied in the same manner as earlier forms of fibrin sealant. No bovine components are used. Aprotinin is an antifibrinolytic protein ingredient that may cause an allergic reaction in some patients. The risk for transmissible viral or prion disease is low, but it still must be considered. Tisseel is used alone and cannot be used with any other hemostatic material—an embolic event can occur. Tisseel is commercially available in freeze-dried or prefilled syringe kits. Frozen kits need to thaw for at least 30 minutes before use. Quick thaw instructions are written in the packaging material. Care is taken to follow the exact steps so the product works effectively. More information is available at www.tisseel.com and www.fda.gov.

Autologous or Homologous Plasma

Plasma collected from the patient (autologous) or a single donor (homologous) is processed into a cryoprecipitate containing clotting factor XIII to produce fibrinogen. Autologous plasma is obtained preoperatively and prepared either in the blood bank or in the OR. A single donor must be tested and found to be negative for human immunodeficiency virus (HIV) and hepatitis before plasma is processed.

Autologous or homologous fibrinogen is warmed to 98.6° F (37° C) immediately before use. Thrombin is reconstituted to 1000 units/mL. Equal volumes of fibrinogen and thrombin are applied simultaneously.

Pooled-Donor Plasma

Fibrin glue commercially prepared from pooled-donor plasma (i.e., blended from multiple donors) has significantly greater bonding strength than does autologous or single-donor plasma. The fibrinogen must undergo purification and viral inactivation, however, to prevent transmission of bloodborne pathogens. Used extensively in Europe, this product has not been approved by the FDA for use in the United States.

Synthetic Adhesives

Synthetic glue-like adhesive substances that polymerize in contact with body tissues effect hemostasis and hold tissues together.

Cyanoacrylate

Butyl cyanoacrylate and octyl cyanoacrylate derivatives may be used for topical skin closure (skin glue). Both types of synthetic adhesives are applied to clean, dry, easily approximated wounds and require no additional dressing material. The glue is introduced over the edges of the approximated wound. The adhesive forms a closure over the incision and secures the closure over the skin. The incision remains visible for inspection and the adhesive forms a protective, occlusive antimicrobial barrier. Conversely, if the wound is contaminated, an infectious process can be sequestered.

Skin glue is available from several manufacturers and comes in blue, violet, and clear varieties. Before using skin glue, check the expiration date. The glue dries after 2½ minutes and remains on the wound for 5 to 10 days. The glue is applied with an applicator along approximated, clean wound edges that are not under tension. The product can be applied in a long strand or in a series of closely aligned dots. Thick layers can produce an exothermic effect, and the patient can experience a burning sensation. This can be minimized by applying thin layers over top of each other. Adherence is compromised by a hairy or greasy surface. A protective dressing or splint can be applied after the glue is completely dry. The patient should be instructed to keep the area dry for 48 hours and not to apply any ointments, which could cause the glue to peel off prematurely. If the glue must be removed from tissue sooner, acetone can be used.

Methyl Methacrylate

Methyl methacrylate is used to augment fixation of pathologic fractures and to stabilize prosthetic devices in bone. It is an acrylic, cement-like substance commonly referred to as *bone cement*. It is a drug supplied in two sterile components that must be mixed together immediately before use. One component is a colorless, highly volatile, flammable, liquid methyl methacrylate monomer in an ampule. The powder component may contain antibiotic gentamycin or tobramycin. Studies are being done to determine whether the inclusion of silver nanoparticles could help prevent infection.[5] Other products such as dressings and urinary catheters have been using silver successfully for this purpose.

This powerful liquid solvent must be handled carefully. The other component is a white powder mixture of polymethyl methacrylate, methyl methacrylate–styrene copolymer, and barium sulfate in a packet. The barium sulfate provides radiopacity to the substance. When the powder and liquid are mixed, an exothermic polymeric reaction forms a soft, pliable, dough-like mass. This reaction liberates heat as high as 230° F (110° C). As the reaction progresses, the substance becomes hard in a few minutes. The mixing and kneading of the entire contents of the liquid ampule and powder packet must be thorough and should continue for at least 2 to 4 minutes. Time may vary by the amount of powder and additives. The substance must be adequately soft and pliable for application to bone. The completion of polymerization occurs in the patient. After it hardens, it holds a prosthesis firmly in a fixed position.

A hazard to OR personnel has been reported in regard to the use of methyl methacrylate in the OR. Some personnel have experienced dizzy spells, difficulty breathing, and/or nausea and vomiting after mixing of methyl methacrylate. The fumes can cause severe eye irritation in people wearing gas-permeable contact lenses

during the use of this chemical compound. The monomer and several of its ingredients are potent allergenic sensitizers when vapor is inhaled. Disposable mixing bowls with covers and vapor suction ports should be used.

Patients can experience physiologic symptoms when the bone cement is used. Most common problems include hypoxia, hypotension, cardiac dysrhythmia, pulmonary vascular resistance, and cardiac arrest. The anesthesia provider must monitor the patient closely and should be alerted to the placement of the cement. The chemicals in the cement can cause many of these symptoms, but other causes, including fat embolism, have been cited.

Implantable Materials

Tissue deficiencies may require additional reinforcement or bridging material to obtain adequate wound healing. Sometimes edges of fascia, for example, cannot be brought together without excessive tension. In obese or older patients the fascia cannot withstand this tension because of weakness caused by the infiltration of fat. Other implantable materials are used to produce subsurface modifications, such as breast enlargement.

Biologic or synthetic mesh materials are used to fill congenital, traumatic, or acquired defects in fascia or a body wall and to reinforce fascia, as in hernia repair.

Implants must be sterile and compatible with the recipient's tissues. The surgeon should note any allergies or sensitivities to metallic substances if any are to be used. Care is taken to assure the correct size and handling regardless of the type of implantable used. Powderless gloves are recommended to prevent particulate distribution in the wound.

Administrative controls concerning implantable materials include documentation of the source material, the lot number in case of a recall, and special preparatory handling. The circulating nurse dispenses the implant to the sterile field and the scrub person readies the material for use. Implants should not be handled excessively to prevent damage to the surface or contamination with particulate or lint from the field.

Examples of implant uses and characteristics include, but are not limited to, the following:

- Dimensional subsurface space-holding devices, as in tissue expanders
- Load bearing as in orthopedic implants
- Passage creation as in a stent
- Bone integration for increased density
- Flexion with low friction, as in hernia mesh
- Subsurface modification such as testicular implants to replace missing parts
- Mechanical-electrical regulation of a body system such as pacemakers
- Drug delivery devices

Implants can be permanent or temporary and composed of many materials. Any implant that is removed (explanted) is usually sent to the pathology laboratory for accession (gross identification). Refer to Fig. 28.20 for a collective comparison of implants for tissue repair and replacement.

Biologic Materials

Cargile Membrane

A thin membrane is obtained from the submucosal layer of the cecum of the ox. Cargile membrane is rarely used, although it is still commercially available in a 4 × 6 inch (10 × 15 cm) sheet to cover peritoneum to prevent adhesions, for isolating ligations, as a covering for packing in submucous nasal resections, and as a dural substitute.

Fascia Lata

Strips of fascia lata are obtained from the fibrous connective tissue that covers thigh muscles of beef cattle. In lieu of commercial fascia lata (allogeneic graft), the surgeon may strip a piece of fascia from the patient's thigh (an **autologous graft**). Fascia lata also is obtained from cadavers and freeze-dried (an **allogeneic graft**). Fascia lata contains collagen. It increases the amount of tissue already present and becomes a living part of the tissue it supports. It is used to strengthen weakened fascial layers or to fill in defects in fascia.

Synthetic Materials

Synthetic Meshes

Synthetic meshes offer several advantages for reinforcing or bridging fascial or other tissue deficiencies:

1. They are easily cut to desired size for the defect.
2. They are easily sutured underneath the edges of tissue to create a smooth surface.
3. They are pliable to preclude erosion into major structures.
4. They are inert to avoid inflammatory response and minimize foreign body tissue reaction.
5. They are porous to allow free drainage of exudate.
6. Fibrous tissue easily grows through openings to incorporate mesh into tissue to maximize tensile strength.

The manufacturer's instructions must be followed for each type of mesh product. Unused mesh should be discarded and not reprocessed.

Polyester Fiber Mesh (Mersilene Mesh). Mesh remains soft and pliable in tissue but has limited elasticity. It is the least inert of the synthetic meshes. It is not preferred in the presence of infection or in contaminated wounds because of its multifilament construction. Polyester fibers are knitted by a process that interlocks each fiber juncture to prevent unraveling when cut. However, a minimum of 1 × 4 inch (6.5 mm) of mesh should extend beyond the suture line.

Polyglactin 910 Mesh (Vicryl Mesh). Mesh is knitted fibers of undyed and uncoated polyglactin 910. Because it is absorbed by hydrolysis, this mesh is intended for use as a buttress to provide temporary support during healing. The mesh acts as a scaffold for ingrowth of connective tissue. It may be used to support a traumatized spleen, kidney, or abdominal wall and to support facial fascia. Absorption is essentially complete in 60 to 90 days.

Polypropylene Mesh (Prolene Mesh, Marlex Mesh). Knitted mesh of polypropylene has high tensile strength and good elasticity. However, Marlex mesh is stiffer and exhibits greater fiber fatigue than does Prolene mesh. Because polypropylene is inert, it may be used in the presence of infection or during healing by second intention. Mesh is used to span and reinforce traumatic abdominal wall defects, incisional ventral hernias, large inguinal hernias, and other fascial deficiencies. It stimulates rapid tissue ingrowth through interstices of mesh. Mesh remains soft and pliable in tissues. It will not unravel when cut.

Polytetrafluoroethylene (Gore-Tex Soft Tissue Patch). A sheet of expanded PTFE may be used to repair hernias and tissue deficiencies that require prosthetic material. This material is flexible, soft, and porous to allow tissue ingrowth. It is not used in the presence of infection. It must be handled only with clean gloves or rubber-shod forceps. Only Gore-Tex suture should be used.

NATURAL (BIOLOGIC)				SYNTHETIC			
Autologous	**Allogeneic**	**Xenograft**	**Biomaterials**	**Chemical**	**Metallic**	**Polymer**	**Mechanical**
Skin	Bone	Porcine dermal collagen	Biodegradable fixation S-1 (CO_2 and H_2O)	Glial antibiotic disc	Plates/screws	Solid	Pacer
Cartilage	Tendon and ligament	Tricalcium phosphate	Hydroxyapatite ceramic	Bone cement	Rods	Expandable	Penile hydraulics
Bone	Cornea	Porcine heart valve	Bioengineered stent endothelial	Drug eluting stent	Stent	Shunts	Medication pump
Muscle	Alloderm	Bovine xenograft screws	Bovine collagen polyester graft	Conduit graft	Joint	Stents	Cochlear components
Gut	Tissue matrix: Periosteal Chondrium	Calcium alginate gel	Bioengineered vessels	Mesh graft	Grid	Thermoplastic polymer	Heart assist device
Hair follicles	Fascia	Coral		Drug eluting birth control device: IUD	Clips and staples	Liquid	Internal cardiovertor defibrillator
Vessels	Saphenous veins	Bovine collagen dressing			Metallic oxide, ceramic	Polyethylene	Nerve stimulator
Adipose	Heart valve	Bovine collagen matrix			Zirconium oxide	Polyurethane	
Stem cells	Ossicles	Porcine collagen matrix			Chromium oxide	Nonabsorbable ligating clip	
Mesenchyme	Bone marrow				Aluminum oxide	3-D printed polymer reconstruction forms	
					Dental ceramic

Tissue Replacement Materials

For centuries surgeons have sought materials to replace parts of anatomy. Tissue may be absent or distorted because of congenital deformity, traumatic injury, degenerative disease, or surgical resection. Replacement or substitution of tissue may be possible with biologic dressings or implanted materials, or with synthetic prosthetic materials implanted in the body. An overview of the types of biologic and synthetic tissue replacement materials is given here. Their uses are referenced in other chapters by surgical specialty or procedure.

Tissue replacement materials may require reconstitution with sterile saline before use. The circulating nurse should record the lot number of the replacement material and the lot number of the saline used for preparation. Avoid the use of saline with preservative when preparing tissue replacement material. Small vials of saline diluent may contain a bacteriostatic preservative and may alter the tissue. IV saline is suitable for this process because it has no preservative.

Biologic Wound Cover

A biologic dressing temporarily covers an open surface defect in skin and underlying soft tissues. Although defects are usually the result of trauma such as burns, vascular or pressure necrosis can cause skin ulcers. Open wounds quickly become contaminated. The dressing arrests loss of fluid, reduces or eliminates microbial growth, and minimizes scarring. It promotes production of granulation tissue and epithelialization before healing by second or third intention. A fibrin-elastin biologic bonding adheres the dressing to exposed surfaces. Biologic dressings are dermal replacements. The source determines the type of dressing.

Autograft

Skin is grafted from one part of the patient's body to another part. Skin grafts are described in Chapter 40 of this text.

Allograft

Human tissue obtained from one genetically dissimilar person (i.e., unmatched donor) is grafted to another person. This is referred to as an *allograft.* Negative HIV and hepatitis B virus (HBV) status of donor and recipient should be determined and documented before use. Any natural body tissue transferred from one human to another must be free of infection.

Cryopreserved Skin. Allograft skin provides a protective covering that initially acquires, and then eventually loses, vascular connection with underlying tissue. A cadaver usually is the source of skin for a dermal allograft. Cryopreservation maintains viability of skin during prolonged storage. Skin is frozen by cooling at a rate of 1.8° F to 9° F (–16.8 to –12.8° C to 5° C) to –94° F (–70° C) until frozen and then stored in a liquid nitrogen freezer. Immediately before use, skin is warmed by immersion in sterile water at 107.6° F (42° C), the maximum compatible with cellular viability.

Skin should be warmed at a rate of 90° F to 126° F (32° C to 52° C) per minute. (The patient's own skin can be cryopreserved for prolonged storage for later use as an autograft.) Allografts may be obtained from a skin bank.

For storage of allografts or autografts up to 14 days, skin may be placed in isotonic saline solution or tissue nutrient medium and refrigerated at 33.8° F to 50° F (1° C to 10° C).

Amniotic Membrane. Prepared from human placenta, amniotic membranes can be used as biologic dressings to promote the healing of burns, skin ulcers, and infected wounds and cover defects such as spina bifida. The placenta has two loosely connected membranes: amnion is used for partial-thickness wounds, and chorion is used for full-thickness defects.[6] Membranes are prepared by cleaning blood and clots from the placenta immediately after delivery, placing the placenta in an iodophor solution, and refrigerating it at 39° F (4° C). Membranes should be stripped from the placenta within 36 hours after delivery. Amnion can be used fresh, preserved, frozen, or dried.[6] It may be obtained from a tissue bank that prepares and stores amniotic membranes.

Xenograft

With **xenograft**, skin obtained from a dissimilar species may be placed on human tissue as a temporary dressing.

Porcine Dermis. Porcine (pig) skin is used to cover body surfaces denuded of full-thickness skin until permanent skin grafting can be accomplished. Vascularization does not occur, but the xenograft adheres tightly while reepithelialization proceeds underneath it. It may remain in place for as long as 2 weeks before it dries up and peels off spontaneously. Porcine biologic dressings are available in rolls or strips. They may be prepared fresh for refrigeration, fresh frozen, irradiated and then frozen, or dried. Some dressings are soaked in an iodophor and should not be placed on a patient allergic to iodine. Dressings must be prepared and used according to the manufacturer's instructions.

Artificial Skin. A skin substitute may be prepared from a layer of collagen obtained from the dermis of a calf or pig and coated with autologous epithelium obtained from the recipient. Another type is synthesized from a bilayered polymeric membrane. The top layer is silicone elastomer. The bottom layer is a porous, cross-linked network of collagen and glycosaminoglycan. This artificial skin is biodegradable, but it can be used as a temporary covering that is similar to porcine xenografts.

Biologic Materials

Autologous tissues may be grafted or transferred from one part of the patient's body to another. Allograft tissues or organs may be transplanted from another human. Xenograft biomaterials may be used to supplement tissues.

Standards are set by the American Association of Tissue Banks for screening donors and retrieving, processing, and preserving allogeneic tissues, including skin, cartilage, bone, and blood vessels. Potential donors of allografts are tested for HIV and HBV. Excluded from donating are people who are HIV-positive, have a history of hepatitis, have an active infection, have an immune disorder, or have a suspected prion disease.

Bone Grafts

A bone graft affords structural support and a pattern for regrowth of bone within a skeletal defect. Cancellous bone is porous. Its porosity permits tissue fluid to reach deeper into it than into cortical bone, and thus most of the bone cells live. Cortical bone is used for bridging large skeletal defects, because it gives greater strength. It may be fixed in the recipient site by means of metallic sutures or screws. Bone obtained from the crest of the ilium or a rib is cancellous and cortical bone; cortical bone is obtained from the tibia. The main purpose of a bone graft is to stimulate new bone growth.

Autologous bone, which is obtained from the patient, usually is taken from the ilium, tibia, or ribcage at the time of the surgical procedure. Calvarial bone from the frontal, parietal, or occipital cranial bones may be harvested for maxillofacial bone grafts. A free bone graft with its vascular pedicle, such as a free fibular graft, may be obtained for revascularization by microvascular anastomosis after removal of dead (avascular) bone. A separate, small sterile table may be prepared for the instrumentation required for the donor site. If the recipient area is potentially contaminated, the donor site must not be cross-contaminated from the recipient site.

Allogeneic bone, which is obtained from a cadaver, is dead bone. This bone is weaker than autologous bone, thus requiring a longer time of immobilization. Union occurs from bone regeneration in the recipient with this type of bone graft. It may be desirable, however, to spare the patient the added operating time and trauma of removing an autologous graft.

Composite bone grafts are freeze-dried allografts combined with autologous particulate cancellous bone and marrow. A crib formed from a cadaver bone (e.g., rib) is packed with the patient's bone particles and marrow. When implanted to reconstruct bony defects, the composite graft induces bone regeneration in the recipient site. The freeze-dried allograft is biodegradable by slow resorption. Eventually it is replaced by mature, functional bone.

Decalcified bone and demineralized bone chips or powder, prepared from homogeneous bone, also are used to stimulate bone regeneration or to fill defects in bone. This material is sterilized and stored at room temperature. For use, it is soaked in lactated Ringer's solution. The powder then becomes a paste that can be used to fill a depressed area or to caulk an irregularity (e.g., in craniofacial reconstruction).

Bone Bank. Bone may be preserved and stored in a bone bank until needed. Autologous bone may be preserved after the surgical procedure by storage in a bone bank for subsequent grafting into the same patient. Bone such as a rib or femoral head may be salvaged from patients (i.e., living donors) who are free of malignancy or infection for an allogeneic graft into another person. Bone also may be obtained from cadavers (i.e., nonliving donors).

Bone used for allografts must be clean and sterile. Immediately after removal, bone marrow, fat, and blood are rinsed out with

sterile distilled water or normal saline solution. The bone may be put in sterile nested glass jars or double plastic or metal containers. If it is to be used for an allogeneic graft, a small piece of bone is put into a sterile Petri dish and sent to the laboratory for culture tests. Bone should never be used until negative results of culture and serology are received. Several methods are used to preserve bone:

- Freezing is the most common method of preserving bone. Bone is quick-frozen in a freezer at –94° F (–70° C) or in liquid nitrogen. If bone will be used within 6 months, it can be stored in a refrigerator freezer at –4° F to –5° F (–20° C to –20.6° C). For prolonged storage of more than 6 months, the freezer temperature must be maintained below –4° F (–20° C) to avoid damage from a buildup of ice crystals. Bone frozen by liquid nitrogen is stored in vapor at about –238° F (–150° C). The container initially is placed on a shelf labeled "Not Ready for Use." It is labeled "Sterile" and moved to the freezer compartment labeled "Ready for Use" when negative results of culture and serology tests are recorded on the identification card. Bone is thawed rapidly immediately before grafting.
- Freeze-drying requires specialized equipment that removes moisture as the freezing process takes place in a condenser with a vacuum cycle.
- Ethylene oxide sterilization ensures safety of bone. It must be aerated for 72 hours before storage at room temperature or in a refrigerator. When protected from air and contamination, sterilized bone can be stored indefinitely, although a 1-year expiration date is recommended if bone is placed in a heat-sealed, peel-apart package.
- Packaged bone may be shipped in dry ice to a center equipped to sterilize it by gamma irradiation.
- Formaldehyde solution, 0.25% to 1% concentration, may have a bacteriostatic effect around the graft site in infected or contaminated wounds, such as in osteomyelitis. During storage, temperature is maintained at 35.6° F to 39° F (2° C to 3.8° C) in a refrigerator.

The container must be labeled with donor information and not used until laboratory reports are available. The donor must be seronegative for hepatitis B surface antigen and HIV. Bone from a living donor is quarantined for 90 days, awaiting results of a repeat test for HIV.

Xenograft Bone Implant

Coralline hydroxyapatite, which is composed of skeletons of sea coral, and collagen may be used to replace facial or cranial bone. This material has hardness, mineral content, and porosity similar to that of human bone. These implants stimulate bone growth into the porous architecture of the coral.

Organ Transplants

Some whole body organs can be transplanted from one human to another. This is done in an effort to sustain life by compensating for physiologic deficits or inadequate function of vital organs. Organ transplants are discussed in Chapter 45 of this text.

Tissue Transplants

Skin and blood vessels are frequently transplanted from one part of the body to another. These are referred to as *autografts,* because the patient is both donor and recipient. The transplanted tissue becomes a part of the living tissue in the recipient site.

Some tissues can be transplanted from one person to another to restore function, such as the cornea, or to provide support in structures, such as cartilage in nasal reconstruction. These are referred to as *allografts.* Some allografts are commercially prepared, such as lyophilized human dura mater and human umbilical cord vein graft.

Human Dura Mater. A trimmed and measured piece of cadaver dura mater is freeze-dried, sterilized by exposure to ethylene oxide, and stored in a vacuum container. It may be stored at room temperature indefinitely, provided the vacuum is maintained. The graft is reconstituted by the addition of normal saline solution to the container for a minimum of 30 minutes. Most of these grafts are used for closure of dural defects, but they also may be used to repair abdominal and thoracic wall and diaphragmatic defects.

Neurologic tissue for transplant may harbor the prion responsible for the development of Creutzfeldt-Jakob disease (CJD). Routine sterilization does not render this material safe for use in the presence of CJD. Routine testing does not reveal CJD contamination.

Human Umbilical Cord Vein Graft

A glutaraldehyde tanning process converts an umbilical vein into an inert, antithrombogenic graft. A polyester mesh covering over the outer surface allows tissue ingrowth and provides added strength. Commercially supplied, an allograft-modified human umbilical vein graft is an acceptable graft material for arterial reconstruction when an autologous saphenous vein is not available.

The glutaraldehyde is thoroughly rinsed from the graft with sterile heparinized IV saline or lactated Ringer's solution before **implantation**. A series of three basins filled with sterile solution of choice are used for the rinse process. The basins should be set up on a separate sterile surface, away from the main sterile field, and discarded after use.

After rinsing, the graft should remain in sterile heparinized IV saline solution to keep it moist until implanted. Only noncrushing clamps should be used to avoid damage to the graft during handling.

Xenograft Biomaterials

In addition to porcine skin used as biologic dressings, artificial skin derived from the collagen of a calf or pig, allogeneic bone, and other materials derived from animals are commercially prepared for tissue replacement. Some are supplied in glutaraldehyde solution and require rinsing before use, as previously described.

Arteriovenous Shunts. Enzymatically treated bovine carotid artery xenografts are used for blood access in patients on hemodialysis therapy who have poor blood vessels or in whom it is difficult to create either fistulas or shunts. Femoral arteriovenous bovine shunts can be punctured innumerable times with a low incidence of thrombus formation.

Collagen. Collagen is used in its natural form, such as a processed bovine graft and microfibrillar hemostatic powder, and restructured into membranes or films. It can be injected into middle to deep dermis to fill and smooth nasolabial furrows and facial creases. It is implanted to correct soft tissue defects and contours. The duration of effect is 4 to 6 months. Collagen can be altered by a variety of techniques to change its physical properties and duration of action in tissue.

Corium. Corium implants are prepared from porcine dermis to replace tissue loss or to support tissues. They can be used as a fascia lata substitute or dural replacement or to repair tympanic membrane, hernia, or bladder sling. Corium will form a collagen matrix to close a defect in soft tissues around teeth. Available in sterile sheets of several sizes, Zenoderm-corium implant (ZenoDERM) is freeze-dried or air-dried before sterilization by gamma irradiation. It should not be resterilized.

Human Skin Equivalent. Bioengineered skin product, referred to as Apligraf, is derived from bovine collagen and human tissue

taken from discarded foreskins of circumcised newborns. The mixture takes 5 days to generate and grow under sterile conditions in the laboratory. It is specially ordered for each patient and cannot be stored for additional uses. The cell culture mixture is applied to nonhealing wounds, such as venous stasis ulcers after debridement. More information can be found at http://www.apligraf.com/

Synthetic Materials

A **prosthesis** is a permanent or temporary replacement for a missing or malfunctioning structure. Some synthetic implants replace vital structures, such as diseased heart valves and blood vessels. Devices such as pacemakers assist the function of vital organs. Other materials are used to repair or replace defects.

Care is taken to determine whether the patient has an allergy to any metals.[7] Some metallic devices can have a nickel component, and patients who are sensitive to nickel can have an augmented inflammatory response to the metal. Prosthetic materials implanted into the body must:

- Be compatible with physiologic processes
- Produce no or minimal tissue reaction
- Be sterile so they will not cause infection or become a culture medium
- Be noncarcinogenic or other disease causative
- Have viable and adequate tissue coverage, unless used as a biologic dressing over denuded skin surfaces
- Have adequate blood supply through or around them
- Be stable so that they will not degenerate or change shape if used for permanent function
- Contour or conform to normal tissue configuration as desired

Permanently implanted devices can provide support, restore function, and augment or restore body contour. Inorganic substances cannot unite with tissue, however. Their physiologic responses may be predictable. All synthetic materials implanted in contact with blood will activate coagulation and promote the process of thrombosis. The surface of some materials is less thrombogenic (i.e., less likely to form clots) than those of others.

The magnitude of the inflammatory response they stimulate varies in patients. An immune response may cause chronic inflammation from bacterial adhesion, such as biofilm. Infection that develops around a prosthesis usually necessitates its removal. Most infections arise from microorganisms inoculated into the wound at the time of implantation. Therefore meticulous sterile technique is mandatory.

Prosthetic implants must not be flash sterilized. They must be sterilized in a standard cycle for the agent used (see Chapter 17). The cycle should be monitored with a biologic indicator, and a negative biologic test result should be confirmed before the implant is used. Implants sterilized by the manufacturer are preferred because the sterilization controls are closely monitored. Biologic testing is imperative for any implant.

Carbon Fiber

Pure carbon fibers braided into a strip are used for ligament replacement and articular resurfacing. Inert in tissue, carbon fiber stimulates regrowth of connective tissue and cartilage. The fibers may be braided with polypropylene or coated with a resorbable gelatin or lyophilized dura. The prosthesis should be soaked in normal saline solution before implantation to facilitate handling.

Metal

Stainless steel, a cobalt alloy (with the trade name Vitallium), and titanium are manufactured into prosthetic implants. Used primarily for stabilization of bone, metal implants must be strong enough to withstand the stress of weight bearing or muscular action and must not corrode in body tissues. They are never reused because of the weakening that can occur with use.

Special care must be taken in handling metal implants to protect the surfaces. A simple scratch on a metal implant can lead to its corrosion in the body. The implant will be bathed continuously by weakly chloride body fluids. If corrosion begins, the implant may fail and have to be removed. It is very important therefore that all metal implants be protected from scratches. This can be accomplished by:

1. Wrapping each implant individually, or wrapping sets with each size implant (i.e., screws and plates) in a separate compartment, for both storage and sterilization. Most prostheses come from the manufacturer in protective coverings or cases. Some of these are suitable for adequate sterilization, with subsequent placement in the sterile field to minimize handling before implantation.
2. Preventing implants from coming into contact with other hard surfaces of metal or glass, both during storage and sterilization and on the instrument table.
3. Not handling or transferring an unprotected implant with any type of forceps. Implants of one metal should not come into contact with those of another metal because an electrochemical reaction occurs between metals. Two different metals are not implanted in the same patient for this reason. Instruments used for insertion also should be of the same metal as the implant (e.g., a stainless steel screwdriver and screw).

Methyl Methacrylate

A highly refined methyl methacrylate mixture can be molded and shaped to fit a defect in bone. When it hardens, this material looks and feels very much like bone. It is used to repair a skull. In some patients the chemicals in the cement can cause neurotoxic effects.

Polyester Fiber

Polyester fibers (Dacron) woven or knitted into seamless cylinders are used to replace major arteries.

Polyethylene

Polyethylene tubing may be inserted into structures such as fallopian tubes or ureters to give support during healing or to bridge a defect in tissue continuity. Polyethylene may be combined with silicon to produce a thromboresistant coating for vascular grafts and artificial hearts.

Implants of porous polyethylene are used for anatomic reconstruction, such as of the external ear. The porosity of the implant encourages both soft tissue and vascular ingrowth. Collagen deposited along the framework adds strength. Porous polyethylene is a strong, flexible material that can be molded or shaped to the desired configuration. When dipped into boiling normal saline solution, the material becomes pliable for molding by hand. An implant can be shaped by cutting with a scalpel blade. Glove powder, lint, and dust particles must not adhere to the implant, because they can cause a foreign body reaction around the implant.

Polytetrafluoroethylene (Teflon)

Some prostheses or parts of prosthetic devices are made of the polymer PTFE. It may be woven into a fabric for arterial grafts, extruded into tubing for struts, or molded into a solid configuration for valves or joints. Its flexibility makes it a useful replacement for tissues when motion is desirable.

Silicone

Silicone is one of the most inert of the synthetic polymers used for implantation. It has a durable and nonthrombogenic surface. It is used in many forms: gel, sponge, film, tubing, liquid, and preformed molded anatomic structures. It may be coated with polyurethane or polyester or used as an elastomer to coat polyester. A medical-grade silicone elastomer (Silastic) in one form or another is used in virtually every surgical specialty for tissue reconstruction or replacement. Silicone may migrate from a ruptured or leaking gel or liquid-filled implant and cause systemic illness.

Complete instructions for cleaning and sterilizing silicone implants before use are supplied by the manufacturer with each type of prosthesis. These instructions must be followed meticulously. Implants are not handled with bare hands, and care must be taken to assure they do not pick up lint and dust. Gloves worn during handling must be entirely free of powder. Skin oil, lint, dust, powder, and other surface contaminants can evoke foreign body reactions around the implant in tissue.

Skin Closure

In addition to sutures, staples, and skin glue, other materials may be used to hold skin edges in approximation.

Wound Silo

A sterile, clear plastic, round or tubular cover can be placed over areas of evisceration or dehiscence until the abdomen can be primarily closed. The silo is sometimes referred to as a *Bogota bag* after the Colombian surgeons who described its use after performing open fasciotomies of the abdomen in compartment syndrome. This device is useful in covering congenital gastroschisis of the abdomen in newborns until a repair can be made.

The silo creates a see-through barrier over the abdomen and viscera as a temporary closure device. It can be used with a wound vacuum dressing. Some facilities use empty sterilized 3-L intravenous (IV) bags sutured or clipped to the skin. Commercial silos are available in adult and pediatric sizes.

Skin Closure Strips

Adhesive-backed strips of microporous nylon (Proxi-Strip) or polypropylene (Steri-Strip) or rayon acetate are placed at intervals across the line of incision. They may be used to approximate skin edges of superficial lacerations, as the primary closure of skin in conjunction with subcuticular suture, or in conjunction with interrupted skin sutures or staples. Often they are used after early suture or staple removal to support the wound during healing. A skin tackifier, such as tincture of benzoin, may be recommended by the manufacturer for ensuring adhesion to skin.

Sterile strips are available in various widths and lengths. They are ethylene oxide gas–sterilized in peel packets by the manufacturer. Skin closure strips have the following advantages:

- They may be used in the emergency department on superficial lacerations to eliminate the need for sutures that would require local anesthesia for placement and subsequent return of the patient for suture removal.
- They eliminate foreign body tissue reaction of suture material in skin.
- They have enough porosity to permit adequate ventilation of clean or contaminated wounds.
- They permit removal of sutures within 32 to 48 hours postoperatively. Crosshatch scarring (referred to as *railroad tracks*) and the possibility of infection are reduced when sutures are removed early. Skin closure strips provide long-term wound reinforcement and support.
- They permit visibility of the healing wound so that the surgeon can see how well the wound edges have coated. Some strips are translucent; others have a color tone or opacity that does not afford this advantage.
- They minimize skin irritation, because they are hyporeactive.
- They can be applied and removed rapidly.
- They can be easily cut to meet exact length requirements.

The team should keep in mind that the external part of the closure is what the patient sees and on which an opinion of the entire surgical experience is based. The shape of the repaired site and scar formation can lead the patient to believe that surgery was unsuccessful. Proper closure and wound care can help minimize scarring and preserve the patient's self-esteem.

Wound Healing and Hemostasis

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify tissue layers specific to the anatomic site of a wound.
- List several factors that affect wound healing.
- Describe the three mechanisms of wound healing.
- List three complications of wound healing.
- Describe three dressing materials and their application.

KEY TERMS AND DEFINITIONS

Adhesion Band of scar tissue that holds together or unites surfaces or structures that are normally separated.
Chronic wound Tissue with an injury in a patient with an underlying condition that takes longer than average to heal.
Cicatrix Firm avascular scar tissue.
Contracture Formation of extensive scar tissue over a joint.
Dead space Space caused by separation of wound edges or by air trapped between layers of tissue.
Debridement Removal of damaged tissue and cellular or other debris from a wound to promote healing and prevent infection.
Decubitus ulcer A chronic wound caused by prolonged pressure.
Dehiscence Partial or total splitting open or separation of the layers of a wound.
Devitalized Tissue that is nonviable, necrotic.
Edema Abnormal accumulation of fluid in interstitial spaces of tissues.
Epithelialization Epithelial cells regenerate over a wound.
Eschar Granular tissue around the edges of a chronic wound. It can be firm and dark or soft and beige.
Evisceration Protrusion of viscera through an abdominal incision.
Exsanguination Tissue is drained of blood.
Extravasation Passage of blood, serum, or lymph into tissues.
Exudate Fluid, cells, or other substances that have been discharged from vessels or tissues. It contains white blood cells, lymphokines, and growth factors that stimulate healing.
Friable tissue Tissue is fragile and bleeds easily.
Granulation tissue Formation of fibrous collagen to fill the gap between the edges of a wound healing with contraction (i.e., second intention).
Granuloma Inflammatory lesion that forms around a foreign substance, such as glove powder or a suture knot.
Hematoma Collection of extravasated blood in tissue.
Hemostasis Arrest of blood flow or hemorrhage; the mechanism is via coagulation (formation of a blood clot).
Hypertrophic scar Excessive raised dense scarring that does not exceed the border of the wound.
Iatrogenic Condition caused by treatment or procedure performed by medical personnel.
Incision Intentional cut through intact tissue (synonym: surgical incision).
Inflammation Increased blood flow to injured tissue as part of the healing process.
Ischemia Decrease of blood supply to tissues.
Keloid Overgrowth of firm rounded scar that extends beyond the border of the wound. Can be painful and may bleed if injured.
Necrosis Death of tissue cells; devitalized tissue.
Occlusive dressing A dressing that permits air, but prevents the passage of fluids in or out of the covering. Sealed over all edges.
Scar Deposition of fibrous connective tissue to bridge separated wound edges and restore continuity of tissues.
Seroma Collection of extravasated serum from interstitial tissue or a resolving hematoma in tissue.
Tensile strength Ability of tissues to resist rupture.
Tissue reaction Immune response of the body to tissue injury or foreign substances.
Ulcer Skin layers are lost as a result of decreased arterial circulation or obstructed venous drainage.
Wound disruption Separation of wound edges.

Mechanism of Wound Healing

Interruption of tissue integrity, either intentional or unintentional, requires understanding of the mechanism and factors that cause wounding and influence wound healing. When tissue is cut, the body's inherent defense mechanisms respond immediately to begin repair. Three mechanisms of wound healing are recognized: first intention/primary union, second intention, and third intention/delayed primary closure (Fig. 29.1). Each mechanism has practical applications in the making and closing of **incisions** or traumatic wounds. The degree of contamination and the amount of viable tissues are factors in the determination of which method of healing is used.

First Intention/Primary Union

Healing by first intention is desired after primary union of an incised, aseptic, accurately approximated wound. Well-approximated wounds form a fibrin bridge that aids healing. A closed system drain may be used. Key elements of first-intention closure include the following[1]:

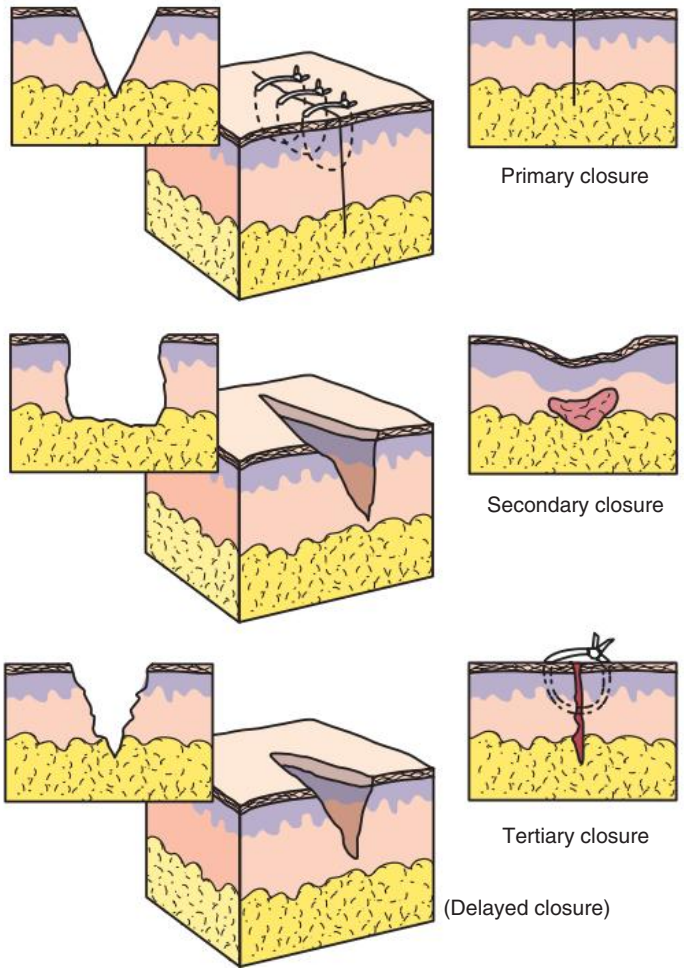
- No tissue loss
- Well-approximated edges with suture, wound sealant, or wound-closure strips
- Minimal or no postoperative swelling
- No serous discharge or local infection
- No separation of wound edges
- Minimal scar formation

The rates and patterns of wound healing differ in various tissues. In general, first-intention wound healing consists of three distinct phases:

1. *Lag phase of acute inflammatory response:* Tissue fluids containing plasma, proteins, blood cells, fibrin, and antibodies exude from the tissues into the wound, depositing fibrin, which weakly holds the wound edges together for the first 5 days.

   Fibrin and serum protein dry out and form a scab that seals the wound from further fluid loss and microbial invasion. At the same time, fibroblasts, fibrous tissue germ cells, and epithelial cells migrate from the general circulation. Subsequent adhesion of these cells, a process known as fibroplasia, holds the wound edges together. Leukocytes and other white blood cells produce proteolytic enzymes to dissolve and remove damaged tissue debris. Macrophages and neutrophils ingest foreign material, cellular debris, and bacteria.
2. *Healing or proliferative phase of fibroplasia:* After the fifth postoperative day, fibroblasts multiply rapidly, bridging wound edges and restoring the continuity of body structures. Collagen, a protein substance that is the chief constituent of connective tissue, is secreted from the fibroblasts and formed into fibers.

   Reepithelialization causes the rapid gain in tensile strength and pliability of the healing wound. **Tensile strength** is the ability of the tissues to resist rupture. The healing phase begins rapidly, diminishes progressively, and terminates on about the 14th day. It may continue for up to 20 days.
3. *Maturation or differentiation phase:* From the 14th postoperative day until the wound is fully healed, scar formation occurs by deposition of fibrous connective tissue. The collagen content remains constant, but the fiber pattern reforms and crosslinks to increase the tensile strength. Wound complete closure occurs over a period of weeks up to 6 months. As collagen density increases, vascularity decreases and the scar grows pale. The scar tissue is only 80% as strong as the original tissue.



• **Fig. 29.1** Mechanisms of wound healing. (From Trott AT: *Wounds and lacerations: emergency care and closure*, ed 3, St. Louis, 2005, Mosby.)

Second Intention

The mechanism of second-intention healing is by granulation, eventual reepithelialization, and wound contraction rather than with suturing closed by first intention. The wound heals from the bottom up; it heals spontaneously if the dermal base is preserved. The following are considerations with this type of healing:

1. Infection, excessive trauma, loss of tissue, and poorly approximated tissue are common. Inflammatory response is exaggerated.
2. The wound is left open and allowed to heal from the inner toward the outer surface. Eschar forms around the edges and can be softened and removed with chemical treatment. Devitalized tissue is debrided.
   a. In some wounds, the use of maggot therapy is useful for debridement.
   b. Debridement of devitalized tissue can be performed with scissors or a knife.
   c. The wound can be packed with dressing material that attaches to the necrotic tissue. When the packing is removed, the dead tissue separates from the wound bed, leaving a red beefy surface.

3. Healing is delayed. The wound may need grafting.
4. Healing may produce a weak union, which may be conducive to incisional herniation later.
5. The risk for secondary infection is proportional to the amount of necrotic tissue present in the wound and to compromised immune response in the patient. Repeated debridement may be necessary.
6. Scar formation is excessive.
7. **Contracture** of skin is pronounced. After healing is complete, the scar may need revision or release.

Third Intention/Delayed Primary Closure

Approximation and suturing are delayed or secondary for the purpose of walling off an area of gross infection or an area where extensive tissue was removed (e.g., in a debridement or from a traumatic injury). The edges are closed 4 to 6 days postoperatively after meticulous debridement.[2] The following are considerations in healing by third intention:

1. The wound is cleaned and debrided.
2. The defect is packed with moist gauze to promote drainage and granulation.
3. Antibiotic therapy is implemented.
4. The wound may be an old traumatic or septic wound.
5. The area should not be devascularized, and deep sutures should be avoided. **Granulomas** can form.
6. Two clean surfaces of granulation tissue are brought together for later closure.
7. A deeper and wider scar usually results.

Types of Wounds

A wound is an injury, either intentional or unintentional, that disrupts the continuity of body tissues with or without tissue loss. Wounds may be surgical (intentional), traumatic, incidental, or chronic.

Intentional Wounds

Surgical-Site Incision or Excision

An incision is a cut or an opening into intact tissue. An excision is removal of tissue. A sterile sharp scalpel, scissors, curette, or other cutting instrument may be used to separate skin and underlying tissues. Thermal instruments that both cut or vaporize tissue and coagulate surrounding blood vessels are used for incision and excision. The location, length, and depth of an incision must be planned.

The surgeon spreads the skin taut between the thumb and index finger in preparation for the skin incision. With one stroke of evenly applied perpendicular pressure on the scalpel, a clean incision is made through the epidermis and dermis into the subcutaneous layers. The following factors influence the ease with which a primary skin incision is made:

- Sharpness, shape, and size of the knife blade
- Resistance of self-adhering plastic drapes
- Toughness of skin or scar tissue
- Thickness of subcutaneous tissue

A clean stroke with a sterile surgical scalpel, followed by attention to all of the principles of sterile technique and tissue handling, is the best insurance for healing by first intention. The line of direction of the incision in relation to the natural lines of direction of the skin may be a factor in wound healing. Excess tension on the healing wound can delay wound healing. Wounds heal side to side, not end to end.

Other Types of Intentional Wounds

Occlusion Banding

Hemorrhoid ligation results in ischemia and degeneration of a hemorrhoid. A Silastic band is placed around the hemorrhoid using a special spring-loaded applicator. Other types of occlusion banding are performed on fallopian tubes with ligatures, Silastic bands, or plastic clips through a laparoscope. Portions of tissue distal to the occlusion point separate from perfused tissues, interrupting the continuity of the lumen of the part in the banding process.

Chemical Wounds

Chemicals can be intentionally applied to skin or other tissue surfaces to denude or coagulate the area. These chemicals cause **inflammation** and reepithelialization of the surface. This procedure is common in facial peels used in plastic and dermatologic surgery.

Traumatic Wounds

After traumatic injury, preservation of life is the first critical concern. The patient's general condition is of prime consideration, and the plan of care is individualized to meet the patient's needs. Injuries are evaluated, and those that pose the greatest hazards to life or to return to normal function are cared for first.

The primary objective after life support is wound closure with minimal deformity and functional loss.[3] Minor injuries are cared for in the emergency department (ED). Patients with major injuries undergo treatment in the ED before going to the operating room (OR) as quickly as the condition warrants. Traumatic wounds can be considered closed or open, simple or complicated, clean or contaminated. Wound closure is predicated on the type, location, severity, and extent of injury.

Closed Wounds

Skin is intact in a closed wound, but underlying tissues and/or organs are injured. A blister filled with serum or a hematoma of blood and serum may form under the epidermis. Torn ligaments and simple fractures are closed wounds.

Open Wounds

In open wounds, the skin is broken by abrasion, laceration, or penetration.

Simple Wounds

Continuity of skin is interrupted in simple wounds but without loss or destruction of tissue and without implantation of a foreign body. These lacerations are usually caused by a sharp-edged object cutting or penetrating at a low velocity. These wounds can be closed by first intention unless underlying structures or organs have been injured.

Complicated Wounds

In complicated wounds, tissue is lost or destroyed by crush or burn or a foreign body is implanted by high-velocity penetration. If a penetrating wound was made by an object, such as a knife or bullet, this object is not removed until the surgeon explores the wound in the OR. The device should be stabilized to prevent

additional injury. Movement of a foreign object may cause further trauma. The depth of a penetrating wound is irrigated and may be excised.

The complicated wound may be closed by second or third intention. Skin grafting may be necessary if the dermis has been destroyed. Any object removed from the patient's wound may be forensic evidence. The hospital's policy and procedure manual should be consulted for guidance on handling potential police evidence.

Clean Wounds

Clean wounds heal by first intention after closure of all tissue layers and wound edges. The cosmetic care of lacerated areas is important, as is treatment to provide normal function and satisfactory appearance of a part.

Contaminated Wounds

When dirty objects penetrate skin, microorganisms multiply rapidly. Within 6 hours, contamination can become infection. Debridement is performed to remove devitalized tissue, and the wound is irrigated. Devitalized tissue is removed because it acts as a culture medium. The wound may be left open to heal by second or third intention. Closure may be delayed for several days.

The patient's history should be assessed for tetanus bacillus immunization. Tetanus is most likely to occur in deep wounds contaminated by soil or animal feces. Adsorbed tetanus toxoid (0.5 mL) may be given as an initial immunizing dose or as a booster if the patient has been immunized within the previous 5 years. Tetanus immune globulin (human, 250 to 500 units) also should be given to any patient who has a severe wound or who has had the wound for more than 24 hours and has not been immunized within the previous 10 years.

Delayed Full-Thickness Injury

Industrial accidents commonly include crush injury or deep injection of substances, such as paint or printer's ink, beyond the level of the dermis. The full extent of the tissue damage may not be apparent for several days after the event because the effects of the injury cause increasing tissue loss. The patient may have occlusive dressings or casting for the initial apparent injuries but should be continually assessed for signs of increasing tissue **necrosis** or full-thickness tissue loss. Electrocution or lightning strikes act similarly by causing deep tissue necrosis several days after the initial wounding.

Incidental and Chronic Wounds

Pressure sores and **decubitus ulcers** may result from compromised circulation over bony prominences or other pressure points for extended periods. Positioning and padding considerations in the plan of care can help prevent incidental pressure-related injuries in the perioperative environment.

Ulcers

Venous stasis or arterial insufficiency in the legs may cause chronic skin **ulcers**. Arterial ulcers are pale, dry, and circumscribed. Venous ulcers are wet and irregular in shape. Tissue necrosis may occur after radiation therapy. These **chronic wounds** have tissue loss and usually have heavy bacterial contamination. Topical application of fibronectin (a platelet-derived wound-healing formula) or some other preparation of growth factors from the patient's own blood may help control infection and promote healing. Growth factors stimulate the growth of tissue, capillaries, and skin. If a wound fails to heal by second intention with formation of **granulation tissue**, debridement and skin grafting may be necessary.

Iatrogenic Wounds

Iatrogenic wounds can happen as the result of therapy or treatment such as radiation burns. Accidental injuries such as trocar wounds on unintended organs caused during a surgical procedure can be classified as iatrogenic. The treatment and healing vary according to the mechanism of injury.

Factors Influencing Wound Healing

Each patient has internal and external forces that influence healing. Most wounds progress to healing unless the closure is poor, an infection ensues, or the tissue is devitalized by other forces. Hemostatic and inflammatory responses must be intact for healing to take place.

The degree of wound contamination is evaluated, and the potential risk for postoperative wound infection is considered. At the conclusion of the surgical procedure, the wound is assigned a classification.

Surgical Wound Classification

The surgical site may be clean or contaminated when the surgeon makes the initial incision. A clean site may become contaminated depending on the type of wound, the pathologic findings or circumstances that create the need for the surgical procedure, the anatomic location, and the techniques of the OR team. After completion of wound closure, the circulating nurse should verify the wound classification with the surgeon.

The wound class should not be assigned until the dressing is applied. This is documented in the patient's intraoperative records. Surgical sites are classified by the degree of microbial contamination or exposure that may predispose a patient to a postoperative wound infection.[4]

According to the Centers for Disease Control and Prevention (CDC), risk for infection increases in proportion to contamination of the incision and surrounding tissues exposed during the course of the surgical procedure. The true extent of risk cannot be evaluated until the procedure is completed. The wound is classified at the end of the surgical procedure as one of the following four types (Box 29.1):

1. Clean
2. Clean-contaminated
3. Contaminated
4. Dirty and infected

Generalized Health Condition of the Patient

Chronic diseases alter normal physiology. Diseases such as diabetes, uremia, fibrocystic disease, cirrhosis, active alcoholism, and leukemia can delay wound healing.

Circulatory Status

Cardiovascular and respiratory insufficiency inhibits tissue perfusion. Oxygenation is essential to wound healing and to inhibition of growth of anaerobic microorganisms. If oxygen does not circulate, the wound does not heal.

• BOX 29.1 Classification of Surgical Wounds from the CDC

Clean Wound (Infection Rate: 1%-5%)

- Elective procedure with wound made in ideal operating room conditions
- Primary closure; wound not drained
- No break in sterile technique during surgical procedure
- No inflammation present
- Alimentary, respiratory, and genitourinary tracts or oropharyngeal cavity not entered

Clean-Contaminated Wound (Infection Rate: 8%-11%)

- Primary closure; wound drained
- Minor break in technique occurred
- No inflammation or infection present
- Alimentary, respiratory, and genitourinary tracts or oropharyngeal cavity entered in controlled conditions without significant spillage or unusual contamination

Contaminated Wound (Infection Rate: 15%-20%)

- Open fresh traumatic wound of less than 4 hours' duration
- Major break in technique occurred
- Acute nonpurulent inflammation present
- Gross spillage/contamination from gastrointestinal tract
- Entrance into genitourinary or biliary tracts with infected urine or bile present

Dirty and Infected Wound (Infection Rate: 27%-40%)

- Old traumatic wound of more than 4 hours' duration from dirty source or with retained necrotic tissue, foreign body, or fecal contamination
- Organisms present in surgical field before procedure
- Existing clinical infection: acute bacterial inflammation encountered, with or without purulence; incision to drain abscess
- Perforated viscus

Smoking

Vasoconstriction caused by smoking decreases blood supply and oxygenation to the wound. Carbon monoxide in smoke binds with hemoglobin (forming carboxyhemoglobin) and further diminishes oxygenation. Smoking contributes to respiratory complications. This can cause forceful coughing that can raise intraabdominal pressure and create increased strain on an abdominal wound and impair healing.

Age

Loss of skin turgor and muscle tone and elasticity is a natural characteristic of the aging process. Thickened connective tissue, decreased subcutaneous fat, diminished capillary blood flow, and reduced vascularity are age-related factors that may delay wound healing. The tension of sutures on aged skin can further inhibit tissue perfusion. Sutures and skin staples should be reinforced with wound-closure strips. Newborn infants, especially those who are preterm, and geriatric patients are especially prone to infection.

Nutritional Status

Wound healing is impaired by deficiencies in proteins, carbohydrates, zinc, and vitamins A, B, C, and K. Protein provides essential amino acids for new tissue construction. Carbohydrates are necessary energy sources for cells and prevent excessive metabolism of amino acids to meet caloric requirements. Vitamin B complex is necessary for carbohydrate, protein, and fat metabolism. Vitamin C permits collagen formation. Although vitamin A and zinc are known to be important in collagen synthesis, their mechanism in wound healing is not well understood. Vitamin K is involved in the synthesis of prothrombin and other clotting factors. Copper and iron assist in collagen synthesis. Calcium and magnesium are important in protein synthesis. Manganese serves as an enzyme activator.

Malnutrition, whether primary or secondary to disease, can be a major factor in wound healing and infection. Impairment of physiologic functions associated with a body weight loss that is greater than 10% and protein energy malnutrition increase the risk for postoperative complications. Liver function, skeletal and respiratory muscle function, overall physical and mental activity, and inflammatory response to wound healing are altered in the patient who is malnourished.

Protein and fat deficiency is especially significant in patients with extensive burns or multiple injuries who have greatly increased caloric requirements. Malnutrition caused by anorexia or cachexia has a deleterious effect on wound healing. Hyperalimentation with vitamin, trace element, and mineral supplements preoperatively and postoperatively usually is indicated for patients who are malnourished.

In obese patients, the bulk and weight of adipose tissue cause difficulty in confining excess fat and securing good wound closure. To minimize dead space, the surgeon may place drains and sutures in subcutaneous fat; both may actually potentiate infection. Of all tissues, fat is the most vulnerable to trauma and infection because of its poor vascularity. Many patients who are morbidly obese, more than 100 lb (45.4 kg) over ideal body weight, have cardiac decompensation and respiratory insufficiency.

Fluid and Electrolyte Balance

The body's system for balancing fluids and electrolytes is extremely complex. As a result of illness, injury, or infection, the patient may not be able to maintain normal fluid and electrolyte balance. Fever associated with infection, for example, can raise fluid requirements as much as 15% for each 1.5° F (or 1° C) rise in body temperature.

Body fluid is intracellular (ICF [within cells]) and extracellular (ECF [outside cells as intravascular plasma and interstitial fluid between cells]). The electrolyte content differs. ECF contains more sodium than ICF; ICF has more potassium than ECF. Changes in this balance can affect kidney function, cellular metabolism, oxygen concentration in the circulation, and hormonal function. Adequate ECF volume is necessary for circulation of blood to tissues.

Hematology

The presence of an abnormal or pathologic condition that affects the blood should be carefully evaluated preoperatively. A low hemoglobin level (low red blood cell count) associated with anemia can result in tissue hypoxia, which alters synthesis of collagen and **epithelialization**. A hematocrit value below 20% lowers oxygen tension in tissues, which disrupts cell regeneration. An elevated leukocyte level (white blood cell count) indicates the presence of infection in the body.

Inflammatory and Immune Responses

The body repairs tissues at the cellular level in response to injury or exposure to foreign substances. It triggers an inflammatory response to mobilize cellular components associated with healing. Some foreign materials cause more inflammatory reaction than do others.

Extremes of inflammation may result in response to allergy, infection, or chronic irritation and may delay wound healing. Inflammation should not be confused with infection, which has a

pathogenic microbe that causes the complications. Patients with an impaired immune response have an altered inflammatory response and do not heal appropriately.

Allergic Response

Hypersensitivity to substances inhaled, ingested, injected, or in contact with skin causes an acute allergic reaction. The type of allergic response displayed by the patient should be considered. A localized sensitivity response may appear as a rash or hives. A systemic allergic response may be more severe and include signs of airway obstruction and cardiac dysrhythmias.

Immunosuppression

The patient's immunologic response may be deficient because of a congenital or acquired immunologic disease, drugs, or radiation therapy. Patients with immunosuppression are easily infected with potentially pathogenic flora within their own bodies. They may not have the usual signs and symptoms of infection, such as initial inflammatory response. Lack of integrity of the immune system, such as leukopenia or defective immunoglobulin synthesis, can be life threatening.

Drug Therapy

Wound healing occurs basically through collagen synthesis. Agents that interfere with cellular metabolism have a potentially deleterious effect on the healing process. Prolonged high dosage of steroids, such as cortisone preoperatively, inhibits fibroplasia and collagen formation.

Some antineoplastic agents used as chemotherapeutic adjuvants to surgery also may delay systemic wound healing or cause localized tissue necrosis from **extravasation** at the site of injection. Immunosuppressants are given to transplant patients to prevent organ or tissue rejection. Leukopenia and susceptibility to infection are common sequelae to administration of these drugs. Other drugs that interfere with wound healing include anticoagulants, antiinflammatory agents, and colchicine.

Radiation Therapy

Healing is delayed if the patient has had radiation in large doses preoperatively. The blood supply in irradiated tissue is decreased, and rapidly growing cells, including healthy cells, are destroyed. However, little change from the normal healing pattern occurs if radiation has been given in low doses and the surgical procedure is performed within 4 to 6 weeks of radiation.

Surgical Technique

Devitalized tissue caused by laser or electrosurgery cannot regenerate. Interruption of blood supply and innervation decreases circulation and prevents epithelialization. Excess tension on the suture line that inhibits tissue perfusion prolongs healing time.

Aseptic Technique

Healthy tissues can combat a certain amount of contamination. Microorganisms are normally present in skin and air. Devitalized tissues have little power of resistance. Infection may occur from any one of a variety of causes that result in a breakdown of the wound postoperatively. The surgeon gives meticulous attention to sterile technique throughout the surgical procedure to minimize contamination of the surgical site.

The entire OR team carefully carries out aseptic and sterile techniques. In addition, many precautions are taken by all OR personnel. Strict adherence to housekeeping techniques, air engineering, sterilization procedures, and all of the principles of aseptic technique is necessary. Infection may be caused by a break in the chain of asepsis.

Method of Hemostasis

Complete hemostasis must be achieved to prevent loss of blood and **hematoma** (blood clot) formation. Blood loss is caused by tissue trauma. The method of dissection and coagulation of bleeders can cause devitalization of tissue. **Devitalized** tissue cannot heal; it only necroses. Delivery of oxygen to healing tissues is affected. Any condition that lowers circulating blood flow and the delivery of oxygen to the tissues impairs healing.

Tissue Handling

All tissues should be handled gently and as little as possible throughout the surgical procedure. The surgeon makes an incision that is just long enough to afford sufficient operating space. Careful consideration is given to underlying blood vessels and nerves to preserve as many as possible. Retractors are placed to provide exposure without causing undue pressure on tissues and organs or tension on muscles. Trauma to tissue in dissecting, handling with instruments, ligating, or suturing may cause **edema** and necrosis with resultant slow healing. The body must rid itself of necrotic cells before the healing phase of fibroplasia takes place.

Tissue Approximation

Tissue edges are brought together with precision, avoiding strangulation and eliminating dead space, to promote wound healing. A closure that is too tight or closure under tension causes **ischemia**, a decrease of blood supply to tissues. Approximation is critical to the healing of flaps and grafts. Constricted or interrupted blood supply can cause flap failure or loss of a vascularized graft.

Dead space is caused by separation of wound edges that have not been closely approximated or by air trapped between layers of tissue. Serum or blood may collect in a dead space and prevent healing by keeping cut edges separated. Wound edges not in close contact cannot heal. A drain may be inserted to aid in removal of fluid or air from the surgical site postoperatively, or a pressure dressing may be applied over a closed wound to help obliterate dead space.

The choice of wound-closure materials and the techniques of the surgeon are prime factors in the restoration of tensile strength to the wound during the healing process.

Wound Security

The quality of approximated tissue and the type of closure material are two factors that determine the strength of the wound. Tensile strength of the tissues themselves varies; some tissues are more **friable** than others.[5] Drains or catheters may be placed in the wound to evacuate serum or fluid and prevent it from accumulating in the dead space postoperatively. Drainage tubes may cause a weak spot in the incision, and underlying tissue may protrude. Also, drains may provide an inlet for microorganisms, as well as an outlet for drainage. When possible, drains are placed through a stab wound in the skin rather than through the surgical incision.

When sutures are used, the suture material provides all of the strength of the wound immediately after closure. Closely spaced sutures give a stronger suture line. The strength of a suture should not be greater than the strength of the tissue in which it is placed.

To minimize **tissue reaction** to sutures, the fewest and the smallest sutures consistent with the holding power of the tissues should be used. Inert surgical staples are used to approximate some tissues.

Immediately after closure, tissue along the incision is at about 40% of its original strength. It reaches its greatest strength in 7 to 15 days. The wound is about one-third healed on the sixth postoperative day and two-thirds healed on the eighth day. The condition of the patient, the type of surgical procedure, and many other factors may cause variance from the average patient response. As tensile strength of the wound increases, reliance on other support for wound security gradually lessens.

Postoperative Complications

Edema, vomiting, or coughing can place stress on the healing wound before fibroplasia takes place. Complications in other parts of the body, far from the surgical site, such as pneumonia, thrombus, or embolus, can inhibit oxygen supply to the wound site.[6] Collagen synthesis is partly a function of the oxygenation of tissues; therefore oxygen perfusion to tissues contributes to the rate of healing, tensile strength of the wound, and resistance to infection. This is particularly important in arterialized and microvascular tissue grafts and flaps used to cover soft tissue defects and in organ transplantation. Ischemic tissue is more susceptible to infection than is well-vascularized tissue.

Physical Activity

Early ambulation postoperatively is one of the most important factors in recovery for the surgical patient. Ambulation may be started immediately after recovery from anesthesia if the patient's condition does not contraindicate it. Some surgeons exempt only the patient whose blood pressure (BP) is not stable, the patient who has a cardiac problem, or the patient whose general condition is poor. If the patient's physical condition does not safely permit ambulation, the surgeon orders otherwise.

Ambulation is started gradually, with the patient first turning onto one side. The patient sits up with the feet over the side of the bed and then stands on the floor for a minute before returning to bed. After repeating this several times, the patient takes a few steps and finally increases the distance walked. Sitting in a chair for prolonged periods is discouraged because this contributes to stasis of blood in dependent parts. The patient must understand the value of early ambulation, which includes the following:

- Early ambulation improves circulation, which aids in the healing process and eliminates stasis of blood, which may result in thrombus and embolus formation.
- The patient is better able to cooperate in deep-breathing exercises to raise bronchial secretions; thus pulmonary complications are reduced.
- Early ambulation decreases gas pain, distention, and the tendency toward nausea and vomiting. It helps prevent constipation. Bodily functions return to normal more readily.
- Increased exercise aids digestion. Thus the patient's oral intake progresses sooner after the surgical procedure, so that less supplementary intravenous (IV) fluid is necessary for hydration and nutrition.
- Early ambulation eliminates the general muscle weakness that follows bed rest.
- Fewer pain-relieving drugs are necessary.
- Early ambulation boosts patients' morale with the knowledge that they will be out of bed early after the surgical procedure, able to care for themselves, and soon ready to go home. This helps the mental outlook and, through it, the physical recovery.
- Early ambulation shortens hospitalization.

Hemostasis

Hemostasis, the arrest of a flow of blood or hemorrhage, is essential to successful wound management. The mechanism is coagulation, or the formation of a blood clot. The clotting of blood takes place in several stages by enzyme reaction.

Hemostatic Process

When severed by incision or traumatic injury, a blood vessel constricts and the ends contract somewhat. Platelets rapidly clump and adhere to connective tissue at the cut end of a constricted vessel. Interaction with collagen fibers causes platelets to liberate adenosine diphosphate (ADP), epinephrine, and serotonin from their secretory granules. In turn, ADP causes other platelets to clump to the initial layer and to each other, forming a platelet plug. This may be sufficient in small vessels to provide primary hemostasis.

The reaction of plasma from vessels with connective tissue cells at the site of injury activates clotting factors and causes a series of other reactions. Prothrombin, normally present in blood, reacts with thromboplastin, which is released when tissues are injured. Prothrombin and thromboplastin, along with calcium ions in the blood, form thrombin. This requires several minutes. Thrombin unites with fibrinogen, a blood protein, to form fibrin, which is the basic structural material of blood clots. This last reaction is very rapid.

The fibrin strands reinforce the platelet plug to form a resilient hemostatic plug capable of withstanding arterial pressure when the constricted vessel relaxes. Massive thrombosis within the vessels would occur once coagulation was initiated, if it continued. However, fibrin is digested during the process. The products of this digestion, and antithrombins normally present in blood, act as anticoagulants. The coagulation mechanism rapidly and efficiently inhibits excessive blood loss so that excessive coagulation does not occur (Fig. 29.2).

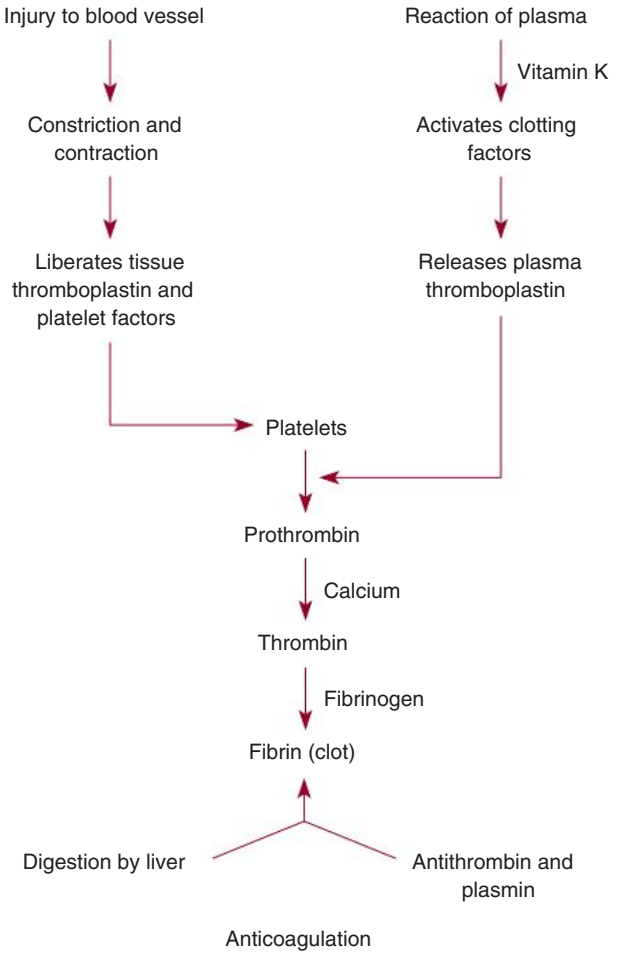
Bleeding during a Surgical Procedure

Two types of bleeding occur during surgical procedures: pulsating arterial bleeding and venous oozing from denuded or cut surfaces. Although the need to control gross bleeding is obvious, insidious but continuous loss of blood from small veins and capillaries can become significant if oozing is uncontrolled. Complete hemostasis, gentle tissue handling, elimination of dead space, precise wound closure, and a protective wound dressing are essential to minimize trauma to tissue and enhance healing.

Incomplete hemostasis may cause the formation of a hematoma. A hematoma is a collection of extravasated blood in a body cavity, space, or tissue caused by uncontrolled bleeding or oozing. It may be painful and firm to the touch. Some hematomas require evacuation to prevent infection; others reabsorb with time.

Methods of Hemostasis

Numerous agents, devices, and sophisticated pieces of equipment are used to achieve hemostasis and wound closure. These various methods can be classified as chemical, mechanical, or thermal.



• **Fig. 29.2** Mechanism of hemostasis.

Chemical Methods of Hemostasis

Chemical forms of topical hemostasis interact with blood to form a clot. Some materials reabsorb during the healing process. Hemostatic materials should not be packed into closed spaces, as in the spinal canal, where they might swell and cause pressure on nerves or other tissues. The material can be applied in confined areas until hemostasis is achieved but removed before closure.

Absorbable Gelatin

Available in either powder or compressed pad form, gelatin (Gelfoam) is an absorbable hemostatic agent made from purified porcine gelatin solution that has been beaten to a foamy consistency, dried, and sterilized by dry heat. As a pad, it is available in an assortment of sizes that can be cut as desired without crumbling. When it is placed on an area of capillary bleeding, fibrin is deposited in the interstices and the sponge swells, forming a substantial clot.

The gelatin sponge is not soluble; it absorbs 45 times its own weight in blood. It is denatured to retard absorption, which takes place in 20 to 40 days. It is frequently soaked in thrombin or epinephrine solution, although it may be used dry after compression.

Before a gelatin sponge is handed to the surgeon, it is dipped into warm saline solution, if used without thrombin or epinephrine, and pressed between the fingers or against the sides of the basin to remove air from it. The same procedure is used with thrombin (human or bovine) or epinephrine solution, but then the sponge is dropped back into the solution and allowed to absorb solution back to its original size.

In powder form, gelatin is mixed with sterile saline solution to make a paste (slurry) for application to cancellous bone to control bleeding or to denuded areas of skin or muscles to stimulate growth of granulation tissue.[7] Gelatin film can be used in neurologic, ophthalmic, and otorhinologic procedures.[8] Gelatin hemostatic products should not be used in infected areas.

Absorbable Collagen

Hemostatic sponges (Collastat, Superstat, Helistat) or felt (Lyostypt) of bovine collagen origin are applied dry to oozing or bleeding sites. The collagen activates the coagulation mechanism, especially the aggregation of platelets, to accelerate clot formation. The material dissolves as hemostasis occurs.

Any residual material absorbs in the wound. Because of an affinity for wet surfaces, the material must be kept dry and should be applied with dry gloves or instruments. Absorbable collagen is contraindicated in the presence of infection or in areas where blood or other fluids have pooled. It is applied directly to the bleeding surface as supplied from the sterile package. Collagen hemostatics absorb within 8 to 10 weeks. Do not let this material accumulate in the skin incision because it creates a mechanical barrier to healing and causes scars.

Microfibrillar Collagen

Available in compacted nonwoven web form or in loose fibrous form, microfibrillar collagen (Avitene, Instat, Surgiflo) is an absorbable topical hemostatic agent. It is produced from a hydrochloric acid salt of purified bovine corium collagen. It is applied dry. When it is placed in contact with a bleeding surface, hemostasis is achieved by adhesion of platelets and prompt fibrin deposition within the interstices of the collagen. The collagen can swell to 20% of its volume within 10 minutes. Bovine products should not be used in patients with known allergy to bovine proteins.

Tissue cohesion is an inherent property of the collagen itself. It functions as a hemostatic agent only when it is applied directly to the source of bleeding from raw oozing surfaces, including bone and friable tissues, or directly to active bleeding from irregular contours, from crevices, and around suture lines. Firm pressure is applied quickly with a dry gauze sponge, which is held either by the fingers in accessible areas or by using forceps in less accessible areas.

The material must be compressed firmly against the bleeding surface before excessive wetting with blood can occur. Effective application is evidenced by a firm adherent coagulum with no breakthrough bleeding from either the surface or edges. Excess material should be removed from around the site without recreating bleeding. The remaining coagulum absorbs during wound healing.

Oxidized Cellulose

Absorbable oxidation products of cotton cellulose or oxidized regenerated cellulose (rayon) are available in the form of a pad or in a knitted fabric strip that is of low density (Surgicel) or high density (Surgicel Nu-Knit). These products are applied dry and may be sutured to, wrapped around, or held firmly against a bleeding site or laid dry on an oozing surface until hemostasis is obtained.

When oxidized cellulose comes into contact with whole blood, a clot forms rapidly. As it reacts with blood, it increases in size to form a gel and stops bleeding in areas in which bleeding is difficult to control by other means of hemostasis.

Except in situations in which packing is required as a lifesaving measure, only the minimal amount necessary to control capillary

or venous bleeding is used. If left on oozing surfaces, it absorbs 10 times its own weight with minimal tissue reaction. It is not recommended for use on bone unless it is removed after hemostasis because it may interfere with bone regeneration. Oxidized regenerated cellulose has some bactericidal properties, but it is not a substitute for antimicrobial agents and is absorbed in 1 to 2 weeks. Thrombin is inactivated in the presence of oxidized cellulose. During the absorption period, the cellulose can look like an abscess on x-ray.

Zeolite Beads

Trauma patients may arrive in the OR with wounds packed with bags of zeolite beads used for emergency hemostasis by emergency squads in the field. The intact sterile gauze bag is radiopaque and can be placed directly into the wound. Pressure is applied. It is packaged in 3.5 ounce gauze bags wrapped in foil. The large volume is necessary to have enough to fill a traumatic wound.

The beads are derived from a form of volcanic pumice that has an exothermic reaction in the presence of moisture. The beads absorb the water from blood and reach temperatures around 140° F to 155° F (60° C to 68.3° C). Later generations of zeolite hemostatic material have been impregnated into dressing material and have minimal exothermic action. Zeolite dressings are available with silver granules embedded for antimicrobial properties.

The OR team removes the bead pack or emergency zeolite dressing as part of the trauma surgery because the beads are not biodegradable and could cause a foreign body reaction.

Kaolin-Based Product

Kaolin (QuikClot) has been incorporated into a new product for hemostasis that is used in the same manner as the dressing materials impregnated with zeolite beads. It is available in various size gauze pads and rolls with radiopaque markers. No exothermic reaction occurs with kaolin. Kaolin is a natural mineral form of hydrated aluminum silicate that is insoluble in water. QuikClot contains no animal, human, botanical, or shellfish protein.

Used in treatment of hemorrhage, the kaolin dressings provide excellent hemostasis by activating the coagulation cascade. In its powder form, it can be used as a sclerosing agent for pleurodesis in pneumothorax. Care is taken to avoid inhaling the powder because it can cause respiratory complications.

QuikClot is approved by the U.S. Food and Drug Administration (FDA) for uncontrolled emergency bleeding and is used for eviscerating wounds. The foil-wrapped packet can be stored in warm or cool temperatures and has a shelf life of 3 years. Prolonged exposure to the air diminishes the effectiveness of the product once opened. American troops have been deployed for combat with this product since 2005. More information about this kaolin-based product can be found at www.quikclot.com.

Oxytocin

Oxytocin is a hormone produced by the pituitary gland. It can be prepared synthetically for therapeutic injection. During cesarean section, oxytocin (10 units) may be directly injected into the uterine muscle to cause contraction after delivery of the baby and placenta. It is a systemic agent used to control hemorrhage from the uterus, rather than a local hemostatic agent per se. Oxytocin is sometimes used to induce labor. It also causes contraction of the uterus after delivery of the placenta.

Ergonovine, another oxytoxic drug commonly referred to as ergotrate maleate, can be used to treat uterine bleeding after childbirth or abortion after the delivery of the placenta. It causes sustained uterine contractions over a period of 3 hours. The drug is derived from ergot, a form of rye. Ergotrate should be stored in a cool, dry area and protected from light.

Monsel's Solution

Persistent intrauterine bleeding at the placental attachment site can be treated IV with additional oxytocin and topically during a cesarean section with Monsel's solution (20% aqueous ferric subsulfate). A surgical laparotomy tape saturated with approximately 16 mL of Monsel's solution can be used to tamponade the bleeding internal endometrial surface. Monsel's solution is acidic and is used with care to prevent contact with perineal surfaces, it can cause denaturation of the tissues. It can also cause dermal tattooing. Additional hemostatic material such as Surgicel can be applied to the area when the pack is withdrawn after several minutes. This method is an alternative to cesarean hysterectomy or uterine or hypogastric artery ligation.

Monsel's solution can be used to create hemostasis over denuded areas caused by shave biopsies of the skin or anorectal or uterine cervix punch biopsies. Ferric subsulfate is applied using a cotton swab and causes the vessels to occlude by denaturing protein. Monsel's solution was developed by Leon Monsel (1816–1878), a French pharmacist, and is recorded in use during 1852 in the Crimean war, in which Florence Nightingale served with her nurses.

Phenol and Alcohol

Some surgeons use a cotton-tipped swab dipped in 95% phenol to cauterize tissue when cutting across the lumen of the appendix. Phenol is caustic and coagulates proteins, and in high concentration, it is so caustic that it can cause severe burns. It is neutralized with 70% alcohol. This would be used on the sterile field and handed off immediately after use.

Styptics

A styptic is an agent that checks hemorrhage by causing vasoconstriction. Styptics have the disadvantage of being rapidly carried away by the bloodstream.

Epinephrine

A hormone of the adrenal gland, epinephrine (Adrenalin) is prepared synthetically for use as a vasoconstrictor to prolong the action of local anesthetic agents or to decrease bleeding. Used in some local anesthetic agents to constrict the vessels locally, epinephrine keeps the anesthetic concentrated within the area injected and reduces the amount of bleeding when the incision is made. It is rapidly dispersed, leaving little local effect. Within the incision, gelatin sponges soaked in 1:1000 epinephrine may be applied to bleeding surfaces. These are especially useful in ear and microsurgical procedures in which localized hemostasis of capillaries is critical. Excess epinephrine can be absorbed systemically and cause cardiac stimulation.

Silver Nitrate

Crystals of silver nitrate in 20% to 50% solution or mixed with silver chloride and molded into applicator sticks are applied topically for vasoconstriction. Both an astringent and an antimicrobial, silver nitrate is commonly used in the treatment of burns or other moist wounds. Silver nitrate can be used to seal areas of previous surgical incisions that are left open to heal by secondary intention. Silver nitrate should not be used on the face because it may cause discoloration of the skin. The staining darkens to black in the presence of light. Silver nitrate 1% was previously used as

eye gonococcal prophylaxis in newborns; however, this practice has been replaced with a single instillation of 0.5% erythromycin ointment.

Aluminum Chloride 30%

Aluminum chloride is applied with a cotton swab to cause the formation of coagulum over a denuded area. It is not as effective as Monsel's solution and does not cause skin discoloration. The area should be covered with an occlusive dressing to prevent drying of the wound.

Zinc Chloride Paste

Zinc chloride causes coagulation over a denuded area. Zinc chloride paste is sometimes used after Mohs' micrographic surgery.

Tannic Acid

A powder made from an astringent plant, tannic acid is used occasionally on mucous membranes of the nose and throat to help stop capillary bleeding.

Thrombin

An enzyme extracted from human or bovine blood is used as a topical hemostatic agent in 5000 to 20,000-unit solutions. Thrombin accelerates coagulation of blood and controls capillary bleeding. It unites rapidly with fibrinogen to form a clot. Topically, it may be used as a dry powder to sprinkle on an oozing surface or as a solution, alone or to saturate a gelatin sponge. Topical thrombin may be sprayed on areas of capillary bleeding that do not lend themselves to other means of hemostasis, such as sealing a skin graft onto a denuded area. It should not be allowed to enter large vessels. Systemic absorption can cause intravascular thrombosis.

Thrombin is used for topical application only. It is never injected. Recommendations are that thrombin be mixed just before use because it loses potency after 3 hours. Thrombin solution should be labeled with the name of the drug and the concentration and kept separate from any other solutions on the instrument table. Manufacturer instructions should be followed for mixing solution. Bovine thrombin is contraindicated if the patient is allergic to bovine products. Human thrombin may carry the risk for viral or prion contamination.

Sclerotherapy

A caustic sclerosing solution may be injected into veins, as in the mucosal lining of the esophagus or anus, to stop or prevent venous bleeding. The solution may be a mixture of equal parts of dehydrated alcohol, bacteriostatic saline, and sodium tetradecyl in a contrast medium base. Other sclerosants are mixtures of absolute ethanol or ethanolamine.

Bentonite Powder

In 2018 the FDA approved an inorganic aluminum phyllosilicate clay powder (Hemospray) for topical use in the upper and lower gastrointestinal tract.[9] The powder is administered from a handheld spray device powered by a carbon dioxide cartridge. The single-use endoscopic device sprays the powder through a catheter to the bleeding site. The powder forms a gel layer and stops bleeding within 5 minutes. More information can be found at www.fda.gov.

Embolization

A hemostatic agent can intentionally be placed inside a vessel to occlude the blood supply to a tumor. Several substances are used as embolic agents to intentionally thrombose a vessel. The embolization depends on the amount of thrombus formed within the substance of the hemostatic agent. Patients on anticoagulant therapy may not form an adequate clot to embolize the desired area. In some circumstances, the embolized area can recannulate in 4 to 6 weeks and become patent. In ischemic tissues, distal embolization may take place.

The hemostatic agent is delivered under fluoroscopy to the site via injection mixed as a suspension or slurry in contrast medium and sterile saline solution for intravascular use. Albumin or dextran can be used to create a more viscous suspension. A commonly used agent is polyvinyl alcohol foam fibers.

Other "off label" materials used in embolization include the following:

- Gelfoam powder can be used as a slurry. The occlusion can last several weeks or months, depending on the physiology of the area to be embolized.
- Avitene provides quick embolization that lasts 2 to 3 months.
- Dehydrated alcohol can be used to embolize low-pressure venous lesions. It is mixed with contrast medium to perform the injection under fluoroscopic guidance.
- Ethiodol (oil-based) can be mixed with chemotherapeutic agents for hepatic chemoembolization. Ethiodol has contrast medium properties.

Other embolization devices, such as coils in various shapes, can be placed via the endovascular route to an area of aneurysm by catheter technique. Coils can be soaked in thrombin. Some lesions can develop collateral circulation, and repeating the coil procedure may not be possible if the blood supply is persistent distal to the coil placement. Several coils can be placed at one time and may take varying amounts of time to be effective.

Silicone balloons can be deployed into a vessel that develops a distal and proximal thrombus at each end of its structure. The balloon deflates over time because it is somewhat permeable, but the lasting thrombus maintains the desired occlusion. Latex balloons are less permeable but pose a risk to patients with latex sensitivity or allergy. Coils are used more often in the United States.

Mechanical Methods of Hemostasis

External Mechanical Methods

Mechanical hemostasis is achieved by occluding severed vessels until normal forces of blood have time to form a clot. During the surgical procedure, the surgeon uses many mechanical devices to apply pressure or create a mechanical barrier to the flow of blood. Pressure also is used prophylactically preoperatively and postoperatively to control the tone of blood vessels and aid venous return.

Mechanical external pressure devices may be applied before the patient arrives in the OR or after the patient is transferred to the OR bed. The intended purpose may be prophylactic to prevent venous stasis, deep vein thrombosis (DVT), or pulmonary embolus (PE) intraoperatively and postoperatively. Or the function may be therapeutic to control internal hemorrhage preoperatively or hematoma postoperatively. A bloodless surgical field also can be created by external pressure devices.

Antiembolic Stockings. Elastic stockings may be applied to the lower extremities to prevent thromboembolic phenomena. Static compression on the legs helps prevent venous stasis. Stockings are available in knee-length and groin-length sizes. To apply the stockings, the circulating nurse rolls the stocking from top to toe. After placement over the patient's toes, the stocking is gently unrolled over the leg from foot to ankle to calf.

Sequential Compression Device. Inflatable double-walled vinyl or woven fabric leg wraps use alternating compression and

relaxation to reduce the risk for DVT in the legs of patients at high risk who are undergoing general anesthesia or experiencing extremes of intraoperative positioning. The leg wraps may be used over antiembolic stockings on each leg, although the compression device alone is sufficient in the prevention of DVT. The patient's foot is not encased within the wrap. The circulating nurse should measure the patient's thigh or calf for the correct size selection (i.e., small, medium, large, or extra large) for either full-leg (thigh-high) or knee-high leg wraps. Proper selection and application are essential for effective compression. Disposable leg wraps are commercially available.

A motorized pump, attached by tubing to each wrap, sequentially inflates leg wraps at the ankles, then at the calves, and then at the thighs for full-leg compression. The pressure of this wavelike action is greatest at the ankles. The leg wraps are divided into chambers so that pressure can be regulated by preset or adjustable gauges. Pressure between 40 and 50 mm Hg applied for 12 seconds and then released for 48 seconds empties blood from deep leg venous sinuses. The action prevents venous stasis and accumulation of clotting factors in deep veins. The pumping action is started before induction of anesthesia because general anesthesia reduces venous return and causes vasodilation.

The circulating nurse should regularly check operation of the pump and periodically inspect the leg wraps and tubing. Care is taken to ensure that the patient is not lying on the tubing. The type of device, time started, pressure and cycle settings, and time discontinued must be documented on the intraoperative record. If the surgeon wants leg wraps to remain on the patient postoperatively, the device is transported to the postanesthesia care unit (PACU) or intensive care unit (ICU) with the patient. Frequently, sequential compression is continued for 24 hours postoperatively or until the patient is fully ambulatory after an abdominal, hip, or neurosurgical procedure.

MAST Pneumatic Counterpressure Device. Although the concept dates back to 1903, external counterpressure was not a popular medical device until the Vietnam War. There it was used to control hemorrhagic shock until definitive hemostasis became available to casualties. Circumferential pneumatic compression counteracts postural hypotension, maintains venous pressure, and controls hemorrhage. Several types of pneumatic antishock garments (PASGs) are used, primarily to treat hypovolemic shock.

The acronym MAST can refer to medical antishock trousers, military antishock trousers, or a military antigravity suit. An inflatable waterproof garment is fastened around the patient from ankles to ribcage. The trouser chambers are inflated first, to prevent venous stasis in the legs. The entire suit or only specific chambers of it can be inflated from the feet up. Each chamber is inflated separately with a foot pump. By increasing pressure on vessel walls of the legs and abdomen, systemic vascular resistance of peripheral vessels increases blood flow to the heart, lungs, and brain. Compression of torn vessel walls reduces the size of the laceration and diminishes blood loss.

The MAST device may be in place when the trauma patient arrives in the OR. Deflation begins after induction of anesthesia, beginning with the abdominal chamber. Leg chambers may remain inflated for counterpressure if BP remains unstable. Deflation must be slow and gradual. The MAST suit is never cut off the patient. Rapid deflation reduces cerebral and cardiopulmonary circulation, with resultant shock. BP is monitored; it should not drop more than 5 mm Hg.

Pneumatic counterpressure devices may be used to prevent air embolism during some head and neck procedures performed with the patient in a sitting position. The increased venous filling produced decreases the possibility of an air embolus. Also, these devices may be used postoperatively to reduce bleeding or stabilize the patient's condition after massive blood loss during the surgical procedure.

Tourniquets. A tourniquet is a device used to provide hemostasis by constricting the flow of blood in an extremity. It is frequently used on the proximal aspect of an extremity to keep the distal surgical site free of blood. A bloodless field makes dissection easier and less traumatic to tissues and reduces surgical time. Bleeding must be controlled before pressure is released.

Precautions for tourniquet application and use are observed. A tourniquet should not be used when circulation in an extremity is impaired or when an arteriovenous access fistula for dialysis is present. A tourniquet can cause tissue, nerve, and vascular injury.[10] Paralysis may result from excessive pressure on nerves. Prolonged ischemia can cause loss of innervation and circulation in the extremity. Tourniquet time should be kept to a minimum. Metabolic changes may be irreversible after 1 to 1½ hours of tourniquet ischemia. Consideration for latex sensitivity may be an issue for some devices used as tourniquets. Rubber materials should be latex-free if the patient is sensitive to latex products.

A tourniquet is dangerous to apply, to leave on, and to remove. A tourniquet may be applied by the surgeon, first assistant, or circulating nurse on the surgeon's orders.

Pneumatic Tourniquet. Similar to a blood pressure cuff, although heavier and more secure, the pneumatic cuff consists of a rubber bladder shielded by a plastic insert inside a fabric cover with a Velcro closure. Many different types of cuffs are available. Some are straight and cylindric; others are contoured. A cuff of appropriate length and width must be used, and various sizes are available. Cuffs are inflated automatically with compressed gas (air or oxygen) by means of tubing interconnected between the cuff and a pressure cartridge, piped-in system, or battery-powered unit.

The desired pressure is uniformly maintained by a pressure valve and registered on a pressure gauge. The tourniquet console, a pressure regulator with a gauge, may be contained in a unit mounted on a portable stand or hung on an IV pole. An automated tourniquet with a computerized microprocessor control signals both audible alarms and visual indicators for deviations from preset pressure and for elapsed time of inflation.

Correct pressure is the minimum amount necessary to produce a bloodless field. The calculation of tourniquet cuff pressure is according to the systolic blood pressure. An exact pressure to which the cuff should be inflated has not been determined. In a healthy adult, upper extremity pressure 30 to 70 mm Hg higher than the systolic value of the blood pressure may be sufficient to suppress arterial circulation.

Tourniquet pressure on an average adult arm usually ranges from 200 to 250 mm Hg (up to 6 lb). In the lower extremity, cuff pressure should be higher than the systolic pressure by one half the value. This may require 250 to 300 mm Hg on the thigh. Thin adults and children need less pressure; muscular and obese extremities may need more. Inflation time also should be kept to a minimum. If needed for more than 1 hour on an arm or 1½ hours on a leg, the tourniquet may be deflated at intervals periodically at the discretion of the surgeon. The limb should be exsanguinated before reinflation of the tourniquet.

A pneumatic tourniquet should be used and maintained according to the manufacturer's written instructions. These and institutional policies and procedures should be available to users of this complex equipment. The cuff, tubing, connectors, gauges,

and pressure source should be maintained in working order. Precautions to be taken when using a pneumatic tourniquet include the following:

1. Inspect and test the pneumatic tourniquet equipment before each use.
   a. Inspect the inflatable cuff, connectors, and tubing for cleanliness, integrity, and function.
   b. Ensure that the cuff and tubing are intact and that the connectors are securely fastened to the tourniquet pressure source.
   c. Check the pressure gauge for accuracy. An aneroid pressure gauge can be checked by comparing it with a mercury manometer. Pressure drifts can be detected by wrapping the cuff around a rigid cylinder, inflating it to 300 mm Hg, and observing for pressure variations.
2. Protect the patient's skin under the tourniquet cuff.
   a. Place a single layer of wrinkle-free padding around the extremity. A length of stockinette or lint-free cotton sheet wadding may be used (Webril). Disposable padded covers are commercially available.
   b. Keep the padding and cuff dry. Antiseptic solutions and other fluids should not contact or accumulate under the cuff. Skin maceration or burns could result. Placement of an impervious drape around the cuff prevents the pooling of fluids.
3. Position the cuff at the point of maximum circumference of the extremity.
   a. Avoid vulnerable neurovascular structures. Nerves and blood vessels may be compressed against bone when the cuff is inflated. Soft tissue provides padding for underlying structures. The cuff should be placed on the upper arm or proximal third of the thigh.
   b. Select a cuff of appropriate width for the size and shape of the extremity. A wide cuff occludes blood flow at a lower pressure than does a narrow cuff.
   c. Select a cuff with adequate length to overlap at least 3 inches (7.5 cm) but not more than 6 inches (15 cm).
   d. Apply the cuff smoothly and snugly over padding before prepping the extremity.
   e. Apply a sterile cuff, if used, after prepping and draping. A sterile cuff may be used for an immunocompromised patient.
4. Preset pressure gauges. The surgeon determines the pressure setting according to the patient's age, limb size, and systolic blood pressure and the width of the cuff to be used.
5. **Exsanguination** of the elevated extremity after prepping and draping, but before cuff inflation, prolongs the tourniquet time and provides a bloodless field. An Esmarch bandage can be latex or nonlatex. Check for patient's allergies before the case begins.
   a. Elevate the limb during the preparation and keep elevated for 2 minutes after the skin prep to encourage venous drainage. Inflation of the cuff over blood-filled vessels may cause intravascular thrombosis and lead to embolus.
   b. A sterile team member spiral-wraps an Esmarch bandage around the extremity to compress the blood vessels. The wrap begins distally at the digit tips and progressively spirals proximally up to the tourniquet cuff. After the limb is completely wrapped, the cuff is inflated and the Esmarch is removed.
   c. The scrub person rerolls the Esmarch bandage and keeps it sterile on the back table for potential reuse during the case.
6. Inflate the cuff rapidly to occlude arteries and veins simultaneously to predetermined minimum pressure.
7. Monitor safety parameters during use of the pneumatic tourniquet.
   a. Monitor the pressure gauge to detect pressure fluctuations within the bladder of the cuff.
   b. Monitor the duration of inflation. Inform the surgeon when the cuff has been inflated for 1 hour and every 15 minutes thereafter. In some ORs the circulating nurse posts the tourniquet time on a tally board in view of the surgeon and anesthesia provider.
8. Document the use of a tourniquet on the intraoperative record.
   a. Record the times the tourniquet is applied, inflated, deflated, and removed. The anesthesia provider also records the inflation time on the anesthesia sheet when a tourniquet is used with a Bier block for regional anesthesia.
   b. Record the location of the cuff, who placed it, and the pressure setting.
   c. Record the model and serial number of the tourniquet used.
   d. Document assessment of the skin condition of the extremity preoperatively and evaluation of skin and tissue integrity after removal of the cuff.
9. Clean and inspect the pneumatic tourniquet after each patient use.
   a. Wash the reusable cuff and bladder according to manufacturer instructions. An enzymatic detergent should be used if blood or body fluid came in contact with the cuff. A disposable cuff cover facilitates cleaning.
   b. Rinse and dry the cuff and bladder. Water droplets inside the bladder can damage the pressure mechanism if forced backward during subsequent deflation. Care should be taken to prevent water from getting into the bladder during washing.
   c. Wipe the connecting tubing with a disinfectant.
   d. Test the cuff, tubing, connectors, and gauges before storage between uses. A malfunctioning device must be removed from service until repaired and tested by appropriate personnel.

A pneumatic tourniquet is used most frequently to produce a bloodless surgical field. Tourniquets without pressure measurement gauges can cause damage to tissues. Other types of tourniquets used occasionally include the following:

- *Blood pressure cuff:* The cuff is inflated with ambient air. The surgeon determines the amount of pressure to be sustained. The regulator valve is tightened. The pressure gauge or sphygmomanometer must be monitored for pressure deviations.
- *Rubber band:* This may be used as a tourniquet for a finger or toe. The surgeon puts a sterile rubber band on the digit after draping. This method is not used for patients with latex sensitivity.
- *Rubber tubing:* When an IV infusion is started, a small length of rubber tubing is tied around the extremity, usually an arm, while the needle is inserted. This stops venous return and makes the vein more visible for venipuncture. A Penrose drain is commonly used as a tourniquet.
- *Rubber bandage (Esmarch bandage):* Friedrich von Esmarch (1823–1908), a German military surgeon, introduced an elastic bandage for the control of hemorrhage on the battlefield in 1869. Known today as the Esmarch bandage, a 3-inch (7.5-cm) roller bandage is used to compress superficial vessels as an emergency tourniquet.

Contraindications for Tourniquet Use. Tourniquets are not used in the presence of infection or venous stasis in the limb. A bolus of infectious material or a clot could become dislodged.

Other situations in which a tourniquet is not used include, but are not limited to, the following:

1. Malignant disease in the limb (may cause spread)
2. Vascular access ports or shunts (can destroy the patency of the structure)
3. Known peripheral vascular disease or history of DVT
4. Extremes of age: neonate or elderly
5. Rheumatoid arthritis
6. Skin grafts

Pressure Dressings. Pressure on the wound in the immediate postoperative period can minimize the accumulation of intercellular fluid and decrease bleeding by eliminating dead space. Pressure dressings are used on some extensive wounds to decrease edema and potential hematoma or **seroma** formation. They may be used as an adjunct to wound drainage to distribute pressure evenly over the wound.

Packing. Packing is used with or without pressure to achieve hemostasis and eliminate dead space in an area where mucosal tissues need support, such as the vagina, rectum, or nose. Packing impregnated with an antiseptic agent, such as iodoform gauze, may be used to ensure closure of an incision from the wound base toward the outside (i.e., healing by second intention), as in a large abscess cavity. The surgeon inserts sterile packing as the final stage of the surgical procedure. It is usually removed in 24 to 48 hours. The intraoperative record and patient's chart should reflect the type, amount, and location of packing.

Internal Mechanical Methods

Meticulous hemostasis during the surgical procedure is essential to control bleeding and minimize blood loss. The surgeon uses many mechanical tools to achieve hemostasis.

Hemostatic Clamps. Clamps for occluding vessels are used to compress blood vessels and to grasp or hold a small amount of tissue. The hemostat is the most frequently used surgical instrument and the most commonly used method of hemostasis. This instrument has either straight or curved jaws that narrow to a fine point. Often the pressure of clamping an instrument is sufficient to constrict and seal a vessel with minimal trauma or adjacent tissue necrosis. A wide variety of hemostatic clamps are used for vessel occlusion, including noncrushing vascular clamps that do not damage large vessels.

Ligating Clips. When placed on a blood vessel and pinched shut, clips occlude the lumen and stop the bleeding from the vessel. Metallic clips, such as stainless steel or titanium clips, are small pieces of thin serrated wire that are bent in the center to an oblique angle. Absorbable polymer clips are similar in configuration. Clips are most frequently used on large vessels or those in anatomic locations difficult to ligate by other means. Many surgeons use clips for ligating vessels, nerves, and other small structures. A specific forceps is required for the application of each type available.

Single clips may be mounted in a sterile plastic cartridge that can be secured in a heavy stainless steel base to facilitate loading the applier forceps. Disposable manual and powered appliers preloaded with multiple clips also are available. Some disposable clip appliers ligate as they apply the clip to a vessel.

Ligating clips were devised in 1917 by Dr. Harvey Cushing for use in brain surgery. Cushing clips are made of silver. Titanium clips are more common today because they cause less interference with computed tomography (CT) and magnetic resonance imaging (MRI) examinations. The serrations across the wire prevent slipping off the vessels. Polymeric clips have a locking device to secure them on vessels.

Metallic clips also may be used to mark a biopsy site or other anatomic areas to permit radiographic visualization and thus detect postoperative complications. For example, migration of a marker clip could indicate the presence of a hematoma in the wound. The artifacts (i.e., distortion) caused by stainless steel clips may be a disadvantage in future radiologic studies or MRI scans. Titanium and absorbable polymeric clips are preferred to eliminate or decrease image distortion of CT and MRI scans.

Ligatures. A ligature, commonly called a tie, is a strand of material that is tied around a blood vessel to manually occlude the lumen and prevent bleeding. Frequently the ligature is tied around a hemostat and slipped off the point onto the vessel and pulled taut to affect hemostasis. Vessels are ligated with the smallest size strand possible and include the smallest amount of surrounding tissue possible. Ends are cut as near the knot as possible.

Large and pulsating vessels may require a transfixion suture. A ligature on a needle (stick tie) is placed through a "bite" of tissue and brought around the end of the vessel. This eliminates any possibility of its slipping off the vessel. All bleeding points should be ligated before the next layer of tissue is incised.

Pledgets. Small pieces of Teflon felt are used as a buttress under sutures when bleeding might occur through the needle hole in a major vessel or when friable tissue might tear, such as cardiac muscle during cardiomyotomy. Placed over an arteriotomy site, they exert pressure to seal off bleeding. Pledgets are used most frequently in cardiovascular surgery and remain in place as part of the suture. Commercially prepared sutures with pledgets attached are available.

Packs. Packs are used to sustain pressure on raw wound surfaces and keep viscera from becoming injured during a procedure. The application of sponges or laparotomy tapes effectively controls capillary ooze by occluding the capillaries. The surgeon usually wants these packs moistened, often with room-temperature but sometimes with warm normal saline solution. Warm packs promote hemostasis by accelerating the coagulation mechanism. Warm saline does promote vasodilation and could augment venous oozing. Do not soak sponges or packs in the irrigation basin. Lint could be transferred to the patient causing adhesions.

PROS/CONS

Irrigation, Solution Basins, and Dispersing Lint

Pros

- Irrigation is a major part of the intraoperative and postoperative processes of surgery. The purpose of irrigation is to keep tissues moist, flush out debris, keep the surgical field visible, wipe instruments clean, and decrease surgical site infections.
- Sponges and towels are two of the most frequently used items in surgery. Moist sponges are used to soak up blood, clean instruments, and retract or pack body cavities. Moist towels are also used as visceral retainers.
- Irrigation should be applied to sponges and towels by an asepto syringe to avoid dispersing particulate in the solution basin. If

Continued

PROS/CONS—cont'd

Irrigation, Solution Basins, and Dispersing Lint

necessary, a separate basin of solution can be used for this purpose.
- Surgeons may request several liters of fresh warm irrigation during the surgical procedure. They may ask for the solution in an asepto syringe or pour directly from the basin into the patient.
- Warm fresh irrigation may be requested to irrigate the surgical site before closure. A clean Poole suction tip with the guard in place should be used to suction large amounts of irrigation fluid.
- Products used in the OR should be powder free and low linting.
- Solutions used on the sterile field as irrigation should be accounted for in their volume entirety to prevent confusion with estimated blood loss.
- Education regarding irrigation and sponges should include moistening all towels and sponges with an asepto in a separate basin or impervious area of the sterile field. If a towel or sponge is dipped into an irrigation basin, that irrigation is not safe for use inside the patient.

Cons

- During a procedure, a surgeon may request a wet sponge or towel. The scrub person commonly dips the sponge or towel and rings it out back into the basin before handing it to the surgeon. Dipping sponges and towels in the irrigation basin disperses fibers and lint into the solution. Floating particulate can be seen on the surface of the solution.
- Sponges and towels lose lint during routine use. This can lead to complications such as inflammation, granuloma or textiloma formation, adhesions, infection, thrombus formation, and tissue necrosis.
- High-lint cotton sponges and towels should be avoided. Cotton balls and cotton gauze should not be used in open body cavities because they shed the most fibers.
- Cases of coronary embolization from fiber fragments during the flushing of catheters with irrigation have been documented. Fibers were found in the solution where sponges were dipped. The catheter-flushing syringe was filled from the same irrigation basin and introduced the particulate and fibers into the patient's vascular system.
- Fibers and particulate have been found on guidewires and instrumentation that came into contact with the sponges, towels, and irrigation on the sterile field.
- Lack of standardization and understanding in perioperative practice puts patients at risk for foreign body reaction from fiber particles.
- Dipping sponges and towels in irrigation without measuring the amount used does not support accurate measurement of irrigation used during the procedure.

Compressed Absorbent Patties. Compressed absorbent radiopaque patties (cottonoids) are used for hemostasis when placed on the surface of brain tissue and to absorb blood and fluids around the spinal cord or nerves. These patties are available in an assortment of sizes. Before use, the scrub person counts and moistens them with normal saline solution, presses out excess solution, and keeps them flat. Some surgeons prefer an antibiotic, thrombin, or epinephrine solution to moisten the patties for hemostasis.

Bone Wax. Composed of a sterile nonabsorbable mixture of beeswax, isopropyl palmitate, and a softening agent, bone wax provides a mechanical tamponade barrier to stop oozing from cut bone surfaces. Each foil packet contains 2.5 g of wax and is opened just before use to minimize drying. The scrub person can warm wax to the desired consistency by manipulating it with the fingers or by immersing the unopened packet in warm solution. Small pieces can be rolled into 1 cm balls and placed around the rim of a medicine cup. When needed, the cup can be presented to the surgeon. Some surgeons prefer to use a freer elevator to apply the wax to the bleeding bone edge.

Bone wax is used in some orthopedic and neurosurgical procedures and when the sternum is split (sternotomy) for cardiothoracic procedures. Bone wax should be used sparingly and is contraindicated when rapid bone regeneration is desired. The wax is not soluble and is a mechanical barrier that can persist for years; it may impede ossification and bone union. It is contraindicated in the presence of infection. Some patients may be sensitive and can develop a foreign body reaction or osteomyelitis.

The product is cobalt sterilized, and the expiration date should be checked before use. It should not be stored in areas that exceed 77° F (25° C).

Bone Wax Alternatives. Biodegradable water-soluble material that looks and feels like bone wax is a physical mechanical barrier on cut bone edges and is intended to be used sparingly. One type, Ostene, is an inert alkylene oxide copolymer, derived from ethylene oxide and propylene oxide. Ostene contains no beeswax and does not cause an inflammatory response like beeswax. It is supplied in 1 to 3 g foil packets for sterile use. More information can be found at www.ostene.com.

Bone wax alternative is sterilized by irradiation and cannot be reprocessed. It should be warmed to body temperature and worked into soft 1-cm balls just like bone wax. It has no biophysical cellular action, and its presence in the wound does not impair osteogenesis. It is contraindicated in the presence of infection.

Digital Compression. When digital pressure is applied to an artery proximal to the area of bleeding, such as in traumatic injury, hemorrhage is controlled. The main disadvantage of digital pressure is that it cannot be applied permanently. Firm pressure is applied on the skin on both sides as the skin incision is made to help control subcutaneous bleeding until vessels can be clamped, ligated, or cauterized. Pressure is applied while the surgical area is sponged to locate a bleeding vessel.

Suction-Irrigation. Suction is the application of negative pressure, either continuously or intermittently. It is used during surgical procedures for removal of blood and tissue fluids from the surgical field, primarily to enhance visibility. An appropriate diameter and style of tip for evacuation of blood is attached to sterile disposable suction tubing. The scrub person hands the end of the tubing to the circulating nurse, who attaches it to a suction collection container.

A powered suction-irrigation system may be used to simultaneously irrigate the wound and evacuate solution. The irrigation may be pulsed (i.e., intermittent to remove debris and clots) or continuous with gravity flow. The surgeon adjusts the flow of irrigation and suction with controls on the disposable tip assembly. Spatter screens that fit around the tip of the irrigator like a cone to minimize splashes and aerosolization are commercially available.

Drains. Postoperatively, drains aid in removal of blood, fluid, and air from the surgical site to obliterate dead spaces and enhance approximation of tissues, thus preventing hematoma and seroma formation. Drains usually are placed through a stab wound in the skin adjacent to the primary incision.

Thermal Methods of Hemostasis

Hemostasis may be achieved or enhanced by application of either cold or heat to body tissues.

Cold Methods of Hemostasis

Cryosurgery. Cryosurgery is performed with the aid of special instruments for local freezing of diseased tissue without harm to normal adjacent structures. Extreme cold causes intracapillary thrombosis and tissue necrosis in the frozen area. Frozen tissue may be removed without significant bleeding during or after the surgical procedure. Cryosurgery is also used to alter cell function without removal of tissue. It tends to be hemostatic and lymphostatic, particularly in highly vascular areas.

Extreme cold is delivered to extract heat from a small volume of tissue in a rapid manner. Liquid nitrogen is the most commonly used refrigerant; however, carbon dioxide gas may be used. The liquid or gas is in a vacuum container and comes through an insulated vacuum tube to a probe. All but the tip of the probe is insulated. Freezing of tissue at this tip is a result of the liquid nitrogen at the lowest temperature of −320° F (−196° C) becoming gaseous. In the process, heat is removed from the tissue. A ball of frozen tissue gradually forms around the uninsulated tip. The extent of tissue destruction is controlled by raising or lowering the temperature of cells surrounding the lesion from −4° F to > −6° F (−20° C to > −21° C).

The machines vary in range of temperatures obtained according to their design and type of refrigerant used. Some are nonelectric with foot switch–operated probes. Special miniature, presterilized, disposable models for single-patient use are particularly suitable for ophthalmic applications.

Because the process is rapid, involves less trauma to destroy or remove tissue, controls bleeding, and minimizes local pain, cryosurgery is used to alter the function of nerve cells and destroy otherwise unapproachable brain tumors. Other techniques for which it is used include removal of superficial tumors in the nasopharynx and the skin, destruction of the prostate gland, removal of highly vascular tumors and some otherwise nonresectable liver tumors, removal of lesions from the cervix and anus, cataract extraction, and retinal detachment. The amount of tissue destroyed is influenced by the size of the tip of the probe, temperature used, duration of use, kind of tissue and its vascularity, and skill of the surgeon.

Hypothermia. Cooling of body tissues to a temperature as low as 78.8° F (26° C) in adults and large children and 68° F (20° C) in infants and small children, well below normal limits, decreases cellular metabolism and thereby decreases the need for oxygen by tissues. The decreased requirement for oxygen decreases bleeding. Hypothermia lowers blood pressure to slow the circulation and increases the viscosity of blood. This process results in hemoconcentration, which contributes to capillary occlusion and microcirculatory stasis to provide an essentially dry field for the surgeon. Hypothermia may be localized or generalized (systemic). Hypothermia is used as an adjunct to anesthesia, particularly during heart, brain, and liver procedures.

Hot Methods of Hemostasis

Diathermy. Oscillating high-frequency electric current generates enough heat to coagulate and destroy body tissues. Heat is generated by resistance of tissues to passage of alternating electric current. A short-wave diathermy machine produces a high frequency of 10 to 100 million cycles per second. The machine should not be activated until the surgeon is ready to deliver this current. Diathermy is useful in stopping bleeding from small blood vessels. It is used primarily to repair a detached retina and to cauterize small warts, polyps, and other small superficial lesions.

Electrocautery. A small battery-operated pencil with a tiny thin wire loop heated by a steady direct electric current to red heat coagulates or destroys tissue on contact. Heat is transferred to tissue from the preheated wire. Electrocautery pencils are commonly used for plastic surgery, eye procedures, and vasectomies.

The hot point of the cautery should be at least 24 inches (61 cm) from the anesthesia machine and the patient's oxygen source (facemask or endotracheal tube), which is an oxygen-rich environment. Cautery should not be used in the mouth, around the head, or in the pleural cavity. Cautery should not be used when any flammable agent is present. To prevent fire, only moist sponges should be permitted on the field while any cautery is in use.

Electrosurgery. High-frequency electric current provided from an electrosurgical unit (ESU) frequently is used to cut tissue and coagulate bleeding points. The concentration and flow of current generate heat as it meets resistance in passage through tissue. Because air has low electrical conductivity, an active electrode tip delivering radiofrequency energy must be in direct contact with tissue. Both cutting and coagulating currents are used in many open and minimally invasive surgical procedures. Some surgeons prefer electrosurgery to other methods of cutting and ligating vessels. ESU is not used on the skin.

Coagulated tissue is devitalized and causes a foreign body reaction that must be resorbed by the body during healing. If a large amount of coagulated tissue is present, sloughing and necrosis may result.

Because the high-frequency electric current goes through the patient's body during monopolar use, a return electrode is applied to the patient and plugged into the grounded generator. When a bipolar ESU is used, the current does not pass through the patient's body and a return electrode is not needed. Smoke, or plume, from use of the ESU should be removed from the air with a smoke evacuator. Combined ESU with smoke evacuator units are commercially available. ESUs are described in detail in Chapter 20.

Fulguration. Sparks of high-voltage electric current char the surface of tissue, producing a thin coagulated crust (**eschar**) without damaging underlying tissues. Fulguration uses a spark-gap monopolar generator that emits a higher frequency current than does electrocoagulation from an ESU. This high-voltage arcing, described as spray coagulation, is used primarily for transurethral bladder and prostate procedures. A return electrode pad is used on the patient.

Argon Beam Coagulator. Argon gas in combination with an ESU pencil effectively delivers radiofrequency energy to tissue in a coaxial, noncontact, white-light beam for the purpose of rapid hemostasis monopolar coagulation. The argon beam coagulator

directs a gentle flow of ionized argon gas from a generator to a pencil-shaped handpiece. The nonflammable gas flow over tissues clears blood and fluid from the target site and allows creation of a superficial eschar directly on tissue by the ESU pencil.

Less necrotic tissue is produced than with the high-current density of electrocoagulation because the temperature never exceeds 230° F (110° C) and penetration is approximately half the depth, which minimizes tissue destruction.

The depth of penetration depends on the power, duration of application, and electrical characteristics of the tissue. Coagulation occurs through the arcing effect of electrical energy, not through the action of the argon gas. The coaxial flow of gas delivers monopolar current that coagulates the surface with practically no smoke or odor. A return electrode is applied to the patient to complete the electrical circuit.

The argon beam coagulator is used to control hemorrhage from vascular structures, surface bleeding of an organ such as the liver, and diffuse oozing and to achieve hemostasis of bone marrow. Handpieces and electrodes are available for use through endoscopes, but they are not used in fluid environments, such as joints.

Hemostatic Scalpel. The sharp steel blade of the hemostatic scalpel seals blood vessels as it cuts through tissue. The disposable blade, size no. 10, 11, or 15, has a heating and sensing microcircuitry between the steel and a layer of copper coated with electrical insulation and a nonstick surface. The blade fits into a reusable handle that contains control switches.

The scrub person hands the end of the electrical cord attached to the handle to the circulating nurse, who plugs it into the controller unit. When the surgeon activates the handpiece, the blade transfers thermal energy to tissues as the sharp edge cuts through them. An audible sound is emitted to signal the activation of the device. The temperature can be adjusted between 230° F and 518° F (110° C and 270° C). The surgeon can raise or lower the temperature in increments of 50° F (10° C). After use, it remains hot to the touch for 30 to 40 seconds. The blade also can be used cold, like any other scalpel.

The hemostatic scalpel can be used to incise skin, soft tissues, and muscle in a long smooth stroke. This is particularly advantageous in vascular areas, such as the scalp, head and neck, and breast. The blade is kept clean by wiping with a damp surgical sponge. Scraping the surface of the blade on a tip polisher decreases its efficiency. Care is taken not to touch the hemostatic scalpel blade to an active ESU tip so that the circuitry is not damaged.

This scalpel may be used to debride burns. Blood flow into the incised area is minimal, which provides the surgeon with a clear dry field, thus shortening surgical time. The rapid hemostasis with minimal tissue damage promotes wound healing and may eliminate a need for blood replacement. It is not effective in a bloody field or for vessels larger than 1.5 mm. Because electric current from the microcircuitry does not pass through the patient's body, a return electrode is not required. This also prevents muscle contractions.

Plasma Scalpel. The plasma scalpel vaporizes tissues and stops bleeding as it simultaneously cuts and coagulates tissue. Within the instrument, which looks like a large ballpoint pen, argon or helium gas passes through an electric arc that ionizes it into a high thermal state. These gases are inert and noncombustible. As the instrument moves over tissue, the gas that flows from the tip is visible, which allows the surgeon to see the depth and extent of the incision.

Tissue damage, with resultant inflammatory response during wound healing, is greater than that caused by a steel knife blade but less than that caused by other electrosurgical instruments and lasers. Because it coagulates blood vessels up to 3 mm in diameter, the plasma scalpel is useful in highly vascular areas.

Ultrasonic-Harmonic Scalpel. The titanium blade of the scalpel moves with a rapid ultrasonic motion that cuts and coagulates tissue simultaneously. The portable generator, a microprocessor with piezoelectric discs, converts electrical energy into mechanical energy. This energy is transmitted through a handpiece to a single-use blade. All three parts of the system lock into a frequency of 55,500 movements per second. When this happens, the system is said to be in harmony: thus the name harmonic scalpel.

The scalpel can be used for sharp or blunt dissection without damage to adjacent tissues. Vibrations from the blade denature protein molecules as it cuts through tissue, producing a coagulum that seals bleeding vessels. The continuous vibration of the denatured protein generates heat within the tissue to cause deeper coagulation. This action does not raise tissue temperature above 176° F (80° C), so that char or smoke is not produced. A fatty particulate mist may be generated. The vibrating blade also produces a cavitation effect (as it cuts through tissue with high water content) that disrupts cell walls and separates tissue, which aids in dissection.

The ultrasonic scalpel is used primarily for laparoscopic and thoracoscopic procedures. Blades and accessories for open procedures make this technology available to all surgical specialties. Because electricity is not required for effects on tissue, a return electrode is not necessary.

Laser. Laser light is used for control of bleeding or for ablation and excision of tissues in organs that can be exposed or are accessible endoscopically. The laser furnishes an intense and concentrated light beam of a single wavelength from a monochromatic source of nonionizing radiation. Thermal energy of this beam may simultaneously cut, coagulate, and vaporize tissue.

The laser wound is characterized by minimal bleeding and no visible postoperative edema. The amount of tissue destruction is predictable by adjusting the width and focus of the beam. Different lasers have selective uses. Lasers are described in detail in Chapter 20.

Photocoagulation. The photocoagulator uses an intense multiwavelength light furnished by a xenon tube to coagulate tissue. Its use is limited to ophthalmology.

Wound Management

Providing appropriate conditions for wound healing has been a quest through the ages. In ancient mythology, the Greek god Hermes carried a staff entwined with two snakes. This signified the snake's ability to repeatedly shed and regenerate its skin. Although humans do not shed their skin, they can regenerate tissue cells if the wound is protected from accumulations of blood and serum, mechanical injury, impaired circulation, and infection.

Drains

The use of devices to drain fluids and pus from the body dates back to the writings of Hippocrates. He wrote of insertion of a hollow tin or silver tube with flushings of wine and tepid oil to treat empyema. This was the first wound drainage system. In the nineteenth century, glass tubes, to be replaced by rubber catheters, were commonly used for gravity drainage.

In 1897, Dr. Charles B. Penrose (1862–1925), an American gynecologist, described a passive tubular drain made of gutta-percha,

the coagulated latex from rubber trees, with a gauze wick inserted through the length of the lumen. This latex drain, which still bears his name, is in use today to maintain a vent for the escape of fluid or air or to wall off an area of **exudate** in the wound. Sump drains, commercially introduced in 1932, offered advantages, such as use with suction apparatus. Suction drainage has been used since 1947. Closed-wound drainage systems, first introduced in 1952, are used to enhance wound healing.

The use of gravity drainage through various types of tubes versus capillary drainage through wicking devices historically has been a controversial issue. Even today, surgeons do not universally agree on the use of systems currently available. The location and purpose of the drain determine the surgeon's selection from the many types available. Drains may be used prophylactically or therapeutically during the surgical procedure or postoperatively.[11] Drains and drainage reservoirs are disposable.

Intraoperative Drainage

Used prophylactically to evacuate gastric contents, intestinal fluids, or urine, intraoperative drainage and decompression help prevent tissue trauma and restore organs to normal function.

Gastrointestinal Decompression

A plastic or rubber nasogastric tube inserted through a nostril down into the stomach or small intestine removes flatus, fluids, and other contents. The tube has holes in several locations near the tip to permit withdrawal of the contents. Several types of nasogastric tubes are used; the most common are the Levin tube into the stomach and the Miller-Abbott tube into the small intestine. A vented tube, such as the Salem sump tube, is preferable for use with nasogastric suction.

To prevent aspiration of stomach contents, the anesthesia provider may insert a nasogastric tube preoperatively to empty the stomach before an emergency surgical procedure. The surgeon may ask the anesthesia provider to insert a tube during an intraabdominal procedure for one of the following purposes:

- Decompression of the gastrointestinal tract
- Relief of distention that obstructs the view of the surgical site
- Measurement of blood loss from gastric hemorrhage
- Evacuation of gastric secretions during intestinal anastomosis

The nasogastric tube may remain in place postoperatively to prevent vomiting and distention caused by decreased peristalsis after anesthesia, manipulation of the viscera during the surgical procedure, or obstruction from edema of tissues at the surgical site. For this purpose, the tube is connected to a suction apparatus. The tube also may be used for nasogastric feeding during the healing process after a surgical procedure on the upper alimentary canal.

Urinary Drainage

Urethral or ureteral catheters inserted preoperatively provide constant drainage from the bladder or kidneys during the surgical procedure. The purpose may be to keep the bladder decompressed or to prevent extravasation of urine into the tissues around the surgical site during and after genitourinary procedures.

Postoperatively, the inflated balloon of an indwelling Foley catheter maintains an even pressure on the bladder neck, which may help control bleeding after prostatectomy, for example. An indwelling Foley catheter may be connected to a bladder irrigation or gravity drainage system until the bladder resumes normal function postoperatively. A suprapubic urinary catheter may be inserted percutaneously to assist with urinary drainage after pelvic surgery.

Postoperative Drainage

Drains are used therapeutically in the presence of purulent or necrotic material. Prophylactically, they may be inserted to evacuate fluids, including blood, or air from a wound or body cavity postoperatively.[11] Drains are usually placed in a separate small stab wound adjacent to the surgical incision and secured with a nonabsorbable monofilament suture. Drains can stimulate a walling-off process around a surgical site in which subsequent drainage may accumulate. This enhances wound healing by the following:

- Eliminating fluid accumulation
- Obliterating dead space
- Allowing apposition of tissues
- Preventing formation of hematomas or seromas
- Preventing tissue devitalization or wound margin necrosis
- Minimizing a potential source of wound contamination
- Decreasing postoperative pain
- Minimizing scarring

The action of drains may be either passive or active.

Passive Drains

Passive drains provide the path of least resistance to the outside. They function by overflow and capillary action through the drain to the absorbent dressing. They are influenced by pressure differentials and may be assisted by gravity.

Penrose Drain. A Penrose drain is a thin-walled cylinder of radiopaque latex. Nonlatex Penrose drains are commercially available. The diameter may be ¼ to 2 inches (6 mm to 5 cm), depending on the surgeon's preference. The drain is usually supplied to the sterile field in a 6 to 12 inch (15 to 30 cm) length for the surgeon to cut as desired. Penrose drains are commercially available prepackaged and sterilized. However, if they are prepared for onsite steam sterilization, a gauze wick is inserted to permit steam penetration of the lumen.

Although Penrose drains generally are used without a wick, the surgeon may prefer that the wick of gauze packing be left in the lumen to absorb drainage from the wound. This is referred to as a "cigarette" drain. For use without a wick, the drain is moistened in normal saline solution before it is handed to the surgeon. After it is placed into the surgical area and brought out through a stab wound in the skin, the drain is secured with a skin suture, or a sterile safety pin is attached on the outside close to the skin to keep the drain from retracting into the wound. The head of the safety pin should be crimped closed with a large forceps to prevent it from opening and piercing the patient.

Constant Gravity Drainage

A drain may be inserted for drainage by gravity flow from the gallbladder, bladder, or kidney. Each OR suite has a supply of sterile rubber or silicone tubes and catheters. Those used for drains, such as a T-tube, should be radiopaque. Some have inflatable balloons (e.g., Foley catheters) or enlarged bulbous ends (e.g., mushroom, Malecot, Pezzer catheters) to help hold them in place. A monofilament nonabsorbable suture may be used to circumferentially secure the drain in place.

A closed or semiclosed system is used to collect drainage. The scrub person keeps the end of the tube or catheter sterile until it is connected to the sterile end of the constant drainage tubing. Tubing should be connected or clamped as soon as the drain is brought through a stab wound in the skin or a tube or catheter is inserted into an organ. The circulating nurse connects tubing to a drainage bag. Constant drainage bags are marked in gradations

from 500 to 2000 mL. The bag must be in a dependent position, lower than the site of the drain, to avoid retrograde reflux.

Active Drains

Active drains are attached to an external source of vacuum to create suction in the wound. A constant gentle negative-pressure vacuum evacuates tissue fluid, blood, and air through a silicone, polyvinyl chloride, or polyurethane drain. Suction levels vary, depending on the system, to create the negative pressure (less than atmospheric).

Closed Wound Suction Systems. These systems are used when suction must be applied to an uninfected closed-wound site in the chest wall (e.g., after mastectomy), in the upper part of the abdomen, and in areas of joint replacement. They also are placed under large tissue flaps or in subcutaneous spaces in obese patients to eliminate dead space and hold tissues in apposition.

The sterile plastic drain has round or flat perforated and nonperforated tubing connected to a sharp stainless steel trocar. The trocar makes a small stab wound through the underlying tissues adjacent to the surgical incision and is brought up through the skin. The trocar is cut off and the nonperforated part of the drain tubing is pulled through the stab wound to the outside of the body. The perforated segment remains within the body. The nonperforated part of the tubing is attached to the disposable drainage collection reservoir. A monofilament nylon suture is used to stitch the tubing in place on the skin to minimize the risk for pulling out.

Several different units are available with reservoirs of different capacities and sizes of drainage tubing. Calibrations on the side of the container measure the drainage, and a line designates when it should be emptied or changed. These units are made entirely or partially of clear plastic so the surgeon can inspect drainage. The drain is radiopaque or has radiopaque markings to aid in checking its location on an x-ray, if desired.

The drainage reservoir can be attached immediately after placement of the tubing or after wound closure; then the vacuum is activated. Directions printed on each unit must be followed to activate the vacuum. The amount of suction in these systems varies depending on the method of creating the vacuum. Manually activated, spring-loaded devices (Hemovac) and grenade-type or bulb evacuators (Reliavac, Jackson-Pratt) have variable preset suction levels between 30 and 125 mm Hg (Fig. 29.3).

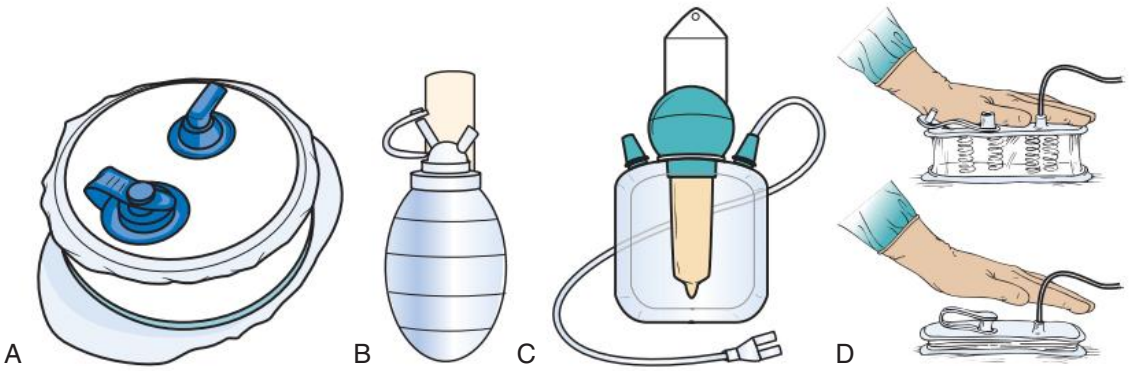
A portable, battery-powered device (VariDyne) can provide a constant and continuous vacuum at any setting between 10 and 350 mm Hg. With this system, the surgeon can determine the suction level on the basis of the material and area to be evacuated. With closed-wound suction systems, the drainage container does not need to be in a dependent position. An antireflux valve guards against backflow of fluids. Great care is taken not to dislodge the drainage tube when moving the patient from the OR bed to the transport cart after surgery.

Sump Drains. Sump drains may be used for aspiration, irrigation, or introduction of medication. Either flat or round, a sump drain has a double or triple lumen. Usually made of radiopaque silicone, it has large lateral openings to minimize clogging. The drain is brought out through a separate stab wound near the surgical site. Sump drains create equalized negative pressure at the site to be drained, usually in the abdomen.

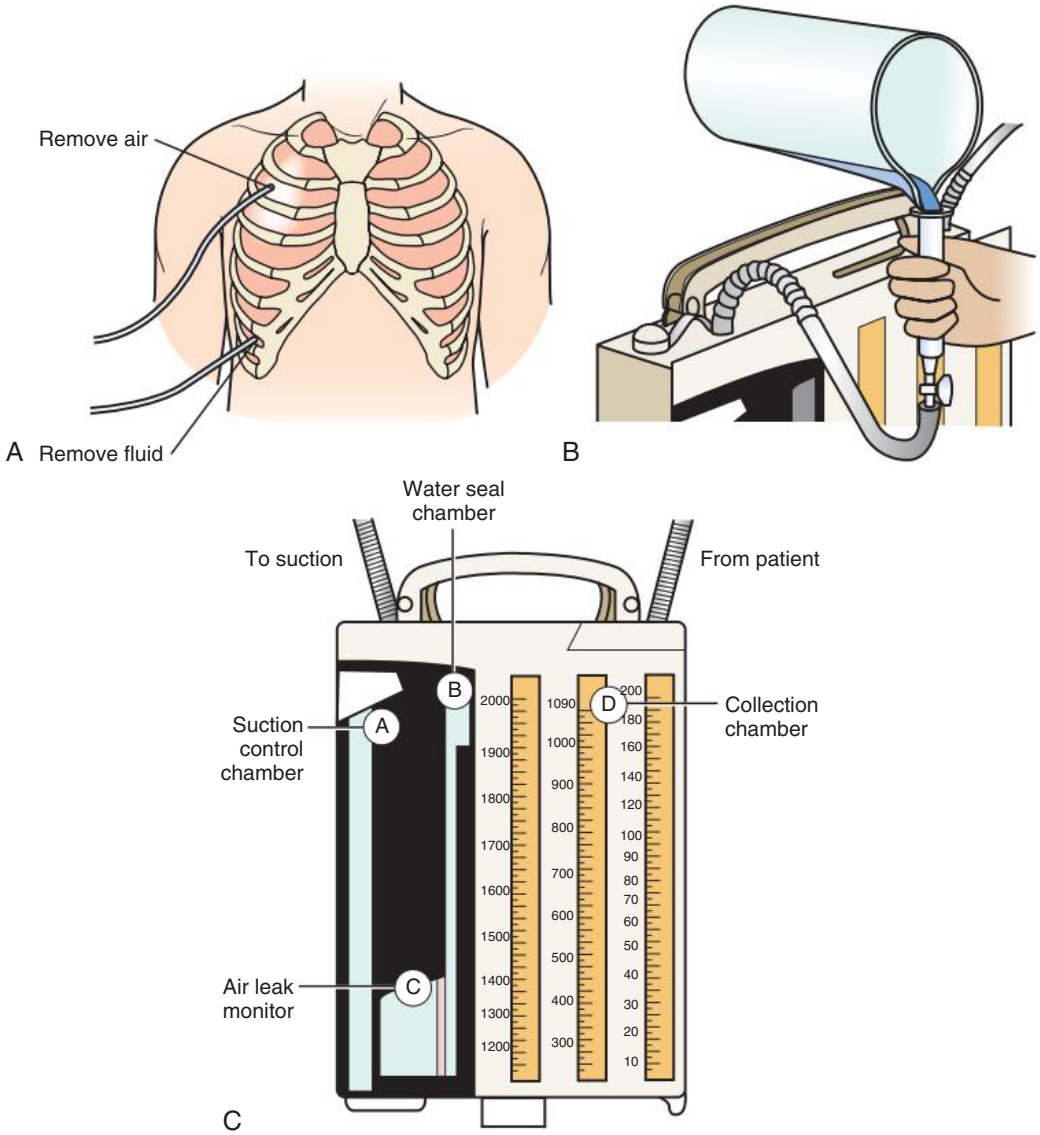
Sump drains are connected to a constant drainage system, with or without suction. Irrigation of the surgical site and connection to suction as soon as possible enhance function. Levels of suction between 80 and 120 mm Hg are desirable. The tubing may be attached to a piped-in (wall) or portable vacuum system. The drain must be clamped when not attached to suction or connected to a closed container. It functions as a passive drain if peripheral suction is not used and must be in a dependent position.

Chest Drainage. Drainage of the pleural cavity ensures complete expansion of the lungs after surgery. Air and fluid must be evacuated from the pleural space after surgical procedures within the chest cavity. One or more chest tubes are inserted. If the surgeon inserts two, the upper tube evacuates air and the lower tube drains fluid. After the chest tube is inserted during closure, the end is covered with sterile gauze until it can be connected to a sterile closed water-seal drainage system. The drainage system must prevent outside air from being drawn into the pleural space during expiration. Water in the collection unit seals off outside air to maintain a negative pressure within the pleural cavity (Fig. 29.4).

Two tubes vent the leak proof top of the collection unit. A short air-outlet tube extends 1 inch (2.5 cm) or more above the stopper to about 3 inches (7.5 cm) below it into the collection unit. The long inlet tube extends from above the stopper, through it, to about 1 inch (2.5 cm) from the bottom of the collection unit. Sterile water is poured into the collection unit to a level 1 to 2 inches (2.5 to 5 cm) above the end of the long inlet tube. Clear sterile tubing connects the inlet tube to the tube placed into the pleural space. On the patient's initial expiration, water rises a short distance up into the inlet tube. With each subsequent inspiration-expiration, the water level in the tube fluctuates. If the water level in the tube remains stationary, the chest tube or connecting tubing may be clogged or kinked. The collection unit



• **Fig. 29.3** Closed system active drainage. **A,** Hemovac drain reservoir. **B,** Bulb vacuum reservoir. **C,** Balloon pump hard canister reservoir. **D,** Activation of a Hemovac drain reservoir.



• **Fig. 29.4** Chest drainage. **A,** Placement of drains. **B,** Scrub person pours sterile water into the unit to create a water seal. **C,** Tubing attachment to three-chamber collection unit.

must be kept well below chest level to prevent water from entering the chest and to keep the tubing free of kinks.

Fluid drains by gravity from the chest into the water. The collection unit should be calibrated so drainage can be measured. Air bubbles through the water and escapes through the outlet tube.

If gravity drainage is not adequate for reexpansion of the lungs, suction may be applied at 15 to 20-cm water pressure to ensure evacuation of air and fluid. This requires the addition of one or two collection units to the system to act as a pressure regulator and the addition of a suction machine to maintain negative pressure. Disposable chest drainage units are available as a single unit or in a series of two or three. Some units have modifications based on the principle described for a closed water-seal system. Manufacturer directions should be followed for use. The unit must be properly connected before the patient leaves the OR.

With some units, the chest tube may be clamped during transportation as a safety measure. The surgeon should be consulted as to whether clamping is contraindicated. Indiscriminate clamping can create a mediastinal shift of the thoracic organs. Only tube clamps are used to occlude the tubing, not crushing clamps such as Kochers.

Patient Care Considerations

Drains, tubes, catheters, drainage tubing, and adapters are used for one patient only; they are never reused for another patient. If not properly handled by the scrub person and circulating nurse, a drain can be a source of wound contamination or irritation. When the surgeon inserts a drain, the following considerations should be kept in mind:

1. Drains, tubes, and catheters are kept sterile, ready for the circulating nurse to open if needed. They are available in many styles and sizes. They are patient charge items. Do not open until the surgeon specifies the style and size. A monofilament nonabsorbable suture on a small cutting needle is used to secure the drain to the skin. A Penrose drain may need a sterile safety pin. Remember to crush the head of the pin with a large clamp to prevent injury to the patient.

2. If the patient has a sensitivity to latex, do not use a drain, tube, or catheter with any latex components. Most drains are available in silicone.
3. The scrub person keeps the end of the drain sterile until it is connected to the sterile end of the drainage tubing.
4. Tubing connections must be physically tight and secured. Do not completely obscure connections by wrapping tape around them.
5. The drain site is dressed separately from the incision site. A nonadherent dressing can be used as the contact layer around the drain. Gauze dressings can be slit in a Y shape to fit around the base of the drain.
6. Avoid tension on the drain and kinks in the drain and tubing. A gentle loop can be made and secured with tape at the time of dressing application.
7. Collection bags or containers connected to passive drains, including chest tubes, must be kept well below the level of the body cavity where the drain is inserted and below the level of the drainage tubing to prevent retrograde flow. The amount of drainage should be recorded.
8. The circulating nurse must check the suction level to be certain it is consistent with the surgeon's orders or should activate the suction as appropriate for the system being used.
9. An x-ray may be taken for verification of placement of the drain or tube.
10. The type of drain, size, and its location are documented on the intraoperative record and reported to the PACU nurse.

Dressings

Most skin incisions and surgical wounds are covered with a sterile dressing for at least 24 to 48 hours to provide an optimal physiologic environment for wound healing. The dressing serves several functions:

- To keep the incision free of microorganisms, both exogenous and endogenous
- To protect the incision from outside injury, especially in children
- To absorb the drainage of exudates and secretions from the wound
- To maintain a moist environment that supports healing
- To give some support to the incision and surrounding skin, or to immobilize surrounding tissue
- To provide pressure to reduce edema or prevent hematoma
- To conceal the wound aesthetically

The function of a dressing is determined by its structure. The overall dressing should be:

- Large enough to cover and protect the wound site and tissue around it
- Permeable to gas and vapor, allowing circulation of air to the skin
- Secure to prevent slippage
- Comfortable for the patient

Types of Dressings

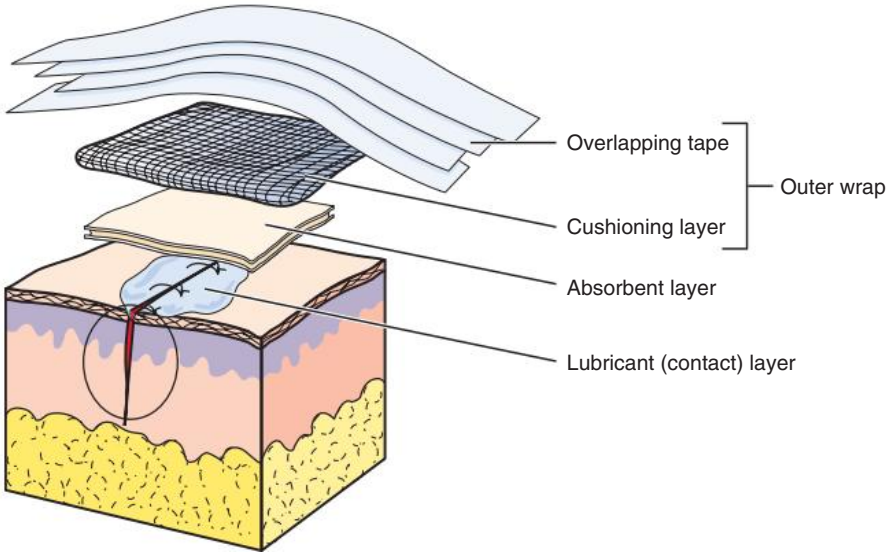
In considering the components to assemble for the dressing, the needs of the particular wound should be kept in mind. One wound may require a dressing that provides a function different from that needed for another type of wound. The dressing materials should be tailored to the location and condition of the wound site (Fig. 29.5).

One-Layer Dressing

A clean incision that is primarily closed with sutures, staples, or skin-closure tapes in which no or slight drainage is expected may be covered with an adhering **occlusive dressing** (e.g., Bioclusive, OpSite). These sterile, transparent, polyurethane film dressings are available in various sizes. The patient can bathe or shower with these in place. They usually are removed in 24 to 48 hours. Liquid collodion or other waterproof material may be used.

Skin-Closure Dressing

A transparent plastic film with an adhesive backing (OpSite) can be placed over the entire length of the incision to hold the skin edges in apposition. The film is vented to allow the escape of exudate. An additional wound dressing may be overlaid to further splint and reinforce approximation of the skin edges. These dressings are available in various sizes.



• **Fig. 29.5** Anatomy of a dressing.

Dry Sterile Dressing

A single-layered or multilayered dressing is applied dry over a clean incision from which no or slight drainage is expected. Dry gauze is not used on a denuded area because it adheres and acts as a foreign body. Granulation tissue grows into it; bleeding can be reactivated when it is removed. A dry sterile dressing can be applied over a dry wound. It is secured with adhesive tape. A circumferential wrap may be preferred on an extremity, but it must not compromise circulation.

Three-Layer Dressing

When moderate to heavy drainage is expected, a complete dressing consists of at least three layers.

Contact Layer. The contact layer acts as a passageway for the secretion and exudates that emanate from a draining wound. It has a wicking action to help reduce the risk for infection and skin maceration. It must conform to body contours regardless of the site and extent of the wound and must stay in intimate contact with the wound surface for at least 48 hours yet be nonadherent for painless removal. Some dressings contain silver nanoparticles for antimicrobial properties with antibiotic intervention. The contact layer may be:

- *Nonocclusive:* Nonadherent materials, such as gauze sponges or compressed material on a thin plastic or aluminum film, draw secretions from the wound but remain air-permeable. The looser the weave of the material, the more nonocclusive it is.
- *Semiocclusive:* Hydroactive materials, such as foams, hydrogels, and hydrocolloids, provide a mechanical surface with permeability properties. Some of these agents actually help debride the wound.
- *Occlusive:* An airtight seal prevents drying of the wound. The dressing is impermeable to air and water but allows passage of exudates. This is usually a fine mesh gauze dressing impregnated with an oil emulsion, such as petrolatum, Xeroform, iodophor, antibiotic ointment, or scarlet red. It is nonadherent to the skin or wound.

Intermediate Layer. This layer absorbs secretions passing through the contact layer. To provide adequate capacity, it should be layered (e.g., with gauze sponges) to the thickness required by the particular wound. It should not be excessively bulky. It must not unnecessarily apply pressure that could compromise circulation.

Outer Layer. This layer holds the contact and intermediate layers in proper position. It should be conforming, stretchable to avoid constriction if edema develops, and capable of clinging to itself so that it stays in position without telescoping if mobility is desired. The following materials are used for this purpose:

1. Nonallergenic tape is used most frequently. Other types of tape in various widths from ½ to 4 inches include foam tape, silk, paper, and linen cloth adhesive.
2. An elastic bandage provides gentle, even pressure to hold bulky dressings in place or to bind a splint onto an extremity. It stretches to conform to body contours, does not constrict, and yet gives firm support. The types available include the following:
   a. Four-ply crinkled-gauze bandage
   b. Cotton elastic bandage
   c. Cotton elastic bandage with adhesive on one side, which is especially useful in holding dressings on the chest because it is firm yet permits chest expansion
3. Montgomery straps are used to hold bulky dressings that require frequent changes or wound inspections. These are pairs of adhesive straps in assorted widths with gauze strings attached to one folded end of each strap. The other end of each strap is secured to the skin on each side of the dressing. The strings are tied across the dressing to hold it in place, usually on the abdomen.
4. Stockinette is put over the dressing on an extremity before application of a rigid cast used for immobilization. Available in several widths, stockinette is a seamless tubing of stretchable knitted cotton.
5. Mesh undergarments can be used to secure perineal dressings on male and female patients. The mesh is a loosely woven elastic fabric that is not compressive, but supports dressings in areas that are not easily taped in place.

Pressure Dressing

Bulky dressings are added to the intermediate layer of a three-layer dressing after many extensive surgical procedures, especially in plastic surgery and surgical procedures on the knee or breast. Pressure dressings are used for the following purposes:

- To eliminate dead space and prevent edema or hematoma
- To distribute pressure evenly
- To absorb extensive drainage
- To encourage wound healing and minimize scarring by influencing wound tension
- To immobilize a body area or support soft tissues when muscles are moved
- To help provide comfort to the patient after surgery

Materials used for pressure dressings include the following:

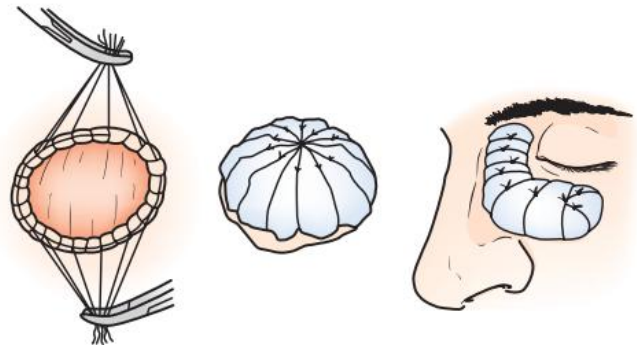
- Fluffed gauze
- Combine pads, which are gauze-covered absorbent cellulose
- Single-piece bulk dressings, which are available for use on the trunk and extremities and save time in application
- Cotton rolls, which are used, for example, to apply pressure on each side of a knee after a surgical procedure on that joint
- Foam rubber

Stent Dressing

Stent fixation is a method of applying pressure and stabilizing tissues when it is impossible to dress an area, such as the face or neck. A form-fitting mold may be taped over the nose. Long suture ends can be crisscrossed over a small dressing and tied.

Bolster/Tie-Over Dressing

Dressing materials may be sutured in place to exert an even pressure over autografted wounds to prevent hematoma or seroma formation. Sterile gauze may be rolled into a tubular shape and tied with the ends of the wound closure suture (Fig. 29.6).



• **Fig. 29.6** Bolster/tie-over dressing.

Wet-to-Dry Dressing

Dressing materials soaked in sterile normal saline solution are applied to the wound and allowed to dry thoroughly. The dried dressing is then removed, taking adhering tissue layers with it. This process is used to facilitate new tissue growth and is commonly used on burn wounds. Because this method of debridement is extremely painful, it is frequently performed in the OR with the patient under general anesthesia.

Wet-to-Wet Dressing

Dressing materials are soaked in sterile normal saline solution or other medicated solution and applied wet. This method provides little mechanical debridement and is less painful for the patient. The dressing material may be changed in the OR or under sterile conditions on the patient care unit.

Silicone Dressing

Silicone dressings are used as a measure of scar reduction and prevention. The sheet of silicone can be cut to fit and is snugly adherent to the wound to prevent overgrowth of the cicatrix. Conventional dressing tape can be used, but is not usually necessary. The dressing can be rinsed off and reapplied by the patient during the healing period. The sheets should be worn a minimum of 6 hours per day and are replaced once per week.

The natural tackiness of the silicone sometimes causes difficulty when gloves are worn for placement of the sheet. Plastic surgeons use this material frequently.

Dialkylcarbamoyl Chloride–Coated Dressing

Dressings coated with dialkycarbamoyl chloride attract bacteria to coated fibers.[12] The bacteria are inactivated and remain attached to the coating. The bacteria are removed with dressing changes.

Negative Pressure Dressing

The negative pressure dressing is an active dressing providing a barrier while augmenting even pressure over the site. These are sometimes called wound vacuum dressings (wound vac). Negative pressure dressings are multilayer wound covers attached to a suction unit for even pressure maintenance. The dressing consists of a fenestrated nonadherent piece of plastic with encapsulated foam, which is placed over the wound and then covered with a sheet of foam material. This multilayer wound cover is sealed with a plastic adherent sheet that is connected to negative pressure.

Application of Dressings

Application of sterile dressings is regarded as part of the surgical procedure. The scrub person and circulating nurse assist the surgeon or first assistant in dressing the surgical site postoperatively. The procedure is as follows:

1. The circulating nurse opens sterile dressings after the final sponge count is completed. Radiopaque sponges are not used because they could distort a postoperative x-ray or cause an incorrect count if the patient's incision must be reopened.
2. Skin surrounding the incision is cleaned of blood with a sponge moistened with sterile saline solution and dried by a sterile team member.
3. The incision and wound drainage sites are dressed separately unless the drain comes out through the incision. The scrub person cuts a Y-shaped slit in dressings to go around the drain.
4. Sterile dressings are applied and held in place by a sterile team member as the drapes are removed. When the drapes are off, the circulating nurse, wearing examination gloves, helps clean and dry the surrounding skin.
5. Benzoin or some other tackifier adhesive substance may be applied on the skin around the intermediate layer before tape is applied, to increase its adhesion.
6. The circulating nurse applies tape or Montgomery straps (as appropriate) firmly but not tightly to avoid wrinkling and traction on skin. Traction and wrinkling can cause skin irritation. If a patient has a known sensitivity to regular adhesive tape, hypoallergenic tape should be used. It is lightweight, yet strong; sticks well; is porous; and allows skin to breathe.
7. The surgeon or first assistant applies elastic wrap bandages, pressure dressings, stockinette and casts, and splints. The circulating nurse provides the necessary supplies and assists as appropriate. A patient care assistant may help hold the patient's torso or extremity during application of an elastic wrap bandage or cast. Cast application is discussed in Chapter 36.

Complications of Wound Healing

The surgeon gives meticulous attention to sterile technique, hemostasis, tissue handling and approximation, and selection of wound-closure materials, including drains and dressings. The entire OR team carries out strict aseptic and sterile techniques to prevent infection and other possible complications of wound healing.

Hematoma/Seroma

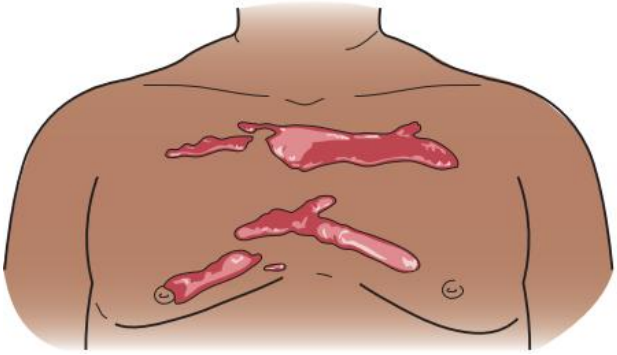
Collections of blood or serum in a wound can act as a mechanical barrier to margination of the wound. Circulation can be interrupted, and neovascularization cannot take place. Studies have shown that biochemical action of the collection causes tissue destruction and promotes bacterial growth. Hematomas in deep tissue can lead to abscess formation.

Scar/Surgical Cicatrix

After the natural process of wound healing, a **scar** (**cicatrix**) remains on the skin surface. To achieve a cosmetically acceptable scar, the surgeon attempts to make the surgical incision along natural creases or within natural skinfolds or hairlines. The location and direction of the incision affect scarring. Tension needed for approximation of wound edges during closure and subsequent movement of underlying tissues can affect wound healing and scar formation. Wounds in mobile skin contract, resulting in a smaller scar.

Hypertrophic scars, which are a result of excessive fibrin formation within the borders of the scar, can develop from too much tension on the wound, poor approximation of wound edges, or infection. Some suture materials may contribute to hypertrophy. Burn wounds are also conducive to excessive scarring. The patient may wish to have an unsightly scar revised at a future time.

Keloids develop when the inflammatory response and fibroblast proliferation are overactive during wound healing (Fig. 29.7). This is an inherited trait, most common among Africans, Asians, and people with dark skin tones or those who freckle. Keloids extend beyond the borders of the scar and can continue to grow and become very large and painful over a prolonged period after the surgical procedure.



• **Fig. 29.7** Keloid scars can form over chest and neck of susceptible patients as a complication of wound healing.

A keloid may be painful, itchy, and prone to bleeding. They can be excised, leaving a small border of scar tissue. The edges are approximated using skin staples or fine monofilament nonabsorbable suture. If a patient is known to have keloids form, an antiinflammatory agent may be injected into tissue before closure. A pressure dressing is useful in minimizing keloid formation. Application of silicone gel sheeting placed over healed bulky tissue scars for 24 hours over a period of 2 weeks can reduce the size of the scar. Use of the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser can decrease the size of the scar.

Nodules and granulomas may form in the scar if excess suture material is used. Scar tissue hypertrophies around the suture, particularly the knot. Some patients extrude suture pieces through the incision line for several months or years postoperatively. This may represent a sensitivity to the suture material.

Adhesions

An **adhesion** is a fibrous scar band that binds together two surfaces or structures that normally are separate. Fibrous bands that develop in the peritoneal cavity can hold viscera together, sometimes causing bowel obstruction or female infertility.

The most common cause is previous abdominal or pelvic surgery, but acute appendicitis or peritonitis can cause adhesion formation. Serosal injury caused by abrasion from sponges or gloves, tissue handling, infection, and tissue ischemia may be a precipitating factor. Other substances, such as blood and biologic debris, can contribute to adhesion formation. Granulomas that form from powder on gloves, lint on sponges, or other foreign material left in the wound also predispose the patient to adhesion formation.

Techniques to prevent peritoneal adhesions include gentle tissue handling, careful irrigation with sterile saline or lactated Ringer's solution, and prevention of foreign body introduction, such as glove powder and lint. Placement of a flap of omentum over the affected organ before closure is another acceptable method.

A single-layer, knitted, absorbable adhesion barrier sheet, such as Interceed (TC7), can be placed over abdominal organs after attaining hemostasis and before closure. It is composed of oxidized regenerated cellulose and absorbs in about 4 weeks. This product is contraindicated in the presence of known infection.

One type of barrier sheet, composed of sodium hyaluronate and carboxymethylcellulose (HA/CMC), can be used over organs at risk for adhesion formation. Once moistened, it adheres to the surface of the organ. No suturing is necessary. It converts to a gel form and is absorbed by the body in 7 days.

Postoperative Wound Disruption

Failure of a wound to heal or closure material to secure it during the healing process leads to **wound disruption**—a separation of wound edges. Disruption usually occurs between the 5th and 10th postoperative days. This is the lag period in healing, the time when the wound is not yet strong. Wound disruption is caused not by a single factor but by a combination of predisposing factors that influence healing.

Although it may occur in any body area, acute wound disruption most frequently follows abdominal laparotomy, surgical incision into the peritoneal cavity. It starts with a small opening in the peritoneum, which allows a wedge of omentum to slip through it. This omentum becomes edematous and extends the opening along the line of incision and upward through other layers of the abdominal wall. Disruption is usually precipitated by distention or a sudden strain, such as vomiting, coughing, or sneezing. Terms used to describe abdominal wound disruption include the following:

- ***Dehiscence:*** Partial or total separation of the superficial layers of the wound. The strength of the tissues and extent of separation determine whether or not the wound must be reclosed. Strangulated sutures can cause devitalized wound edges that may fail to heal. Wound infection can cause dehiscence.
- ***Evisceration:*** Protrusion of viscera through the full thickness of the abdominal incision. Although wound disruption of any degree calls for emergency care, an evisceration requires immediate replacement of viscera and reclosure of the incision.
- ***Herniation:*** The surface layers remain intact, but the deep layers separate, permitting the underlying muscles or organs to bulge.
- ***Fistula:*** Draining tunnels may form between two organs, such as between loops of bowel and the bladder.
- ***Sinus tract:*** An abscess may form in deeper tissues and form a tunnel to the outside of the body.

Symptoms

Patients who subsequently experience wound disruption often do not have a smooth course immediately after surgery. They may have undue pain, discomfort, nausea, drainage, slight fever, vomiting, or hiccups. Acute symptoms of wound disruption include the following:

- Tachycardia
- Vomiting
- Abnormal serosanguineous discharge
- Change in contour of the wound
- Sudden pulling pain during straining (the patient feels something "give")

Any seepage of serosanguineous fluid is suspicious and should be sent for culture and sensitivity before the skin prep is started. A swab culture for both aerobic and anaerobic microorganisms should be obtained. If the patient has had antibiotic therapy, this should be noted on the laboratory request. The patient's wound, rather than the eschar, should be swabbed. Gloves should be worn when culturing a patient's wound or handling dressing material.

Any of these symptoms should be investigated at once. Examination of the wound may show it gaping somewhat, or viscera may appear at the skin surface.

Treatment at the Bedside

1. Place an emergency call for the surgeon. Have a nasogastric tube ready for insertion to relieve distention (if appropriate).
2. Reassure the patient.
3. Apply sterile towels over the wound and saturate them with saline solution to keep the area moist.
4. Give drugs according to the surgeon's order.
5. Do not give the patient anything by mouth.
6. Prepare the patient for return to the OR. Treatment in the OR consists of secondary wound closure. Grossly infected wounds may require delayed primary closure.

Compartment Syndrome

Extreme inflammation can cause swelling between the fascial layers in any plane of the body. Compartment syndrome is frequently seen in limbs, although it can happen in any area of the body where skeletal muscle is encapsulated with fascia. Fluids, exudates, and transudates build up between the tissue layers and cause tissue ischemia and destruction of cells.

Compartment syndrome is a surgical emergency that requires linear fascial incisions (fasciotomy) to release the pressure within the capsule. Fasciotomy is performed to save the tissue from necrosis. The fascial incisions are left open to drain for weeks or months. Primary closure is complex after repeated debridement, and the wound may remain open at various degrees for several months. Scarring is deep and disfiguring because much vital tissue is lost. Skin grafts may be necessary.

Postoperative Wound Infections

Wound healing can be interrupted by infection at almost any phase. Infection results from introduction of virulent microorganisms into the receptive wound of a susceptible host. Moisture and warmth in the wound create an environment conducive to bacterial growth. Wound infections warrant special attention because many occur in clean wounds as a result of microorganisms introduced at the time of the surgical procedure. Secondary contamination is uncommon because fibrin seals the wound within hours after the surgical procedure.

A postoperative wound infection may occur in the incision or in deep structures that were entered or exposed. Its nature and severity vary because of local, systemic, technical, and environmental factors. Each factor is important; all are interrelated in clinical infection. Usually a postoperative infection is localized, but severe systemic reaction is possible. The specific pathogen and site of infection determine its gravity. Postoperative wound infections are classified as follows:

- *Incisional infection:* An infection occurs at the site of the incision within 30 postoperative days. It involves skin, subcutaneous tissue, or muscle. The incisional area is usually inflamed and sore. Purulent drainage or an organism identified by culture is present. The surgeon usually must open and drain the wound.
- *Deep wound infection:* An infection occurs at the surgical site within 30 postoperative days if a prosthesis was not implanted or within 1 year around the site of an implant. The infection involves tissues or spaces at or beneath the fascia. Pus may be present. The wound may spontaneously dehisce. The surgeon may need to open and drain the wound or remove an implant.

Infection that involves an implant or gross necrotic tissue is prone to serious sequelae.

Compromised patients and geriatric patients are highly likely to develop an endogenous infection. Procedures on potentially contaminated areas, such as the gastrointestinal tract, are more apt to result in postoperative infections. Wound infections can progress to septicemia and multisystem organ failure.

Necrotizing Fasciitis

Necrotizing fasciitis is also known as flesh-eating bacteria. Signs of the acutely rapidly spreading infectious condition are swelling, bright red surface, pain, and fever. Mortality is high because the toxic effects of the necrosis become system-wide rapid destruction of organ systems. Surgical treatment requires wide debridement of muscle and fascia. The three types of necrotizing fasciitis are:

1. *Type I:* Aerobic (gram negative) and anaerobic (gram positive) microorganisms
   a. Streptococci other than group A
   b. *Escherichia, Enterobacter, Klebsiella,* and *Proteus*
   c. *Corynebacterium*
2. *Type II:* Most common type
   a. Beta-hemolytic *Streptococcus*
   b. *Staphylococcus aureus* (less common)
3. *Type III:* Water-borne microorganisms from fish or insects
   a. *Vibrio*

Prevention of Wound Infections

Prevention of wound infection and a successful outcome of surgical intervention are goals of the team administering perioperative care to surgical patients. In summary, preventive measures should focus on the following:

- Adherence to aseptic and sterile techniques and standard precautions with all patients
- Control of endogenous infection
- Meticulous surgical technique and wound closure
- Reduction of exogenous or environmental sources of contamination, such as airborne microorganisms
- Thorough prompt cleansing and debridement of traumatic wounds
- Prevention of intraoperative contamination of a wound
- Appropriate use of prophylactic antibiotics
- Frequent handwashing
- Sterile technique for dressing changes

Serious sequelae, such as wound disruption or septicemia, may follow wound infection. Therefore they must be assiduously prevented so that wound healing can occur naturally.

Wound Assessment

The stages of wound healing vary among individuals according to generalized health and age. Other factors influence the mechanism and should be considered when assessing the progress of healing postoperatively

Objective Inspection of the Postoperative Wound

The perioperative nurse should inspect the patient's wound and document its condition. The nurse should have a basic

understanding of the mechanism of the injury or the source of the wound, such as a surgical incision, and should be able to assess the wound for complications. All complaints of pain should be investigated and referred to the physician. Gloves should be worn during wound assessment. Sterility should be maintained as appropriate. Assessment of the wound should include the following:

1. Location of single or multiple sites.
   a. Laparoscopy can yield multiple puncture sites. If a uterine manipulator was used, some vaginal tenderness may occur.
   b. Trauma can cause multiple wounds that vary in type.
   c. Some injuries are not immediately visible, such as organ trauma.
   d. Incidental wounds, such as pressure sores, may not be obvious for several days postoperatively.
   e. Iatrogenic injury may manifest as a change in vital signs, indicating bleeding or severe inflammatory response. Sepsis from bowel perforation may not be evident for several days postoperatively.
2. Color of the wound and surrounding tissue. It may be a combination of one or many colors. Estimate the volume of each color in percentages of the total wound.
   a. A red, beefy wound bed indicates healing granulating tissue. Pink indicates epithelialization. The edges may have tan or beige eschar.
   b. Yellow to yellow-white color indicates exudate caused by microorganisms. The color can range from greenish to beige, depending on which organism is present and whether antibiotic therapy is in place.
   c. Black indicates necrotic tissue that can interfere with healing and supports the growth of microorganisms.
   d. Redness combined with swelling surrounding the edges of the wound may indicate infection.
   e. Macerated tissue around a wound may indicate the need for thicker dressing material or a pouch to collect drainage.
3. Perfusion of the patient's tissues.
   a. Capillary refill should be assessed.
   b. Blanching of surrounding tissues may indicate lack of blood flow.
4. Size in length, width, and depth.
   a. The wound should be measured in centimeters.
   b. The depth can be measured with a sterile cotton-tipped swab.
   c. Tunneling should be noted for direction and depth.
   d. Anatomic description pertaining to lines of direction should be described like the face of a clock. The direction of the patient's head should be considered as 12 o'clock.
5. Temperature of the site and the patient.
   a. Hot to warm tissue surrounding the wound may indicate infection.
   b. Elevated body temperature may indicate systemic sepsis.
6. Dressing type and condition.
   a. Is the dressing wet or dry?
   b. Is the dressing constrictive?
   c. Is the dressing effective for its intended purpose?
7. Drainage or drainage device.
   a. Odors usually indicate drainage and infection.
   b. The presence of embedded material may become obvious as the wound bed sloughs. Traumatic or industrial wounds may entrap foreign material that could be extruded in exudate.
   c. Drainage of more than 50 mL/day should be pouched for collection.
   d. Gastrointestinal contents, such as bile, stool, or pancreatic enzymes, should not be permitted to contact surrounding skin. An ostomy appliance should be used.

Basic Wound Care

Gloves are worn for all dressing change procedures. Eye protection or full face shields should be worn if syringes are used for irrigation. The wound should be cleansed before the dressing is replaced. Rinsing with sterile normal saline solution provides a moist environment for healing and promotes granulation formation. Some antiseptics, such as povidone-iodine, hydrogen peroxide, and acetic acid, can cause tissue injury and delay wound healing. The wound should be cleaned before the surrounding area is cleaned to prevent contamination of the open site. Gauze used for cleansing surrounding tissue should not drag across the open wound.

Debridement may be necessary. Nonsurgical methods of debridement include chemical autolysis and mechanical packing materials. Autolysis involves placement of proteolytic enzymes in the wound to break down necrotic tissue. The viable tissue is unaffected. Mechanical debridement is accomplished using wet-to-dry dressings. The results of debridement are fresh granulation tissue and a clean wound bed. Surgical debridement may be performed with dissection instruments, such as scissors or a scalpel. A laser is sometimes used, although it can cause devitalization of tissue by charring.

Dressing material and wound care products are determined by physician orders. Types, advantages, and disadvantages of various wound care materials can be found in Table 29.1.

TABLE 29.1 Wound Care Materials

Dressing Material	Composition and Properties	Indications for Use	Advantages	Disadvantages	Notes
Alginate	Originates from brown seaweed; highly absorbent; becomes a gel when exposed to exudate, creating a moist environment	Used for infected and noninfected wounds with moderate to heavy drainage; some are used for tunneling wounds	Can absorb 20 times its own weight in fluid; rehydrates wound and facilitates debridement; requires secondary dressing cover	Contraindicated for use with light exudate or dry eschar; can promote bacterial growth if used with occlusive dressing cover; not used with third-degree burns	Packaged as ropelike fibers or pad; do not use with alkaline solutions; packaged sterile; remains in place 2 to 4 days
Composite	Composed of two or more moisture-enhancing materials in combination with absorbent material	Used for partial-thickness or full-thickness wounds with moderate to heavy exudate; can also be used over fresh granulation or necrotic tissue	Facilitates debridement and allows for moisture/vapor exchange; safe for use over healthy or infected tissue; easy to apply and remove	Should be placed in area with border of healthy intact tissue for anchoring; should not be used for light exudate; may cause excess moisture loss; can become very adherent	Check manufacturer recommendations about use with adjunct topical medications
Exudate absorber	Added to wound surface to eliminate dead space and absorb exudate; minimizes odors	Used for full-thickness wounds with moderate to heavy exudate; can be used with necrotic wounds; some can be used as lining material before packing and surface dressing	Can absorb five times its own weight in fluid; rehydrates wound and facilitates debridement; requires secondary dressing cover	Contraindicated for use with light exudate or dry eschar	Supplied in bottles or packets; clean wound and irrigate before use; fill the wound cavity to eliminate dead space and line the defect
Foam	Semipermeable, either hydrophilic or hydrophobic	Creates a moist environment and affords thermal insulation	Nonadherent; repels contaminants and is easy to apply and remove; absorbs light to moderate exudate; can be used with compression dressings; requires secondary dressing cover	Not used for dry wounds; can cause maceration of adjacent skin	Some erythema or itching may occur during the first 24 hours; not used with occlusive dressings; change more frequently if exudate is heavy
Gauze	Composed of woven or nonwoven materials; can be impregnated; used as primary or secondary dressing; can be natural or synthetic material; nonocclusive	Used for wound protection, wicking, and absorption; can be used wet or dry; packaged in rolls, pads, or strips	Moderately absorbent; less expensive to use and can be used in combination with other material; can be used as packing	Needs to be changed frequently; can leak or strike-through; can dry out, causing injury to healing tissue	If applied wet and allowed to dry, gauze can be debridement agent; may be saturated with oils, iodophor, bismuth, petroleum jelly, scarlet red
Hydrocolloid	Occlusive, adhesive wafer; the contact layer may differ in composition; creates a moist environment; supplied in packets, tubes (paste), oral discs, and wafers; can be cut to fit	Clean wounds granulate, and necrotic wounds debride autolytically	Impermeable to contaminants; self-adhesive and can remain in place for 3 to 5 days without tissue damage; slight to moderate absorption	Not used with heavy exudate, sinus tracts, or infection; not intended for full-thickness wounds exposing bone; visualization of the wound not possible; occlusive properties inhibit air exchange; can injure fragile tissue at wound edges	Safe to use under compression devices and wraps; can be used at ostomy sites or areas affected by incontinence

TABLE 29.1 Wound Care Materials—cont'd

Dressing Material	Composition and Properties	Indications for Use	Advantages	Disadvantages	Notes
Hydrogel	Water- or glycerin-based gel, gauze, or sheet dressing that has high moisture content; supplied in tubes, packets, spray, liquid	Used for partial- and full-thickness wounds; good for burns, necrosis, and irradiated tissue	Very soothing; can rehydrate dried tissues; used to fill dead space and facilitate debridement	Not used for absorption of exudate because of inherent moisture content; can dry out easily; not a bacterial barrier; may be difficult to secure to wound	Keep covered after application to prevent evaporation of the gel
Transparent film	Adhesive, semipermeable membrane; bacterial and water barrier permeable to oxygen	Waterproof, but permeable to air and moisture vapors; bacterial barrier	Promotes a moist environment for new granulation and autolysis of necrotic tissue	Not used for infected wounds; periphery of wound needs to be intact to apply the film; may be hard to apply	Used for superficial and partial-thickness wounds with minimal exudate
Skin sealant	Barrier film applied in liquid form that dries to form a plastic-like barrier coating; supplied in liquid form and individual wipes	Used on intact skin surrounding a wound or ostomy site or over a surgical incision closed by primary intention	Waterproof barrier	Can sting raw skin when applied; has alcohol base to cause drying by evaporation	Some have vapors that may be harmful to inhale as product evaporates

30 Postoperative Patient Care

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- List several functions of a postanesthesia recovery unit.
- Discuss the role of the perianesthesia nurse.
- Define the differences in postanesthesia phases as compared with patient condition.

KEY TERMS AND DEFINITIONS

Dermatome Segment of skin and subcutaneous tissue innervated by a single dorsal afferent sensory nerve root. Level is named for the area of the spine from which the afferent nerve originates.

Dermatome map Topographic outline of bilateral sensory nerve root distribution, beginning with the cervical spinal nerves and ending at the sacral spinal nerves.

Myotome Group of muscle fibers innervated by a single anterior efferent motor nerve root. Level is named for the area of the spine from which the efferent nerve originates.

Perianesthesia nursing Providing patient care before and after the administration of anesthesia for a surgical procedure.

Postanesthesia Care

Surgical procedures are performed in many diverse settings, including surgeons' offices, ambulatory surgery centers, and hospital-based surgical suites and specialty units. In general the selection of the surgical setting is influenced by the anticipated complexity of the procedure, the patient's health status, available technology, and financial resources.

Regardless of the surgical setting or procedure, the patient should be observed and monitored postoperatively for physiologic and psychologic condition in a controlled postsurgical or postanesthesia environment before transfer to a patient care unit or discharge from the facility.

The postoperative phase of the surgical patient's perioperative experience begins after the surgical or interventional procedure is completed and the patient is admitted to a postprocedure area (usually a postanesthesia care unit [PACU] or an intensive care unit [ICU]) or discharged to home.

Ideally, an area is designated for the postoperative or postprocedure care of patients. It may vary in name or location according to its specific function within the health care facility. In some settings in which only local anesthetics are used, the patient has a brief postoperative observation period in the room where the procedure was performed. When the patient's condition is determined to be physiologically stable using criteria set by the surgeon, the patient is discharged from the facility. Dental, podiatric, and dermatologic offices often function in this capacity.

Immediate postoperative patient care is usually provided in a designated area of the hospital or ambulatory care facility. This area may be called the recovery room (RR) or postanesthesia recovery (PAR) unit. In this text the term *postanesthesia care unit (PACU)* is used to describe a specialized area for patient care during recovery from anesthesia. Institutional policies and procedures guide patient care activities in the PACU according to protocol established by the anesthesia and surgical services departments. The American Society of Anesthesiologists (ASA) has devised a scale of physical assessment ratings in which patients are categorized by perioperative or perianesthesia risk and outcome (Table 30.1). The ASA score is assessed and documented at admission and discharge from the PACU.

Organized in 1980, the American Society of PeriAnesthesia Nurses (ASPAN), formerly known as the American Society of Post Anesthesia Nurses, has established standards of practice for

TABLE 30.1 American Society of Anesthesiologists Physical (P) Status Classification

Status[a]	Definition
P1	A healthy patient
P2	Mild systemic disease without functional limitations
P3	Severe systemic disease associated with definite functional limitations
P4	Severe systemic disease that is an ongoing threat to life
P5	Patient is unlikely to survive 24 hours without the surgical procedure
P6	Patient is brain dead and being prepared as an organ donor

[a]With P2, P3, and P4, the systemic disease may or may not be related to the cause for surgery. If a patient (P1-P5) needs emergency surgery, an E is added to the physical status (e.g., P1E, P2E). ASA 1 through ASA 6 (or I-VI) is often used for physical status.
From American Society of Anesthesiologists: *Manual for anesthesia departments*, Park Ridge, IL, 1997, The Society.

the postoperative care of diverse populations, such as pediatric, adult, and geriatric patients. ASPAN has identified specific phases of care, as follows:

- *Preanesthesia phase:* Focuses on the emotional and physical preparation of the patient before a surgical procedure. The patient is assessed to establish the nursing diagnoses for the perianesthesia period. Baselines are established for the patient's preoperative physiologic and psychologic condition.
- *Postanesthesia phase I:* Focuses on providing immediate postoperative care from an anesthetized state to a condition that requires less acute intervention. The patient's condition may be ASA III or IV. The patient's condition is compared to the baseline set in the preanesthesia phase. The patient transitions from phase I to phase II.
- *Postanesthesia phase II:* Focuses on preparing the patient for self-care or care in an extended-care setting.
- *Extended care level:* Focuses on the patient who is preparing for discharge to home or other care facility.

The goal of postanesthesia or postprocedure care is to assist the patient in returning to a safe physiologic level after receiving an anesthetic agent or undergoing a surgical procedure.[1] In some settings, perianesthesia nurses follow up with the patient through a phone call to the patient's home within 24 to 48 hours of discharge. (More information about ASPAN position statements concerning patient care is available at www.aspan.org.)

Postanesthesia Care Unit

Located in proximity to the operating room (OR), the basic PACU design consists of a large room (approximately 80 ft^2) divided into a series of individual cubicles separated by privacy curtains. The beds should be a minimum of 4 ft apart, and equivalent spacing should be between the bedside tables and walls. Each cubicle has a cardiac monitor, pulse oximeter, blood pressure measurement device, suction apparatus, and oxygen administration equipment.

Additional supplies that are available include warming devices, airway management equipment, intravenous (IV) fluids and administration sets, dressing reinforcement materials, medications, indwelling Foley catheters and drainage systems, emesis basins, and bedpans. Lead screens and lead shielding should be available for surrounding patients and staff when x-ray scans are performed.

Other equipment, including crash carts with defibrillators, should be positioned strategically throughout the room for easy accessibility. More than one emergency setup should be immediately available in case the other is in use. Foot-controlled or elbow-controlled handwashing stations should be in proximity to patient care areas. Hand sanitizer should be readily available. Trashcans should have foot-controlled lids.

Some facilities include isolation rooms for patients who are highly contagious or highly susceptible to infection. If the PACU does not have a partitioned isolation area, these patients may be placed at one end of the room and separated from other patients with screens or curtains. Isolation procedures should be used in handling bedding and equipment per institutional policy. All patients have the right to receive the same level of care regardless of extenuating circumstances.

Ideally, the amount of cubicle space is allotted according to the number of ORs in the OR suite. This allotment may vary between one and a half to two cubicles per OR and is based on the caseload, duration of surgical procedures, and room turnover time in the OR. A rapid succession of short procedures could easily fill the PACU and leave no vacancy for additional patients. This scenario is more common in facilities in which the PACU doubles as a special procedure care unit for ambulatory patients who are receiving nerve blocks for pain therapy.

Some institutions allow an uncomplicated endoscopy to be performed in the PACU. The rationale behind this practice is that patients undergoing special procedures need to be monitored by experienced personnel for a short time after a treatment or test. For some procedures the PACU nurse monitors a patient receiving IV sedation and may assist the physician, thus depleting the staff available for postoperative care.

In larger institutions where prolonged and complex surgical procedures are performed (e.g., transplantation, multiple trauma), patients may remain in the PACU for more than 24 hours because of the potential need to return to the OR for an additional surgical procedure. In such cases the PACU doubles as a surgical ICU.

Increased patient load and acuity increase the need for adequate staffing, space allocation, education of personnel, and management of resources. The consolidation of facilities and personnel should not jeopardize the delivery of safe postoperative patient care. Use of the PACU as an overflow ICU depletes the resources intended for the adequate care of postsurgical patients.[2]

Postoperative Observation of the Patient

The duration and type of postoperative observation and care vary according to the following factors:

- Patient's condition (e.g., alert and oriented vs. unresponsive)
- Need for physiologic support (e.g., ventilator-dependent vs. awake and extubated)
- Complexity of the surgical procedure (e.g., open laparotomy vs. laparoscopy)
- Type of anesthetic agent administered (e.g., a general inhalation agent vs. local infiltration)
- Need for pain therapy (e.g., intermittent analgesic administration vs. continuous epidural infusion)
- Prescribed period for monitoring parameters for evaluation of physiologic status (e.g., stable vs. unstable vital signs)

Perianesthesia Patient Care Personnel

Adequate numbers of personnel should be available to monitor patients and provide appropriate care as needed.[3] The education and training of PACU nurses should include knowledge and skill in the following areas:

- Airway management techniques, including positioning, chin lift, jaw thrust, suctioning, bagging, and placement of an airway
- Circulatory assessment, including hemodynamics, neurovascular condition, and renal function
- Neurologic condition, such as level of consciousness or **dermatome** level associated with epidural infusion (Box 30.1 and Fig. 30.1)
- Neuromuscular activity in **myotome** groups after neuromuscular blockade anesthetic
- Anesthetic agents and their actions (e.g., physiologic depression associated with general anesthesia; anesthetic techniques are discussed in detail in Chapter 24)
- Medications and their actions (e.g., narcotics, opioids, and tranquilizers)
- Most invasive and minimally invasive surgical procedures (e.g., open laparotomy, laparoscopy)

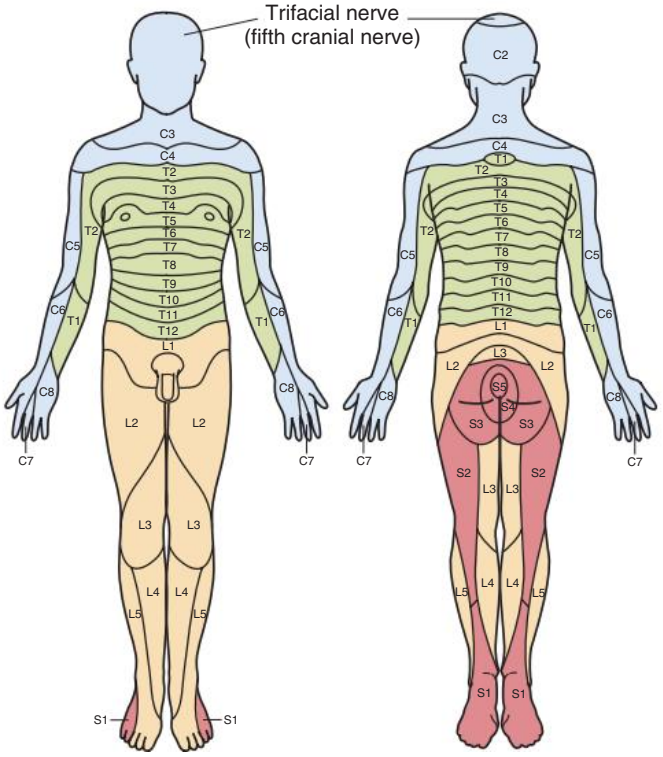
PACU nurses should demonstrate competency in the following:

- Physical assessment (e.g., heart, lung sounds)
- Recognition of physiologic complications (e.g., airway obstruction, hypothermia, malignant hyperthermia, pain, hydration, nausea or vomiting, and oropharyngeal aspiration)
- Management of physiologic emergencies (e.g., airway obstruction, hemorrhage, cardiac arrest, and malignant hyperthermia). Postoperative complications are discussed in detail in Chapter 31
- Interpretation of monitoring data from electrocardiogram (ECG) and oximetry devices (patient monitoring is discussed in Chapter 27)

Additional competencies should include current certification in CPR, both basic cardiac life support (BCLS) and advanced cardiac life support (ACLS). If pediatric patients are involved, credentials should include pediatric advanced life support (PALS). Reviews and drills should be planned and implemented by the perianesthesia nurse manager.

• BOX 30.1 Dermatome Sensory Somatic Landmarks

C2	Occiput
C5	Shoulder
T1	Little finger
T4	Nipple line
T6	Xyphoid process
T12	Iliac crest
L1-L5	Groin to dorsum of foot
S1	Dorsum of foot
S3	Heel, lateral foot to sole of foot
S5	Genitalia and perineal area



• **Fig. 30.1** Dermatome levels.

Professional Activities

In 1986, ASPAN developed specialty certification for perianesthesia nurses. Eligible nurses must have a current active nursing license in the state of practice and 1200 hours of PACU patient care within 2 years of the examination. A baccalaureate degree is not required. Eligibility includes 1200 hours of perianesthesia direct care nursing experience as a caregiver, manager, educator, or researcher. A nurse who specializes in the care of phase I postanesthesia patients in hospital-based or extended-recovery care facilities may attain certification as a certified postanesthesia care nurse (CPAN) by taking and passing an examination offered by the American Board of Perianesthesia Nursing Certification (ABPANC).

In ambulatory surgery settings, nurses who specialize in the postanesthesia care of patients who move rapidly from phase I to phase II can attain board certification from ABPANC in ambulatory postanesthesia care (CAPA).

The certification for both CAPA and CPAN is valid for 3 years and can be renewed by passing a written examination or by obtaining 90 contact hours of continuing education credits. A perianesthesia nurse may hold both credentials simultaneously. Current active licensure and a minimum of 1200 hours in **perianesthesia nursing** are required during the 3-year term of certification. ASPAN has produced a core curriculum as an additional reference for perianesthesia nurses who plan to take the certification examination. Additional information about PACU certification can be found at www.cpancapa.org.

Other personnel in the PACU may include licensed practical nurses or licensed vocational nurses (LPNs/LVNs) and other unlicensed patient care personnel. These caregivers are supervised by a registered nurse (RN), who is responsible for their training and assignments within the PACU. Their duties vary according to the needs of the department and their level of knowledge and skill.

Admission to the Postanesthesia Care Unit

Before the phase I or phase II patient leaves the OR, the circulating nurse should call the PACU nurse to give the estimated time of arrival in the PACU and advise of a need to have special life support equipment on standby for immediate use.

As the patient enters the PACU the immediate physiologic and psychologic status is reported to the PACU nurse by the accompanying personnel (usually the circulating nurse, first assistant, anesthesia provider, or resident). This reporting is referred to as the *hand-over report*. Any necessary life support equipment, such as a ventilator, is connected. The PACU nurse connects the ECG electrodes, attaches a pulse oximeter lead, and places a blood pressure cuff on the patient.

Many PACUs are supplied with automatic or computerized equipment that provides an immediate display of vital signs and physiologic data from monitors that are attached to the patient in the OR and remain on the patient during transport. The phase I PACU nurse simultaneously assesses the patient and assimilates the data. The flow of activity is fast paced but directed toward the immediate physiologic needs and support of the patient.[3]

Postoperative Hand-Over Report

The postoperative hand-over report provides information from the anesthesia provider (if one was in attendance), the surgeon (or appropriate designee, such as the first assistant), and the circulating nurse. Much of the report is delivered verbally, but postoperative orders and pertinent information regarding the patient's condition and intraoperative care are documented in writing. If the surgeon gives a verbal order, he or she should cosign the chart within 24 hours. The content of the postoperative report to the PACU nurse should include, but is not limited to, the information discussed in the following sections.

Anesthesia Provider's Report

- Patient's name, sex, age, preoperative and postoperative diagnosis, surgical procedure, and surgeon
- Type of anesthesia and the patient's response
- Baseline preoperative vital signs and summary of vital sign flow during the surgical procedure up to the point of discharge from the OR
- Sensitivities and allergies, including reaction to allergen
- Any physiologic changes or existing conditions and interventions to counteract them (e.g., diabetes, chronic obstructive pulmonary disease, previous myocardial infarction, hypertension)
- Medications administered preoperatively, intraoperatively, and postoperatively (e.g., preoperative sedation, intraoperative antibiotic, continuous infusion of medication)
- IV fluid administration and body fluid output (e.g., blood products and estimated blood loss, urine, ascites, gastric contents)
- Specific patient care orders to be performed in the PACU or in the immediate postoperative period (e.g., aerosol or mist mask)

Surgeon's Report

- Postoperative orders that pertain to immediate treatments or therapies to be performed in the PACU or in the immediate postoperative period (e.g., passive-range-of-motion device, radiographic study to check placement of central line catheter)
- Serial diagnostic tests that are to be initiated in the PACU and continued through the immediate postoperative period (e.g., blood counts at specified intervals)
- Specific interventions that pertain to care of the surgical site (e.g., dressing change, reinforcement)

Circulating Nurse's Hand-Over Report

- Baseline physiologic and psychologic assessment data
- Positioning and skin preparation, including the condition of the skin preoperatively and postoperatively
- Condition of patient return electrode site
- Use of specialized surgical equipment (e.g., laser, endoscope)
- Intraoperative irrigation fluids
- Administration of medication, hemostatics, contrast media, or dyes in the surgical field
- Any implants, transplants, or explants
- Type of dressings and the presence of drains or stents
- Intraoperative urinary catheterization and output
- Patient's indication of pain (verbal score of 0 to 10 or nonverbal grimace, crying, restlessness)
- Any pertinent information not reported by the anesthesia provider or surgeon
- Location of family member or significant other who may be waiting

Postoperative reports vary according to the type of anesthesia and the surgical procedure, the preferences of the anesthesia provider and surgeon, and institutional policy and procedure. The main emphasis is the patient's needs in the immediate postoperative period. This continues until the patient transitions to phase II and is discharged from the PACU.

Patient Care Activities

The application of physiologic and psychosocial knowledge, principles of asepsis, and technical knowledge and skills is necessary to promote, restore, and maintain the patient's physiologic processes in a safe, comfortable, and effective environment.[2] Particular attention is given to monitoring of oxygenation, ventilation, and circulation. PACU care includes maintaining adequate ventilation, alleviating postoperative nausea and vomiting (PONV), preventing shock, and alleviating pain.[2]

Patient Assessment for Pain

Patients are assessed for vital signs and level of discomfort. Pain is referred to as the fifth vital sign. Pain has been described as both physiologic and psychologic. The adult patient is offered an opportunity to describe pain according to a numbered scale of 0 to 10. The patient's ethnicity and sex can influence the expression of pain. Some groups consider showing pain to be a form of weakness.

The perianesthesia nurse should be aware that the patient's demeanor may not adequately relate to the patient's comfort level.[4] Pediatric patients may better describe pain according to the Wong-Baker pain rating FACES scale (see Fig. 8.2). Before administration of medication for pain, the patient's communication level should be determined regardless of age. Assessing for vision, speech, language, and hearing can give the perianesthesia nurse significant clues about patient understanding of the pain scales in use.[4]

Some patients have alternative methods for managing pain, such as imaging, breathing exercises, meditation, reiki, and acupressure. Other nonpharmacologic methods of pain management include electronic nerve stimulators applied to the skin, such as TENS, or implanted within the neural pathway. Alternative therapies should not be considered replacements for medications when providing comfort for the patient.

Postoperative Care Orders

Postoperative medical orders are coordinated by the anesthesia provider and the surgeon and include monitoring requirements, oxygen and fluid therapies, pain medications, and other special considerations. Patients are evaluated continually using appropriate monitoring methods and frequent observations by the perianesthesia nurses. Clinical evaluation of each patient's status

through listening, watching, and feeling is augmented by electronic monitoring devices. Machines should not be the only method of determining the patient's condition.

As in all other patient care areas, standard precautions are carried out for the disposal of needles and the handling of any item contaminated by blood and body fluids. Handwashing is essential after each patient contact to prevent cross-contamination.

Family members are notified when a patient is admitted to the PACU to let them know the surgical procedure is complete, which helps relieve the anxiety experienced during the hours of waiting. Depending on institutional policy, some facilities allow parents or other visitors in the PACU.[5] No special attire is required unless the patient is in an isolation setting.

Postsurgical Overflow Considerations

PACU nurses are very knowledgeable and skilled in the care of critically ill patients. This measure of versatility sometimes places the PACU nurse in the position of keeping and monitoring patients who should be housed in the ICU. Sometimes the ICU does not have readily available bed space for the critical postoperative patient, and therefore the PACU nurse provides this care. In some circumstances the general postoperative patient population is maintained in the PACU when space is not immediately available on the patient care floors. Some facilities have developed a specialty float pool to work in combination with the PACU team to manage the patient load.

Patients who are normally discharged to the patient care unit from the PACU can be consolidated with float pool nurses to relieve the PACU nurses for more postprocedure or postoperative patient care. Consideration must be given at all times to the availability of appropriate qualified staff and bed space for care of immediate postanesthesia patients, despite the extra load of patients who should be housed elsewhere.

The perianesthesia nurse manager should collaborate with the OR scheduling personnel and OR manager to preview pending schedules a day or two before the schedule commences to plan for staffing needs. Patient overflow conditions cannot always be predetermined, but the managers of both areas should be apprised of extremely full OR schedules so they can plan for the event of emergent admissions over the usual caseload.

Documentation

Most facilities have implemented electronic medical records. The charting may be done on a computer and can be reviewed in real time by physicians and staff as the patient progresses through the perianesthsia phases of care. Institutional policies and procedures should be followed in documenting PACU care.

Observations of respiratory and circulatory functions and level of consciousness are recorded at frequent intervals. Postoperative physiologic and psychologic status are documented at the time of any significant event (e.g., the administration of medication), and routinely at 5- to 7-minute intervals for the first hour and at 15- to 30-minute intervals for the second hour and thereafter. Pertinent observations are recorded as appropriate or necessary.

Discharge from the Postanesthesia Care Unit

Most patients remain in the PACU at least 1 hour or until they have sufficiently recovered from anesthesia so their vital signs have stabilized and they are capable of reasonable self-care. The patient's condition is scored using a postanesthesia scoring system according to vital signs, activity level, and consciousness; several standardized formats are available for this purpose. The anesthesia provider assesses the patient as necessary and may determine when the patient's condition is stable enough for discharge from the PACU. After discharge from the PACU the patient is transported to a patient care unit or an ICU or is released from the ambulatory care facility.

A physician is responsible for the patient's discharge from the PACU. The anesthesia department staff and medical staff may approve discharge criteria for the PACU nurse to use in determining readiness for discharge. These criteria should be consistent with the standards of the ASA and the accreditation standards of The Joint Commission (TJC) or the Accreditation Association for Ambulatory Health Care (AAAHC).

The continuity of care is maintained when the PACU nurse provides a hand-over report to the RN at the receiving patient care division. The hand-over report should include the following information:

1. Patient name, age, and sex
2. Physiologic condition and assessment, allergies, vital signs, preoperative medical and surgical history. May include information about physiologic ability (paralysis, etc.)
3. Surgeon and the procedure performed
4. Anesthetic used and patient's response
5. Any unusual circumstances during the procedure. May include known infectious findings
6. Blood loss and fluid replacement (includes intake and output)
7. All medications given in PACU for pain, postoperative nausea and vomiting (PONV), IV. Medication report should include any special circumstances, such as addiction or recreational drug use/alcohol abuse
8. Dressings and drains, including Foley catheter
9. Tests and treatments performed in PACU and any postoperative orders
10. Valuables and their disposition (prosthetics, spectacles, hearing aid, etc.)
11. Location and contact information for significant other or caregiver. May include social information such as communication barriers (language or cognition)

Postoperative Evaluation of Expected Outcomes

Ideally, the perioperative nurse who preoperatively assessed the patient and intraoperatively developed and implemented the plan of care has the opportunity to assess or interview the patient postoperatively and evaluate patient care outcomes.[3] An assessment is performed in person if possible, or the patient may be interviewed with a follow-up telephone call within 24 to 48 hours of discharge.

The plan of care should be evaluated in terms of the attainment of expected outcomes. The identification of influencing factors provides a foundation for ongoing improvement of perioperative patient care services. Considerations for the design of the postoperative evaluation include, but are not limited to, the following:

1. Was a preoperative visit made, and was it helpful to the patient?
2. Were the patient and family adequately prepared for the surgical procedure physically, psychologically, emotionally, and spiritually? Did the patient receive written preoperative instructions?
3. What could have been improved?
4. Were all pertinent patient needs, problems, and health status considerations identified in the nursing diagnoses?

5. Did the plan of care address the nursing diagnoses?
6. Did the patient experience any complications?
7. Was preoperative teaching used? Was it adequate and helpful?
8. What were the patient's perceptions of the surgical experience?
9. Were the expected outcomes achieved to the patient's satisfaction?
10. To what degree do the patient's observable physiologic and psychosocial responses indicate the attainment of expected outcomes?
11. Was the patient given a postage-paid, follow-up survey of satisfaction to complete and return to the department?

The evaluation of patient outcomes helps identify environmental influences and procedural activities that may need to be modified by the OR staff. For example, if the patient has had a reddened pressure area develop over a bony prominence, was the positioning equipment at fault or was the area unpadded? A reevaluation of products currently being used may be indicated. Injury to skin may be caused by the pooling of skin prep solutions under the patient, inadequate padding of bony prominences, or faulty electrical equipment.

The subjective data received from the patient help evaluate how much discomfort the patient is experiencing, especially paresthesia (a numb, tingling sensation). Neurovascular injuries may be related to positioning on the OR bed. Each level of the **dermatome map** should be evaluated. The perioperative nurse may suggest comfort measures to help this patient, but an adverse outcome indicates a need to improve positioning procedures for subsequent patients.

The postoperative assessment or follow-up telephone call terminates the direct perioperative nurse–patient relationship. The evaluation of the degree of attainment of expected outcomes completes the perioperative nursing process.

To be successful, a postoperative evaluation program requires the cooperative effort of and input from all personnel involved with patient care, including RNs, technicians, and physicians.[1] Administrative personnel may seek specific information and should be consulted for input. They should participate in structuring the program at its inception to avoid duplication of action and to promote a collegial effort. Postoperative evaluation data may be collected through the following measures:

- Interview and assessment of the patient
- Conferences with physicians, nurses, and other caregivers
- Review of responses on the patient evaluation form

The postoperative evaluation program should be reviewed periodically and revised as necessary. An interdisciplinary conference is an effective medium for the accomplishment of these objectives. An effective perioperative evaluation program and positive patient experiences promote good public relations and demonstrate a caring image to the public it serves.[1]

Potential Perioperative Complications

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Describe several respiratory complications that are possible in the perioperative period.
- Identify three potential dysrhythmias that may complicate the patient's perioperative course.
- Demonstrate the procedure for weighing surgical sponges in the operating room.
- List the primary drugs used in the management of an acute malignant hyperthermic crisis.
- Identify three methods for preventing hypothermia in the perioperative patient.

KEY TERMS AND DEFINITIONS

Anabolism Buildup of tissues or properties.
Anaphylaxis Life-threatening form of allergy.
Anemia Reduction of the number of functioning red blood cells capable of containing enough hemoglobin to transport oxygen.
Anoxia Absence of oxygen; not synonymous with hypoxia.
Aspiration Entry of gastric, oropharyngeal, or other substance into the lungs.
Atelectasis Collapsed or airless lung.
Cardiotonic Drug that increases the tone of the heart, such as digitalis.
Catabolism Breakdown of tissues or properties.
Coagulopathy Disorder that causes problems with blood clotting.
Dysrhythmia Abnormal, disordered, disturbed rhythm.
Embolus Blood clot or other substance, such as air, plaque, amniotic fluid, or fat, that occludes a segment of the cardiovascular system.
Hemoglobinopathy Any one of a group of blood diseases that are characterized by abnormal forms of hemoglobin in the blood.
Hemorrhage Abnormal internal or external loss of blood from an arterial, venous, or capillary source.
Hypertension Elevated blood pressure. If on several occasions the systolic pressure is greater than 140 or the diastolic pressure is greater than 90, the patient is considered hypertensive.
Hypotension Low blood pressure. If on several occasions the systolic pressure is lower than 100, the patient is considered hypotensive. This should be compared with other assessment parameters.
Hypoventilation Reduced rate and depth of breathing that causes an increase in circulating carbon dioxide.
Hypoxia Decreased concentration of circulating oxygen.
Metabolic crisis Physical and chemical changes that cause catabolic or anabolic activity that may be life threatening.
Thrombus Blood clot within a blood vessel.
Vasoconstrictor Drug that causes narrowing of a blood vessel.
Vasodilator Drug that causes relaxation of a blood vessel or causes opening (dilation).

Potential for Complications during and after Surgery

Many facilities use scoring systems as guidelines to predict the potential for complications during the perioperative care period. The patient receives care from a multidisciplinary team that plans for his or her safety by assessing risks and benefits of the surgical procedure. Preoperatively the patient is assessed by the anesthesia provider using the American Society of Anesthesiologists (ASA) scoring system. Intraoperatively the patient's risk for infection is assessed using the Centers for Disease Control and Prevention (CDC) wound classification scheme. In the postanesthesia care area the patient's readiness for discharge is scored according to one of several predictive indicator grids based on his or her physiology.

All of the scoring systems add up to a number that is used in decision making concerning the plan of care and progression toward wellness.

The purpose of this chapter is to acquaint the caregiver with the potential complications that patients experience during and after surgery. A satisfactory score in one care period is not always a predictor of how the patient will do in subsequent phases of care after the physical changes associated with surgery.

Each organ system interacts with other organ systems to produce homeostasis in the patient. An alteration in one organ system will affect all of the others, causing the potential for a poor outcome. Morbidity and mortality can be minimized with prompt detection and precise intervention.

Respiratory Complications

One of the primary areas of postoperative complications is the respiratory system. The patient's potential for developing pulmonary problems depends on several factors. Any preexisting lung disease, such as emphysema, infection, or asthma, predisposes the patient.[1,2] Smokers have the highest risk for succumbing to postoperative pulmonary problems because of chronic irritation of the respiratory tract with consequent production of excess mucus. Chest wall deformities, obesity, and extremes of age are other pertinent preoperative influences.[2] Intraoperative factors include the following:

- Types of preoperative medications
- Type and duration of anesthesia
- Type and duration of assisted ventilation
- Position of the patient during the surgical procedure
- Extent of the surgical procedure

Postoperatively one of the most critical factors is the patient's ability to mobilize secretions by deep breathing, coughing, and ambulation.[2] Patients undergoing chest and abdominal surgery are likely to breathe shallowly because of pain and therefore may not adequately raise accumulated secretions. Development of one pulmonary complication often predisposes the patient to development of another. Acute respiratory distress syndrome (ARDS), also known as *progressive pulmonary insufficiency* or *shock lung,* may develop in the first 24 to 48 hours after a traumatic injury.[1]

Aspiration

Aspiration of gastric contents into the lungs may occur because of decreased throat reflexes when the patient is unconscious or is conscious with the throat anesthetized, as for bronchoscopy. Residual effects impede lung function and blood-gas exchange.

A chemical pneumonitis results from aspiration of highly acidic gastric juices. Edema forms, alveoli collapse, ventilation-perfusion mismatch occurs, and hypoxemia results. Aspiration of solids in emesis results in edema, severe **hypoxia**, and respiratory obstruction. Bronchospasm and atelectasis may be followed by pneumonitis or bronchopneumonia. Most aspirate is irritating, but it can be infectious if nasopharyngeal or gastric flora are aspirated. Pneumonia or lung abscess may result with necrosis of the pulmonary parenchyma.

Etiology

Every patient who has food in the stomach is a poor risk for anesthesia. Increased intragastric pressure is an aspiration hazard and may result from conditions such as diaphragmatic hernia, gastrointestinal bleeding, intestinal obstruction, or gas forced into the stomach by application of positive pressure ventilation without use of a cuffed endotracheal tube.

Symptoms

Symptoms include central cyanosis, dyspnea, gasping, and tachycardia, followed by cardiac embarrassment, lung collapse, and consolidation.

Treatment

Most effective treatment occurs during the first minutes after aspiration. The strategy is to remove as much aspirate as possible and limit the spread of what is left in the lung. The head of the operating room (OR) bed is lowered with a right lateral tilt for postural drainage; the right mainstem bronchus bifurcates slightly higher than the left mainstem bronchus. The oropharynx and tracheobronchial tree are suctioned. If the patient has aspirated particulate matter that causes obstruction of the airways, bronchoscopy must be performed to remove the aspirate. Suctioning must be interrupted every 10 to 15 seconds to administer oxygen. Oxygenation and carbon dioxide removal are high priorities.

Aspiration of acid gastric content injures the alveolar capillary interface, resulting in intrapulmonary shunting and pulmonary edema. Intensive pulmonary care is aimed at improving ventilation-perfusion ratios and decreasing abnormal gas exchange.[2] This may require endotracheal intubation for mechanical ventilation with continuous positive pressure. Most cases of severe hypoxemia occur rapidly within the first 30 to 60 minutes after aspiration. Careful cardiovascular monitoring and frequent blood-gas and acid-base determinations guide therapeutic measures to maintain intravascular volume. Prophylactic antibiotics may be given for aspiration of bowel-contaminated fluid to prevent infection, and a bronchodilator may be used to treat spasm. Most cases of permanent injury or death result from the initial hypoxemia.

Prevention

Prevention involves adequate preoperative preparation (withholding oral intake 8 to 10 hours before induction) and careful administration of anesthetic agents. The anesthetic is decreased near the end of the surgical procedure, hastening the return of throat reflexes. All trauma and obstetric patients receiving general anesthesia should be treated as if they have a full stomach and therefore should be intubated using cricoid pressure (Sellick's maneuver). The cricoid pressure should be released after verification of endotracheal tube placement. Gastric evacuation is delayed during labor and by analgesic medications. A nasogastric tube may be inserted preoperatively or intraoperatively.

Laryngospasm and Bronchospasm

Laryngospasm is a partial or complete closure of the vocal cords as an involuntary reflex action. Bronchospasm is contraction of smooth muscle in the walls of the bronchi and bronchioles, causing narrowing of the lumen. Spasms or abnormal narrowing is produced by a marked increase in smooth muscle tone of the airway walls. Marked elevation of airway resistance profoundly alters gas flow into and out of the lungs. Accompanying changes result in a decreased ventilation-perfusion ratio with a subsequent reduction in Pao_2 and rise in $Paco_2$. Many factors can precipitate spasm.

Etiology

Etiologic factors for laryngospasm and bronchospasm include mechanical airway obstruction, use of certain anesthetics and

drugs, allergic conditions such as asthma, vagal reflex, stimulation of the pharynx and larynx with the patient under light anesthesia, traction on the peritoneum, foreign material in the tracheobronchial tree, movement of the head or neck or traction on the carotid sinus, and painful peripheral stimuli. The degree of spasm varies from mild to severe.

Symptoms

Symptoms include wheezing respirations or stridor, reduced compliance, central cyanosis, and respiratory obstruction.

Treatment

Treatment depends on the precipitating factor. Methods generally used include positive pressure ventilation, oxygen, tracheal intubation, and neuromuscular blockers for relaxation. Bronchodilator drugs such as aminophylline, isoetharine, and metaproterenol are given with caution because they act as cardiac stimulators and, in the presence of hypoxia, may contribute to cardiac **dysrhythmia** and cardiac arrest.

Patients may be refractory (unresponsive) to bronchodilators because of acid-base abnormalities. Correction can reduce the side effects and augment the beneficial effects of bronchodilators. If the etiologic factor is an allergy, steroids and antihistamines may be given. Vagal reflexes are inhibited by atropine. If reflex is the cause, anesthesia is deepened. Drying agents are given for excessive secretions. Immediate effective treatment is mandatory to counteract hypoxia and prevent cardiac arrest.

Prevention

Prevention involves maintenance of a patent airway, appropriate premedication such as glycopyrrolate, avoidance of factors stimulating the vagal reflex, and treatment of the predisposing pulmonary condition.

Airway and Respiratory Obstruction

An airway is maintained with an oral airway or endotracheal tube. Airway obstruction is the most frequent cause of respiratory difficulty in the immediate postoperative period. The patient may exhibit paradoxic respiration (i.e., downward movement of the diaphragm occurring with contraction rather than expansion of the chest), resulting in hypoxia and carbon dioxide retention. As the condition worsens the patient becomes restless, diaphoretic, cyanotic, and finally, unconscious. If not relieved within seconds, this serious complication may lead to cardiac arrest.

Etiology

Etiologic factors include blocking of the airway by the tongue, soft tissue, excessive secretions, or a foreign body; laryngospasm or bronchospasm; or positioning of the head with the chin down.

Symptoms

Symptoms of respiratory obstruction include increased respiratory effort with inadequate ventilatory exchange, visible use of accessory muscles, and respiratory motion of the chest and abdomen without audible air movement at the airway. If the airway is totally obstructed, breath sounds will be absent; if it is partially obstructed, a snoring sound will be elicited. The pulse is rapid and thready.

Assessment of oxygenation is essential if the patient's airway patency is in question. Visual inspection of the patient may reveal peripheral cyanosis (i.e., pallor, duskiness, or bluish color of the nail beds and extremities). This is caused by a decrease in capillary oxygen levels. Peripheral cyanosis is not always indicative of impending danger to the patient. It can be caused by hypothermia, stress, medications, or other physiologic factors that cause peripheral vasoconstriction.

If the patient is in an arterial hypoxemic state, he or she will exhibit central cyanosis—pallor, duskiness, or bluish color of the lips, face, and generalized body surface. Central cyanosis is a serious sign that requires immediate airway and ventilatory assessment followed by emergent treatment.[3] Central cyanosis may develop more slowly if the patient has been breathing a high concentration of oxygen.[2]

Treatment

Suctioning blood, mucus, or emesis, gently hyperextending the neck, and elevating the chin may eliminate the cause of obstruction. Oxygen is administered by positive pressure; a nasal airway or endotracheal intubation may be necessary. If the anesthesia provider has been unable to manually ventilate or intubate the patient in two or three attempts, it may be necessary to establish an indirect airway by opening the patient's anterior neck; a needle is inserted through the cricoid cartilage for a cricothyrotomy or, if time permits, a tracheotomy.[3]

Hypoventilation

Hypoventilation, the ability to oxygenate, depends on the condition of the lungs, hemoglobin concentration, cardiac output (CO), and oxygen saturation. Inadequate or reduced alveolar ventilation can cause a deficit in oxygenation. This can lead to hypoxia (a decreased level of oxygen in arterial blood and tissues), hypoxemia (a decreased level of oxygen in arterial blood), and hypercapnia, also known as *hypercarbia* (an elevated level of carbon dioxide in arterial blood).

The body compensates for mild hypoxia with increased heart and respiratory rates, bringing oxygen to the blood and tissues at a faster rate. If hypoxia progresses, this compensation is inadequate. If hypoxia is prolonged, cardiac dysrhythmias or irreversible brain, liver, kidney, and heart damage result. Retention of carbon dioxide also leads to acidosis.

Etiology

Contributing factors to hypoventilation include alveolar impairment, pain, faulty positioning, a full bladder, or a short, thick neck. Inadequate pulmonary ventilation from depression of the medullary center in the brain by narcotics or anesthetics, neurologic effects of spinal or epidural drug administration, reduced CO, severe blood loss, obstruction to the respiratory passages, or abnormality of the ventilation-perfusion ratio also can contribute to hypoxia and hypercapnia.

Symptoms

Symptoms of hypoventilation and hypoxia include an increased pulse rate, pallor or central cyanosis from hypoxia or a flushed or reddened appearance from hypercapnia, decreased volume of respirations, stertorous or labored respirations, and dark blood in the surgical field. The acid-base balance can be affected.

Treatment

The immediate administration of oxygen in the proper dosage is the treatment of choice for hypoventilation and hypoxia.[4] Oxygen is a medication requiring proper dosage for safe, effective administration. In the healthy patient, changes in the concentration of

carbon dioxide in the blood stimulate the primary central chemoreceptor (respiratory center) in the medulla of the brain. In response to this stimulation the patient takes a breath to increase oxygenation.[2]

Patients with chronic obstructive pulmonary disease (COPD) have higher than normal levels of circulating carbon dioxide and exhibit a decreased primary chemoreceptor response. They rely on secondary chemoreceptors in the carotid and aortic bodies to sense the changes in carbon dioxide levels in the blood. High concentrations of oxygen decrease the sensitivity of the secondary chemoreceptors in patients with COPD, causing respiratory depression known as *carbon dioxide narcosis*.

To minimize the risk for respiratory arrest in patients at risk for carbon dioxide narcosis, a 2 to 3-liter per minute (L/min) flow of oxygen per nasal cannula is recommended postoperatively.[4] An endotracheal tube may be left in place postoperatively to support assisted ventilation in select patients.

Patients are encouraged to cough and breathe deeply postoperatively. If a patient received naloxone hydrochloride (Narcan) to reverse the respiratory depressant effect of a narcotic, the patient may awaken rapidly and cough, inadvertently causing extubation. The patient must be watched closely during recovery.

Prevention

A patent airway, appropriate oxygenation, and proper positioning help prevent hypoventilation. Intraoperative measurements of arterial pH, Pco_2, and Po_2 enable the anesthesia provider to evaluate oxygenation and carbon dioxide gas exchange. To prevent hypoventilation and hypoxia, patients may be given oxygen and assisted ventilation during transport to the recovery area.

Emboli

Pulmonary **embolus** (PE) is a major cause of death during a surgical procedure and in the immediate postoperative period. Some intraoperative problems may extend into postoperative recovery.

PE is an obstruction of the pulmonary artery or one of its branches by an embolus, most often a blood clot, but can be fat or other material. The most common cause of PE is stasis of blood, particularly in the low-pressure regions such as deep veins of the legs and pelvis, where the majority of thrombi arise. These clots become detached and are carried to the lungs.

Injury to the intima of vessel walls and coagulative changes in blood also are important factors. A prolonged period on the OR bed may decrease blood flow to the lower extremities by more than 50%. Blood flow is impaired further if the knees are raised on a hard, rolled towel, putting occlusive pressure on the deep veins of the legs.

Venous stasis also is correlated with obesity, dehydration, congestive heart failure, and atrial fibrillation. Local trauma to a vein or venous disease enhances the chance of **thrombus** formation. Hypercoagulability may coexist with conditions such as pregnancy, fever, myocardial infarction, and some malignancies and after abrupt cessation of anticoagulant therapy. Prevention consists of a regimen of prophylactic anticoagulants or antiplatelets for high-risk patients and routine measures to prevent venous stasis, such as intermittent compression or antiembolic stockings.

Because of the origin of thrombi in deep veins, it is important to observe the patient postoperatively for thrombophlebitis, evidenced by heat, edema, redness, pain in the calf, or a positive Homan's sign, which is pain in the calf on forceful dorsiflexion of the foot.

Nonspecific symptoms depend on whether the embolism is mild or massive. The patient may have dyspnea, pleural pain, hemoptysis, tachypnea, crackles, tachycardia, mild fever, or persistent cough. Patients with massive emboli have air hunger, hypotension, shock, and central cyanosis. Treatment of pulmonary emboli consists of bed rest, oxygen therapy, anticoagulant therapy, thrombolytic agents, and sometimes a surgical procedure to remove the emboli or place a vena cava filter to prevent additional clots reaching the lungs.

Fat embolism occurs primarily after fracture of a long bone, the pelvis, or ribs. However, it sometimes occurs after a blood transfusion, cardiopulmonary bypass, or renal transplant. Fat globules enter a venous sinus and become bloodborne. Symptoms develop when globules block pulmonary capillaries, causing interstitial edema and **hemorrhage**.

Frequently, ARDS ensues 24 to 48 hours after injury, with hypoxia and decreased surfactant production, resulting in collapse of the alveolar membrane and microatelectasis. The syndrome develops most often in patients older than 10 years, especially those who have traveled long distances with an immobilized fracture. Symptoms include disorientation, increased pulse rate, elevated temperature, tachypnea, dyspnea, crackles, and pleuritic chest pain.[4] Other significant signs are fat in the sputum and urine and a petechial rash on the anterior chest. Treatment is supportive. Mortality is high.

Air embolism may occur intraoperatively with the patient in a sitting position for a craniotomy or posterior cervical operation. Cerebral diploic veins are noncollapsible; venous sinuses in the skull remain open. The pull of gravity on the venous drainage exerts a significant negative pressure that sucks air into the veins and into the right atrium of the heart. The air embolus blocks the tricuspid valve. This can be a complication in handling central venous catheters and using syringes to obtain blood for gas analysis.

Cardiac dysrhythmias and unexplained hypotension are prime signs and symptoms. A characteristic heart murmur may be audible with a precordial stethoscope or Doppler. Immediate treatment of air embolus is to place the patient into Trendelenburg's position with the right side slightly elevated (Durant's procedure). The anesthesia provider can place a central venous catheter into the patient's jugular vein and pass it into the right atrium to evacuate the air with a large syringe.

Intrauterine fetal death, abruptio placenta, or placenta previa may precipitate an embolism of amniotic fluid. Also, tumors may cause emboli from primary or metastatic sites. Other material such as plaque or hemostatic material can embolize, causing injury or death to the patient.

Pneumothorax

Although it is rare, insertion of a needle into the thoracic cage can occur during a nerve block or subclavian catheter insertion. Excision of a breast mass close to the chest wall can precipitate pneumothorax. The primary symptoms are pain and shortness of breath. Confirmation is made by x-ray. If the pneumothorax is extensive and the lung fails to reexpand, a chest tube with an underwater seal is required.

Patients with pleural effusion may require thoracentesis, which involves draining the chest for relief of symptoms. Careful placement of the needle can prevent pneumothorax.

Intercostal Muscle Spasm

A "rigid chest" may occur after large doses of IV fentanyl or on emergence from general anesthesia. It may reverse itself, or neuromuscular blockers may be needed.

Atelectasis (Pulmonary Collapse)

Partial collapse of a lung, **atelectasis**, is one of the most common postoperative problems. If mucus obstructs a bronchus, air in the alveoli distal to the obstruction is resorbed. That segment of lung then collapses and consolidates. Retained mucus becomes contaminated by inhaled bacteria; the patient may develop bronchopneumonia.

Etiology

Factors that promote increased production of mucus (e.g., certain irritating anesthetics) and decreased mobilization of mucus (e.g., from a tight abdominal dressing) predispose the patient to pulmonary collapse. Furthermore, normal respiration includes a deep sigh several times an hour to help keep the lungs expanded. This natural sigh is inhibited by anesthetics, narcotics, and sedatives. Oxygen and carbon dioxide are absorbed into the pulmonary blood flow, and the alveoli collapse. Low tidal volume intensifies the problem. High concentrations of oxygen remove nitrogen from the lungs, leaving oxygen, carbon dioxide, and water in the alveoli.

Symptoms

Atelectasis increases the temperature, pulse, and respiratory rate. The patient may appear cyanotic and uncomfortable, with shallow respirations and pain on coughing. Breath sounds are diminished, with fine crackles. Chest x-ray reveals collapsed areas of the lungs as patch opacities, generally involving the lung bases.

Treatment and Prevention

Measures to help prevent or treat atelectasis are abstention from smoking, a regimen of coughing and deep breathing, and early ambulation. An upright position allows for better lung expansion. Medication for pain, when appropriate, before breathing exercises or ambulation improves the ability to breathe deeply and cough effectively. Splinting the thoracic or abdominal incision with a pillow also helps decrease the pain of coughing. Repeated vigorous coughing is contraindicated in some patients (e.g., after cataract extraction, craniotomy, herniorrhaphy).

Pulmonary Edema

Pulmonary edema may be defined as an abnormal accumulation of water in extravascular portions of the lungs, including both alveolar and interstitial spaces. In surgical patients the most probable cause is increased microvascular pulmonary capillary permeability or capillary endothelial injury. Blood stagnates in the pulmonary circulation. Fluid exudes from capillaries into the alveoli and interstitial spaces. Reduction of capillary membrane perfusion leads to hypoxia. Symptoms, usually seen postoperatively in the postanesthesia care unit (PACU) or intensive care unit (ICU), may include a bounding, rapid pulse; crackles; dyspnea; and engorged peripheral veins.

Cardiovascular Complications

The emotional and physical stresses to which a surgical patient is subjected may lead to cardiovascular complications. The patient who fears dying while under anesthesia runs a greater risk for cardiac arrest on the operating bed than do patients with known cardiac disease. Psychologic stress can have physiologic manifestations. Extreme preoperative anxiety predisposes the patient to a difficult induction and intraoperative period and postoperative discomfort.

Patients with a history of cardiovascular problems are prone to develop complications. These may include dysrhythmias, hypotension, thromboembolism and/or thrombophlebitis, myocardial infarction, or congestive heart failure. Cerebral thrombosis or embolism may result in prolonged coma. Patients must be closely monitored for symptoms of cardiovascular complications. **Anoxia**, the complete or almost total absence of oxygen from inspired gases, arterial blood, or tissues, is a precursor to cardiovascular collapse. Cardiac arrest can result in death in the OR.

Hypotension

Reduced blood pressure (BP), with resultant inadequate circulation, may accompany depression of the myocardium, depression of the vasomotor center in the brain, a decline in CO, or dilation of the peripheral vessels. **Hypotension** also may occur when positive pressure is applied to the airway. Progressive deepening of general anesthesia usually produces peripheral vasodilation and diminished myocardial contractility. Adequate blood flow to the brain and heart, the two most vulnerable vascular beds because of their high metabolic demand, must be maintained. If arterial hypotension is uncontrolled, it may cause a cerebrovascular accident, myocardial infarction, or death.

Etiology

Overdosage of general anesthetic agents or rapid vascular absorption of local agents may result from the patient receiving an amount of the agent that exceeds his or her tolerance. Tendency for overdosage occurs during prolonged anesthesia with large amounts of drugs absorbed, in age-extreme patients, or with unrecognized hypothermia during lengthy abdominal or thoracic procedures. Circulatory effects of spinal or epidural anesthesia, such as diminished CO or reduced peripheral resistance, also produce hypotension.

Other causes of hypotension include the following:

- Volume depletion and/or hemorrhage
- Circulatory abnormalities (e.g., cardiac tamponade, heart failure)
- Cerebral or pulmonary embolism (fat embolism from fracture sites, amniotic fluid emboli during delivery, or air emboli from introduction of air into the circulation during an infusion or procedure)
- Myocardial ischemia or infarction
- Changes in position, especially if executed rapidly or roughly
- Excessive preanesthetic medication (postural hypotension may follow narcotic administration)
- Epidural or spinal anesthesia above the level of T6 (sympathetic block)
- Potent therapeutic drugs (e.g., tranquilizers, adrenal steroids, antihypertensives) given before the anesthetic
- Hypoxia

Surgical manipulation may mechanically induce hypotension by obstructing venous return to the heart with packs, retractors, or body rests, or hypotension and bradycardia may result from a vagal-induced reflex precipitated by intraperitoneal traction, manipulation in the chest or neck area, rapid release of either increased intraabdominal pressure or overdistention of the bladder,

anorectal stimulation, or stimulation of the periosteum or joint cavities. Other causes are transfusion reaction (suggested by accompanying cyanosis and oozing at the surgical site), septic shock, severe hyperthermia, and anaphylactic reaction.

Symptoms

Early reversible shock is accompanied by unstable BP, vasoconstriction, and elevated serum pH and catecholamine levels. Late manifestations are pallor or central cyanosis, clammy skin, dilated pupils, decreased urinary output, tachycardia, decreased bleeding in the surgical field, or pallor of organs caused by compensatory vasoconstriction, nausea, vomiting, sighing respirations, or air hunger in conscious patients.

Diagnosis

Determination of arterial BP and pulse rate and estimation of pulse volume are indicative of the volume of cardiac ejection. Arbitrary figures of measured BP are not as important as individual circulatory status. A specific measurement in a healthy adult may be relatively insignificant, whereas the same figure in a geriatric patient could be hazardous. In critically ill patients, direct arterial pressure, central venous pressure (CVP), and urinary output are monitored.

Treatment

Treatment must be prompt to avoid circulatory collapse. The aim is to increase perfusion of the vital organs and treat any specific cause while giving general supportive therapy. Supportive measures include oxygen by mask with assisted respiration; elevation of the legs to increase BP by draining pooled blood, especially after sympathetic blockade; and rapid IV fluid therapy to increase blood volume.

Because the volume of fluid is more vital than its composition, various solutions are applicable for early treatment in an emergency. If whole blood is not available, crystalloid solutions (e.g., lactated Ringer's solution), 5% dextrose in water (D_5W), physiologic saline solution (0.9% saline), plasma or serum albumin, or 6% dextran (plasma expander) may be given. Rapid infusion under pressure may be necessary. Vasoactive drugs are given as necessary; these are usually vasopressors to constrict arterioles and veins while increasing the myocardial contractile force. Blood gases should be monitored.

Prevention

The causes must be reversed or avoided. Therefore the patient should be observed constantly throughout anesthesia. In individuals suspected of having hypotension the cardiovascular response to the desired surgical position should be tested before induction. Overdosage of premedication and anesthetic drugs is avoided. The patient's position is changed slowly, tissue is manipulated gently, and blood and fluid loss are replaced promptly. The anesthesia provider administers a minimal amount of the anesthetic and takes adequate time to induce and deepen anesthesia so as not to raise the blood level of the anesthetic too rapidly. Positive pressure is applied to the airway prudently.

Some narcotics and anesthetic agents, surgical trauma, anoxia, and blood loss can lead to postoperative hypotension. When combined, these factors interfere with the complex physiologic mechanisms that support BP. Peripheral vessels dilate. A degree of cardiovascular collapse ensues. Vasoconstriction reduces renal blood flow, causing decrease or failure of kidney function. Patients must be monitored postoperatively for sudden drops in BP or other signs of shock. Vasoactive drugs and oxygen may be administered. To avoid hypotension, fluid management is critical to renal function after restoration of systemic BP.

Hypertension

Abnormal elevation of the BP, **hypertension**, may occur, especially in a hypertensive or arteriosclerotic patient. Even mildly hypertensive patients are prone to myocardial ischemia (inadequate blood flow to the heart) during induction of and emergence from anesthesia. Intubation stimulates the sympathetic nervous system. Other predisposing factors include pain, shivering, hypoxia, hypercapnia, effects of vasopressor drugs, or hypervolemia from excessive replacement of fluid losses. Treatment consists of administration of oxygen, diuretics, and antihypertensive beta-blocker drugs as indicated. If not controlled, hypertension may precipitate a cerebrovascular accident or myocardial infarction. It may cause bleeding from the surgical site or may threaten the integrity of a vascular bypass.

Venospasm

If caused by cold IV fluid infusion, venospasm may manifest as very slow flow. It may result from pressure infusion or extravasation. IV procaine relieves spasm. Thrombophlebitis may follow venospasm.

Coronary Thrombosis

Coronary thrombosis can occur from severe hypoxia and lack of oxygen to coronary vessels. Sometimes its occurrence is the reason for a patient not to regain consciousness after a surgical procedure.

Venous Stasis

Venous return of blood from the lower extremities can be slowed by the effects of general or spinal anesthesia and by the position of the legs during prolonged surgical procedures. The venous stasis that develops in most patients during a surgical procedure can be effectively counteracted. To prevent thrombophlebitis and thrombosis in patients with thromboembolic disease, anticoagulants may be administered. Antiembolic stockings, with or without a sequential pneumatic compression device, augment venous flow from the legs. Elevation of the legs as little as 15% above horizontal can assist in venous return.

Postoperatively the patient may be placed in Trendelenburg's position with the legs elevated. Flexion and extension of the legs and feet, frequent turning, and early ambulation, unless contraindicated, aid circulation.

Deep Vein Thrombosis

Venous stasis, changes in clotting factors in the blood, and damage to vessel walls are the primary causes of deep vein thrombosis (DVT) in the lower extremities. Age, obesity, immobility, and a history of thromboembolic or other cardiovascular disease are predisposing factors. The type, location, and extent of the surgical procedure can contribute also. Preoperative prophylactic interventions, including anticoagulants, sequential compression devices, or antiembolic stockings, can reduce the risk for postoperative pulmonary embolism, which is a life-threatening complication of DVT.

Disseminated Intravascular Coagulation

Although it occurs rarely, disseminated intravascular coagulation (DIC) is a life-threatening syndrome. It is a complex derangement of clotting factors. The hemostatic process involves vasoconstriction with platelet aggregation and clotting. In DIC the normal clotting mechanisms do not function. Instead, a repetitive, overactive cycle of clot formation (**coagulopathy**) and simultaneous clot breakdown (fibrinolysis) occur. This leads to consumption of platelets and coagulation factors and release of fibrin degradation products that act as potent anticoagulants.

DIC can follow hemorrhage, thrombi, emboli, infection, or allergic reaction to an incompatible blood transfusion. It may be precipitated by septic shock, abruptio placenta during pregnancy, or massive soft tissue damage of extensive trauma or burns. As blood becomes depleted of platelets and major clotting factors, coagulation is initiated throughout the bloodstream, especially in microcirculation.

Prolonged bleeding may be noted; hematomas and cutaneous petechiae may appear. Massive hemorrhage and ischemia of vital organs may ensue. Bleeding may be noted from various sites, such as through the nasogastric tube.

The patient may have hypotension and oliguria. Postoperatively the patient may have nausea and vomiting, severe muscular pain, and convulsions and may lapse into a coma. Diagnosis is based on laboratory blood studies. Treatment begins with control of the primary condition. Blood, plasma, and dextran can be administered IV. Heparin and clotting factors, if given early, may prevent hemorrhage.

Cardiac Dysrhythmias

An alteration of normal cardiac rhythm may decrease CO, exhaust the myocardium, and lead to ventricular fibrillation or cardiac arrest. Bradycardia is the slowing of the heart or pulse rate. Tachycardia is an excessive rapidity of the heart's action. Ventricular tachycardia and ventricular fibrillation are the dysrhythmias of most serious consequence and thus most feared.

Etiology

Etiologic factors include hypoxia; hypercapnia; acidosis; electrolyte imbalance; coronary disease; myocardial infarction; vagal reflexes; anesthetic agents; toxic doses of digitalis, epinephrine, or other drugs; and laryngospasm and coughing initiated by the presence of secretions in the airway after induction. Other causes may be hypotension, hemorrhage, hypovolemia, pneumothorax, and mechanical injuries.

Ventricular Dysrhythmias

An impulse originating in the ventricles must travel to the rest of the myocardium from one ventricle, then proceeding to the other. Because the impulse does not travel via the rapid, specialized conduction system, depolarization of both ventricles takes longer and is not simultaneous. The complexes of dysrhythmias have an abnormal appearance on an electrocardiogram (ECG) compared with normally initiated and conducted impulses.

Premature Ventricular Contraction

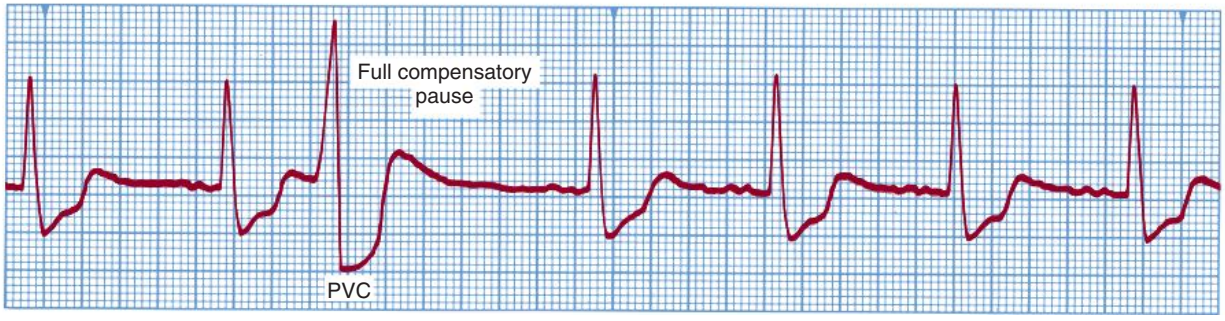
An ectopic focus in the ventricles stimulates the heart to contract or beat prematurely before the regularly scheduled sinoatrial impulse arrives (Fig. 31.1). Primary precipitating factors are electrolyte or acid-base imbalance, myocardial infarction, digitalis toxicity, and caffeine. The premature ventricular contraction (PVC) must be distinguished from a premature atrial contraction (PAC). Isolated PVCs may not require treatment, but those occurring in clusters of two or more, or more than five or six per minute, require therapy. The aim is to quiet the irritable myocardium and restore adequate CO.

Treatment consists of a lidocaine bolus followed by a continuous drip by infusion, correction of the cause (e.g., hypoxia), and other antidysrhythmic drugs if indicated (e.g., procainamide, quinidine). Temporary pacing may be used for severe bradycardia. Paired PVCs pose an increased danger of ventricular tachycardia.

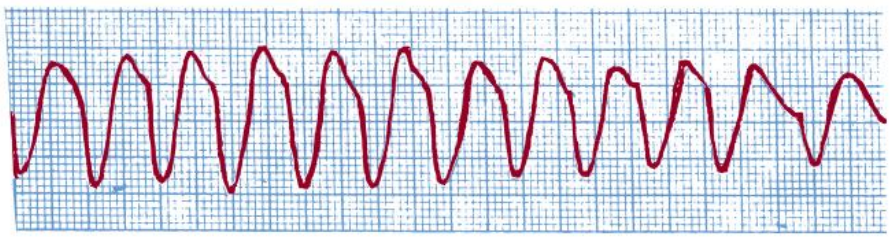
Ventricular Tachycardia

A rapid heart rate (100 to 220 beats/min) may be caused by ventricular ischemia or irritability, anoxia, or digitalis intoxication. The heart rate does not allow time for ventricular filling (Fig. 31.2). The resultant reduced CO predisposes the patient to ventricular fibrillation or cardiac failure. Ventricular tachycardia is treated by prompt IV administration of lidocaine or procainamide, or intramuscular (IM) quinidine.

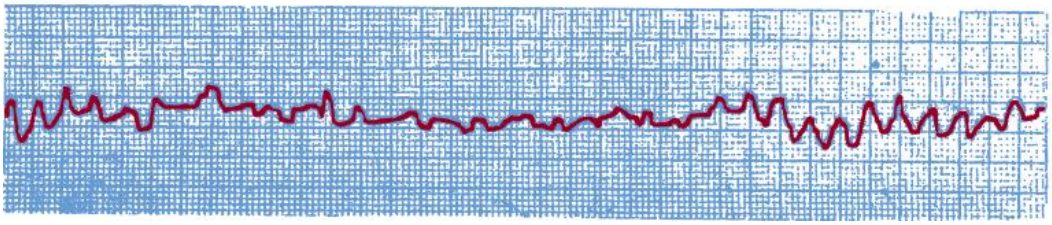
Synchronized cardioversion of 10 to 200 joules may be used if the BP is palpable. This is the application of a high-intensity, short-duration electric shock to the chest wall over the heart to produce total cardiac depolarization. This countershock is timed to interrupt an abnormal rhythm in the cardiac cycle, thereby permitting resumption of a normal one. Cardioversion is usually applied in instances of nonarrest for a dangerous ventricular tachycardia. It may be an elective or emergency treatment. Asynchronous cardioversion is used if the patient is pulseless. Treatment includes correction of the underlying cause.



• **Fig. 31.1** Premature ventricular contractions.



• **Fig. 31.2** Ventricular tachycardia.



• **Fig. 31.3** Ventricular fibrillation.

Ventricular Flutter

Often called fine ventricular fibrillation, the flutter appears as a transient state between ventricular tachycardia and ventricular fibrillation. The patient will show signs of poor CO.

Ventricular Fibrillation

The most serious of all dysrhythmias, fibrillation is characterized by total disorganization of ventricular activity (Fig. 31.3). There are rapid and irregular, uncoordinated, random contractions of small myocardial groups without effective ventricular contraction or CO. Circulation ceases. The patient in fibrillation is unconscious and possibly convulsing from cerebral hypoxia.

Treatment

Because respiratory and cardiac arrest quickly follow, ventricular fibrillation is rapidly fatal unless successful defibrillation is effected as follows:

1. *Precordial thump:* In a monitored patient a fast, sharp, single blow to the midportion of the sternum (using the nipple line as a landmark) may be delivered with the bottom fleshy part of a closed fist struck from 8 to 12 inches (20 to 30 cm) above the chest. The blow generates a small electrical stimulus in a heart that is reactive. It may be effective in restoring a beat in cases of asystole or recent onset of dysrhythmia. A precordial thump can be used in a witnessed, monitored cardiac arrest.
2. *Asynchronous cardioversion:* Prompt defibrillation by short-duration electric shock to the heart produces simultaneous depolarization of all muscle fiber bundles, after which spontaneous beating (conversion to spontaneous normal sinus rhythm) may resume if the myocardium is oxygenated and not acidotic. Defibrillation of an anoxic myocardium is difficult. The start time of the fibrillation should be noted. The electric shock is coordinated with controlled ventilation and cardiac compression. Cardiopulmonary resuscitation (CPR) begins as soon as fibrillation is identified. Many variables may affect defibrillation, such as body weight, paddle position, electrical waveform, and resistance to electric current flow. Procedures follow an established protocol.
3. *Adjunct drug therapy:* Drugs are given as necessary: vasopressor, cardiotonic, and myocardial stimulant drugs to maintain a useful heartbeat; **vasodilator** or antidysrhythmic drugs to prevent recurrence; and sodium bicarbonate to combat acidosis. Continuous monitoring of the heart and laboratory analysis of arterial blood gases are essential.

Defibrillation: Equipment and Technique. Necessary equipment for defibrillation includes a defibrillator machine and two paddle electrodes. Defibrillators use direct electric current. Most have integrated monitors; monitor and defibrillator switches may be separate or combined. An operational monitor does not always indicate that the fibrillation power is on.

Many monitor-defibrillator units can monitor the ECG from the paddle electrodes, as well as from separate patient leads. These paddles and patient leads cannot operate simultaneously, however. Depending on the type of defibrillator, the electrical cord must be plugged in or batteries charged. All defibrillators should be checked regularly with suitable test equipment. Paddles must be cleaned immediately and prepared for reuse. This is emergency equipment and must be available at all times.

External Defibrillation. External defibrillation of the heart is used unless the chest is already open, as for intrathoracic surgery. Standard electrode paste or jelly or saline-soaked 4 × 4–inch gauze pads reduce the resistance of the skin to passage of the electric current. If paste is used on paddles, it should not extend beyond the electrodes or onto any part of the handles.

Gel pads between the paddles and the patient's skin provide the advantage that if external cardiac compression is resumed after defibrillation, hands will not slip on the chest. The large diameter of the paddles increases the area of skin contact, thus reducing the possibility of skin burns by spreading of the current. The paddles must be held flat against the skin and more than 2 inches (5 cm) apart to prevent electrical arcing. They must be kept scrupulously clean because foreign material reduces the uniformity of the shock. The electrodes must be pressed firmly against the chest wall for good contact. One of two external paddle positions may be used:

1. *Standard position:* One electrode is placed just to the right of the upper sternum below the clavicle. The other is positioned to the left of the cardiac apex (i.e., left of the nipple at the fifth intercostal space along the left midaxillary line). The delivered current flows through the long axis of the heart.

2. *Anterior-posterior position:* One electrode is placed anteriorly over the precordium between the left nipple and the sternum. The other is positioned posteriorly behind the heart immediately below the left scapula, avoiding the spinal column. This allows for more energy passage through the heart, but placement is more difficult.

Internal Defibrillation. For internal defibrillation, sterile electrodes are placed on the myocardium—one over the right atrium and the other over the left ventricle. If these electrodes are gauze covered, they are dipped in sterile saline solution before use. Minimal current is needed when paddles are placed directly on the heart.

Perioperative team members must understand the functioning of the defibrillator for the patient's safety as well as their own. The person holding the electrode paddles delivers the electric charge by pressing a switch on the handle or a foot switch. The safest method is to activate both paddles simultaneously for discharge of electrical energy. The operator should have dry hands and stand on a dry floor.

To avoid possible self-electrocution when using a defibrillator, neither the person holding the electrodes nor anyone else should touch the metal frame of the OR bed or the patient while the current is being applied. No part of the operator's body should touch the paste or the uninsulated electrodes. Loud verbal warning is given before discharge. Countershock is repeated at intervals if fibrillation persists. Transthoracic impedance falls with repetitive, closely spaced electrical discharges. After each countershock, the ECG and pulse should be reassessed.

Myocardial damage resulting from defibrillation efforts is in direct proportion to the energy used; therefore maximal settings, when not required, may increasingly impair an already damaged myocardium. The energy level delivered through a specific ohm load should be indicated on the front panel of the defibrillator. Delivery output ranges vary among machines.

The strength of the countershock is expressed in energy as joules or watt-seconds—the product of power and duration. If the patient's chest muscles do not contract, no current has reached the patient. The defibrillator's connection to the electrical source and the "off" button to the synchronizer circuit should be checked. If the machine is battery operated, the battery must be charged enough to energize the capacitor. Personnel must be familiar with and follow operating instructions for the defibrillator in use.

Appropriate preoperative sedation and skillfully administered anesthetic help prevent hazardous cardiovascular reflexes. Because PVCs are precursors to ventricular fibrillation, in itself a precursor to cardiac arrest, any cardiopulmonary emergency in a prearrest phase requires the following procedures:

1. *Monitoring of the heart rhythm and rate:* The ability to recognize the rhythms that precede arrest permits intervention that may prevent arrest. If the cardiac status is not under constant monitoring, hypoxia and acidosis may be present and require correction before other therapeutic modalities can be used effectively.
2. *Establishment of an IV lifeline:* Venous cannulation provides access to peripheral and central venous circulation for administering drugs and fluids, obtaining venous blood specimens for laboratory analysis, and inserting catheters into the right side of the heart and pulmonary arteries for physiologic monitoring and electrical pacing. If cardiac arrest appears imminent or has occurred, cannulation of a peripheral or femoral vein should be attempted first so as not to interrupt CPR. To keep the infusion open, the rate should be kept slow. The usual complications to all IV techniques should be guarded against.

Cardiac Arrest

In cases of cardiac arrest there is cessation of circulatory action; the pumping mechanism of the heart ceases. Cardiac standstill represents total absence of electrical cardiac activity (asystole), reflected as a straight line on an ECG rhythm strip.[5] It may occur as primary cardiac failure or secondary to failure of pulmonary ventilation. The types of circulatory arrest are profound cardiovascular collapse, electromechanical dissociation, ventricular fibrillation, and ventricular asystole or standstill.[6] Cardiac arrest may precede or follow failure of the respiratory system, because the systems are interrelated.

Incidence

Arrest may occur during induction of anesthesia, intraoperatively, or postoperatively. Occurrence during cardiac surgery or after massive hemorrhage is not uncommon. Patients more prone to arrest include those at age extremes and those with previously diagnosed paroxysmal dysrhythmias, primary cardiovascular abnormalities, myocarditis, heart block, or digitalis toxicity. An unexpected arrest is one that happens in a patient of general good health who is undergoing a low-risk or relatively routine procedure. These arrests are associated with major morbidity and mortality.

Etiology

A single factor or combination of factors may precipitate cardiac arrest, but the general cause is inadequate coronary arterial blood flow. Defective respiratory function produces systemic hypoxemia, causing myocardial hypoxia and depression. It also increases myocardial irritability and the heart's susceptibility to vagal reflexes.

Some of the specific precipitating factors are dysrhythmias, emboli, extreme hypotension or hypovolemia, respiratory obstruction, aspiration, effects of drugs, anesthetic overdosage, excessively rapid or unsmooth induction, sepsis, pharyngeal stimulation, metabolic abnormalities (acidosis, toxemia, electrolyte imbalance), poor cardiac filling caused by positioning, manipulation of the heart, central nervous system trauma, **anaphylaxis**, and electric shock from ungrounded or faulty electrical equipment.

Symptoms

Symptoms include loss of heartbeat and BP; sudden fixed, dilated pupils; sudden pallor or cyanosis; cold, clammy skin; absence of reflexes; unconsciousness or convulsions in a previously conscious patient; respiratory standstill; and dark blood or absence of bleeding in the surgical field.[5,6]

Diagnosis

The ECG monitor readily detects arrest during anesthesia, with absence of BP and precordial heart sounds and the lack of a palpable carotid pulse. The onset of pupillary dilation is within 45 seconds after cerebral anoxia; full dilation is reached about 90 to 110 seconds after cessation of cerebral circulation.

Treatment

CPR is initiated immediately to restore oxygenation to vital organs.[5] Defibrillation may be needed for ventricular fibrillation. IV drugs generally are used to improve cardiopulmonary status.

Prevention

Optimal psychologic preoperative assessment to identify the level of anxiety and testing for abnormalities and sensitivities is an

important preoperative preparation. Intraoperative precautions include the following:

- ECG and temperature monitoring
- No stimulation during induction
- Maintenance of an adequate airway
- Oxygen and carbon dioxide monitoring
- Arterial BP monitoring
- Medications
- Appropriate positioning and slow position changes with the patient under anesthesia; no weight on the patient
- Gentle handling of tissues with minimal traction and manipulation
- Skillful anesthetic administration

Intravenous Cardiovascular Drugs

An important factor in optimal anesthesia management is prompt recognition of the causes of hypotension, shock, and other complications that could lead to cardiac arrest. Prompt correction of reversible precipitants is critical. Many intravenous (IV) drugs are used to correct hypoxia and metabolic acidosis, manipulate cardiovascular variables, or treat pulmonary edema.

Pharmacodynamics

Uptake, movement, binding, and interactions of drugs vary at the tissue site of their biochemical and physiologic actions. Drug action is determined by how the drug interacts in the body. Some drugs alter body fluids; others, such as anesthetics, interact with cell membranes; most act through receptor mechanisms.

Receptor Mechanisms

Most drugs mimic naturally occurring compounds and interact with specific biologic molecules to produce biologic responses. For example, some cardiovascular drugs are sympathomimetics. They evoke physiologic responses comparable to those produced by the sympathetic nervous system. A receptor is a structural protein molecule on a cell surface or within cytoplasm that binds with a drug to produce a biologic response. Three types of receptors are noteworthy in understanding the drugs used to counteract complications that may occur during anesthesia.

Adrenergic Receptors. Adrenergic receptors are innervated by sympathetic nerve fibers and activated by epinephrine or norepinephrine secreted at the postganglionic nerve endings. These receptors are classified as alpha or beta, depending on their sensitivity to specific adrenergic activating and blocking drugs. $Alpha_1$ and $alpha_2$ receptors are located primarily in peripheral and renal arteriolar muscles; $beta_1$ receptors predominate in the heart; $beta_2$ receptors are primarily in smooth muscle of the lungs and blood vessels.

Cholinergic Receptors. Cholinergic receptors are sites where acetylcholine exerts action to transmit nerve impulses through the parasympathetic nervous system to regulate the heart rate and respirations.

Opiate Receptors. Opiate receptors are regions in the brain capable of binding morphine in areas related to pain.

Drug Interactions

No drug has a single action. Each modifies existing functions within the body by interactions to stimulate or inhibit responses. The desired action may be accompanied by side effects or an exaggerated response. An allergic reaction may occur immediately after exposure or may be delayed.

Anaphylaxis is a life-threatening, acute allergic reaction in which cells release histamine or a histamine-like substance.[7] Anaphylaxis, a form of vasogenic shock, causes vasodilation, hypotension, and bronchial constriction. Within seconds of receiving a drug that induces an allergic reaction, the patient will exhibit edema, wheezing, cyanosis, and dyspnea. Treatment includes epinephrine and antihistamines to control bronchospasm. Isoproterenol, vasopressors, corticosteroids, and aminophylline also may be administered.[6,7]

In combination with local, regional, or general anesthetics, drugs must be carefully administered and monitored. The action of one drug may counteract the action of another drug. Patients who do not respond to one drug (e.g., a catecholamine) may respond to another. Physicians do not always agree on the use of potent drugs. For example, a **vasoconstrictor** used to treat hypotension may possibly cause ischemic damage to organs. The physician's orders should be followed for all drugs.

Intravenous Administration

The speed of administration and dosage will depend on the drug and its intended action. Dosages given in this text vary according to individual patient circumstances. The technique of IV administration also varies.

Continuous Intravenous Drip. The drug is diluted in a volume of dextrose or normal saline solution. The rate of administration is regulated by adjusting the number of drops per minute from the solution container into the IV tubing. A drug that might be absorbed by plastic should not be added to solution in a plastic infusion bag.

Bolus. A bolus is a single rapid injection of the full dosage of a drug that cannot be diluted. It is usually given through an existing IV line, and it may be injected directly into a vein or an intrathecal catheter. Some drugs can be given via an endotracheal tube for absorption through the alveoli or mucous membranes. The drug quickly reaches peak level in the bloodstream.

Intravenous Push. A drug may be injected slowly into an IV line or through an intermittent infusion pump over a period of minutes. The total dose may be diluted and given in repeated doses over a period of hours. An infusion pump may be used to control the rate of delivery precisely.

Titration. Dosage is calculated on the basis of body surface area (BSA) and hemodynamic parameters. CO is evaluated in terms of BSA. This may be determined by the ratio of the patient's height and weight on the BSA scale or by thermodilution. The patient's physiologic responses also will determine total dosage.

Considerations for Drug Administration

Some drugs are inactivated by others. The IV tubing should be flushed or changed to avoid precipitation, such as can occur with sodium bicarbonate. Many potent drugs should be infused through an IV catheter, which is safer than a needle to prevent extravasation. If a drug extravasates at the site of injection, the area must be promptly infiltrated with phentolamine (Regitine) to prevent the necrosis that can result from some vasoactive drugs.

Drugs by Classification

Pharmacokinetics includes the mechanisms of absorption, distribution, and metabolism of drugs in the body and elimination from the body. Nurses must have knowledge of drug actions and of how to prepare and administer drugs. The following drugs are classified by their pharmacodynamics to counteract adverse cardiovascular and pulmonary status.

Sympathomimetics are used most often for the following purposes:

- To increase force (inotropic effect), maintain contractility (noninotropic effect), or decrease the stroke volume of myocardial contractions
- To increase the pulse rate
- To increase or decrease arterial BP
- To correct dysrhythmias
- To increase renal blood flow
- To stimulate the central nervous system
- To treat bronchospasm
- To prolong the effect of local anesthetics
- To manage life-threatening emergencies

Patients receiving any of the following drugs must be carefully monitored.

Antidysrhythmics

Antidysrhythmics control the heart rate and rhythm. They may induce a decreased rate and CO. They may reduce cardiac conduction and increase dilation of peripheral vessels.

Lidocaine (Xylocaine). Lidocaine increases the threshold for ventricular irritability by exerting a focal anesthetic effect on the myocardial cell membrane. It is used for ventricular tachycardia and fibrillation, especially if resistance to defibrillation effort occurs. It can be given IV, intrathecally, or by endotracheal tube. Dosage is 1 mg/kg or 75 to 100 mg by IV push over 30 to 60 seconds, followed by half the initial dose every 8 to 10 minutes to a total of 3 mg/kg if ectopic heartbeats continue. After conversion, a maintenance dose of 2 to 4 mg/min can be given by IV drip. Half these dosages are used to treat shock or pulmonary edema.

Amiodarone. Amiodarone is the first line of treatment in shockable rhythms such as ventricular fibrillation, supraventricular tachycardia, or pulseless ventricular tachycardia. Dosage is 15 mg/kg IV over 10 minutes, followed by 1 mg/kg/min over 3 hours. Total should not exceed 100 mg over 24 hours. Amiodarone is not used in second- or third-degree atrioventricular (AV) block unless a pacemaker is present or in electrolyte imbalance of potassium or magnesium. Complications include the potential for thyroid, liver, or lung tissue damage. Amiodarone can interact with oral anticoagulants, digoxin, and other class I antidysrhythmics.

Bretylium (Bretylol). Bretylium lowers the defibrillation threshold, permitting otherwise refractory rhythms to be electrically converted. It is indicated in cases of ventricular tachycardia and fibrillation unresponsive to other therapy. Dosage is 5 mg/kg by rapid IV bolus, followed by defibrillation. If fibrillation continues, the dose can be doubled and repeated as necessary. For ventricular fibrillation, 300 to 600 mg may be required. The drug may be diluted for continuous IV drip at a dosage of 1 to 2 mg/min for ventricular tachycardia and to prevent fibrillation. Some degree of hypotension may occur.

Procainamide (Pronestyl). Procainamide suppresses PVCs and recurrent tachycardia. This drug may be used if lidocaine is contraindicated or has not controlled ventricular tachycardia. Dosage is 100 mg by IV push every 5 minutes until dysrhythmia ceases, or to a total of 1 g. Maintenance IV drip is 1 to 4 mg/min. Marked hypotension may occur if infusion is too rapid.

Adenosine (Adenocard). Adenosine slows AV node conduction. This action converts supraventricular tachycardia to normal sinus rhythm. Dosage is 6 to 12 mg by IV bolus followed immediately by a saline bolus. Incremental doses of 0.05 mg/kg can be given as necessary. This drug is contraindicated for patients with asthma.

Verapamil (Isoptin, Calan). A calcium channel blocker, verapamil inhibits calcium ions to slow myocardial contractility, the heart rate, and the demand for oxygen. It is used as an antidysrhythmic to treat paroxysmal supraventricular tachycardia, acute atrial flutter, and atrial fibrillation. Dosage is 5 to 10 mg (0.075 to 0.15 mg/kg adult body weight) by slow IV push over 2 minutes; may be repeated after 30 minutes. This drug is not given to patients with severe hypotension, malignant hyperthermia (MH), or cardiogenic shock, nor is it given concurrently with an IV beta-adrenergic blocker, such as propranolol.

Propranolol (Inderal). A beta-adrenergic receptor blocking agent, propranolol is used to control supraventricular dysrhythmias and treat hypertension. It reduces myocardial oxygen consumption by blocking catecholamine-induced increases in the heart rate, BP, and cardiac contractions. It may be used if control of ventricular fibrillation is not achieved with lidocaine or other drugs. Dosage is 1 to 3 mg by IV push, not to exceed 1 mg/min, titrated for heart rate and rhythm. This drug is contraindicated for patients with asthma, bronchospasm, or cardiac depression.

Isoproterenol (Isuprel). A beta-adrenergic receptor stimulant, isoproterenol stimulates the sympathetic tone, rate, and strength of myocardial contractions and CO. It increases the myocardial demand for oxygen. It may be used for ventricular dysrhythmias, but it may produce tachycardia or dysrhythmia. It is indicated to control hemodynamically significant bradycardia in a patient who has a pulse but is unresponsive to atropine. It is a vasodilator and bronchodilator. Dosage is IV drip of 1 mg to 500 mL of dextrose or saline solution at the rate of 1.25 mL/min, titrated according to the heart rate and rhythm.

Antimuscarinics/Anticholinergics

Antimuscarinics/anticholinergics block passage of impulses through the parasympathetic nerves to the heart and smooth muscles. When both the sympathetic and parasympathetic components of the autonomic nervous system are stimulated, the parasympathetic dominates to slow the heartbeat and respirations. An anticholinergic allows the desired sympathetic action.

Atropine. Atropine reduces cardiac vagal tone, enhances AV conduction, and increases CO. It accelerates the cardiac rate in sinus bradycardia with severe hypotension or in bradycardia associated with hypoxia and reduced CO. It may restore cardiac rhythm in AV block or ventricular asystole. It is a primary drug used in cardiopulmonary arrest. Atropine may be given IV, intrathecally, or via an endotracheal tube. Dosage is 1 mg by IV bolus for asystole, 0.5 mg for bradycardia, at 5-minute intervals until the desired rate is achieved or to a total dose of 2 mg. Full vagal blockage could result from overdosage.

Vasodilators

Vasodilators are noninotropic drugs that relax smooth muscle in the capillaries and cause peripheral dilation. They dilate arteries and veins almost equally without increasing myocardial contractility. This reduces venous return to heart. They are used to alter blood flow and lower BP in patients who have severely reduced CO or are in hypertensive crisis.

Sodium Nitroprusside (Nipride, Nitropress). Sodium nitroprusside acts rapidly as a direct peripheral vasodilator to increase CO and redistribute cardiac work in patients with pump failure. It increases tissue perfusion without reflex tachycardia. Dosage is IV drip, not to exceed 10 mcg/kg/min, of 50 mg dissolved in 2 to 3 mL of dextrose added to 250 to 1000 mL of 5% dextrose in water for infusion. An infusion pump or microdrip-regulating system ensures a precise flow rate. The solution deteriorates in light, so it must be protected by opaque material such as a dark

bottle or aluminum foil. No other drug should be injected into the IV line while sodium nitroprusside is infusing.

Nitroglycerin (Nitrostat IV, Nitrol IV, Tridil). Nitroglycerin decreases venous return to the heart and reduces preload and afterload, thus lowering myocardial oxygen demands. It is used for control of BP in hypertension associated with cardiovascular procedures or endotracheal intubation or in the immediate postoperative period. Dosage is up to 50 mcg/min by IV push. The drug should be titrated to increase the dose, and the time intervals between infusions should be adjusted, depending on lowering of the BP. This potent drug must be diluted in dextrose or saline solution. It is absorbed by polyvinyl chloride (PVC) plastic, so glass solution bottles and tubing that is not made of PVC should be used. The drug is also light sensitive.

Trimethaphan (Arfonad). A ganglionic blocking agent, trimethaphan is used to produce controlled hypotension during surgical procedures and lower BP in patients with hypertension or those experiencing an acute hypertensive crisis. Dosage is 500 mg diluted in 500 mL of 5% dextrose in water (1 mg/mL) IV drip. Initially the drug is infused slowly at the rate of 1 to 2 mg/min and increased gradually to an average dose range of 3 to 6 mg/min.

Cardiotonics

Cardiotonics combine inotropic effect on the contractility of muscle with vasodilation of blood vessels. They stimulate myocardial function. Vasodilation reduces cardiac afterload, thereby improving cardiac performance and correcting peripheral vascular compensations.

Inamrinone (Inocor). Inamrinone possesses significant vasodilator activity to improve tissue perfusion, especially to the kidneys, and improve CO. It is used for short-term effect in patients with ischemic heart disease and severe heart failure. The BP and heart rate remain unchanged, whereas peripheral arteriolar resistance falls. Dosage is 0.5 to 3.5 mg/kg by IV bolus followed by IV drip of 5 to 10 g/kg/min. Titrated to hemodynamic response, a second bolus can be given after 30 minutes.

Dobutamine (Dobutrex). A synthetic derivative of dopamine, dobutamine increases myocardial contractility while producing little systemic arterial constriction. It is used for short-term treatment of refractory heart failure, cardiogenic shock, and hemodynamically significant hypotension. Dosage is 2.5 to 10 mcg/kg/min IV drip. Tachycardia or dysrhythmia may result from a larger dose. It is incompatible with alkaline solutions and drugs such as sodium bicarbonate.

Catecholamines

Catecholamines are vasoconstrictors that improve tissue perfusion by maintaining perfusion pressure, preventing or diminishing blood loss, decreasing tissue vascularity, and improving coronary blood flow. Among indications for their use are anesthetic overdose, hypotension associated with blood loss, and adrenergic insufficiency. They raise the BP. They are antispasmodic.

Epinephrine (Adrenalin). An endogenous catecholamine and alpha-adrenergic receptor stimulant, epinephrine plays an essential role in restoration of spontaneous circulation in asystole; therefore the drug epinephrine is the first drug administered in instances of cardiac arrest. By increasing systemic vascular resistance, it improves coronary perfusion pressure and CO produced by cardiac compression during CPR. It improves myocardial contractility and tone and causes vasoconstriction of arteries.

Epinephrine may be given IV, intrathecally, by endotracheal tube, or by intracardiac injection. Dosage is 0.5 to 1 mg by IV bolus, repeated every 5 minutes as necessary. It is available in preloaded syringes of 1:10,000 dilution (1 mg/10 mL). It may be added to an IV infusion of 250 mL of 5% dextrose in water. It is inactivated by alkaline solutions. Continuous infusion may increase the heart rate, BP, and CO. Side effects include elevated myocardial oxygen demand and possible PVCs or ventricular fibrillation.

Norepinephrine (Levophed). An endogenous catecholamine, norepinephrine restores and maintains BP. It may be given after peripheral vascular collapse as a result of severe hypotension or cardiogenic shock. It constricts renal and mesenteric vessels and may cause severe peripheral vasoconstriction. Dosage is 16 mg/L administered at the rate of 0.5 to 1 mcg/min and titrated up to 30 mcg/min IV drip in 5% dextrose in water, titrated to the desired BP; average dose range is 2 to 4 mg/min. The drug is toxic if extravasation occurs. Hypotension from hypovolemia is a contraindication.

Diuretics

Diuretics increase the amount of urine excreted. Potent diuretics are used to treat pulmonary edema and postarrest cerebral edema. They inhibit resorption of sodium. They are used with caution because they may have a direct vasodilating effect or may lead to fluid and electrolyte depletion.[8] The following two drugs are the most commonly used:

- *Furosemide (Lasix):* 0.5 to 2 mg/kg injected slowly over 1 to 2 minutes by IV push; the dose can be repeated in 2 hours
- *Ethacrynate sodium (Sodium Edecrin):* 40 to 50 mg or 0.5 to 1 mg/kg injected slowly by IV push

Vasopressors

Vasopressors exert an inotropic vasoconstriction action on arterioles and veins through stimulation of alpha-adrenergic receptors, and they increase the heart rate, BP, and myocardial contractility by activation of beta-adrenergic receptors. These drugs cause vasomotor depression of the peripheral circulation but increase coronary flow. They may increase ventricular contractile force, alter sinoatrial nodal activity, constrict smooth muscles, and dilate renal and mesenteric blood vessels. They may produce ventricular dysrhythmia, which can be intensified by hypoxia or hypercapnia. Drug effectiveness is reduced in the presence of respiratory or metabolic acidosis.

Dopamine (Intropin). In high dosages (greater than 10 mcg/kg/min IV drip), Dopamine causes peripheral vasoconstriction to increase CO and BP. It may be used during cardiogenic shock, severe hypotension, and asystole and then be titrated to the desired BP. Discontinuance should be gradual. A low dose, 1 to 5 mcg/kg/min IV drip, dilates renal and mesenteric blood vessels to maintain urinary output but may not increase the heart rate or BP. The drip rate may be increased until organ perfusion is evidenced by the BP and urinary output. Tachydysrhythmias are an indication for reduction in dose or discontinuation. Dopamine is inactivated in alkaline solution and by sodium bicarbonate. It is caustic if it extravasates. It should be diluted immediately before use.

Metaraminol (Aramine). Metaraminol produces marked vasoconstriction and increases CO and BP, which may be useful to treat severe hypotension. It may be given IV or via endotracheal tube. Dosage is 0.4 mg/min IV drip in 5% dextrose in water.

Other Vasopressors. These drugs have various actions. Selection will depend on the action needed. Drugs that may be used include the following:

- Isoproterenol (Isuprel)
- Methoxamine (Vasoxyl)

- Mephentermine (Wyamine)
- Norepinephrine (Levophed)
- Phenylephrine (Neo-Synephrine)
- Vasopressin (antidiuretic hormone)
- Dobutamine (Dobutrex, catecholamine)

Other Drugs

The foregoing list is not intended to be all-inclusive. Other drugs are used for specific problems. Life-threatening acid-base or electrolyte imbalances associated with cardiovascular or pulmonary complications may need to be corrected (e.g., after CPR). The following two drugs may be used with caution; they are not recommended for routine administration at the onset of CPR.

Calcium Salts. Calcium should be avoided unless the patient has hyperkalemia, hypocalcemia, or calcium channel blocker toxicity. It may be administered by IV bolus as calcium chloride, 2 mL of 10% (1 g/10 mL) solution repeated as necessary at 10-minute intervals; calcium gluconate, 5 to 8 mL; or calcium gluceptate, 5 to 7 mL.

Sodium Bicarbonate. Metabolic acidosis secondary to accumulation of lactic acid produced by respiratory metabolism may need to be corrected. Bicarbonate binds with hydrogen ion from lactic acid to produce carbonic acid that breaks down into carbon dioxide and water. Sodium bicarbonate may be given after other resuscitation measures to reverse acidosis. Dosage is 1 mEq/kg by IV bolus initially, titrated according to blood gas analyses for subsequent doses, usually no more than 0.5 mEq/kg at 10- to 15-minute intervals. An excessive dose can produce metabolic alkalosis. Sodium bicarbonate should not be mixed in an IV line with any other drug; it will precipitate calcium salts and inactivate catecholamines.

Cardiopulmonary Resuscitation

CPR is aimed at rapidly restoring oxygen delivery to vital organs to reverse the processes that lead to death. To prevent irreversible brain damage, resuscitative measures must be instituted immediately, within 3 to 5 minutes after the arrest. The combination of anoxia and acidosis can make restoration of normal function impossible.[9]

Resuscitation in the OR is not a one-person job. The team must be completely familiar with the preplanned routine before the necessity for its use arises. Success depends on prompt diagnosis and immediate effective treatment.[9] Outcome is directly related to the rapidity with which a functional, spontaneous heart rhythm can be restored. Patients who experience arrest in an OR may be on monitors with an IV line already in place and resuscitation equipment on hand. These arrests are referred to as *witnessed arrests*. The time of onset of arrest should be noted and the time-elapsed clock started. Basic life support is instituted at once to reestablish oxygenation and restore the heartbeat.

Basic Cardiac Life Support

Basic cardiac life support (BCLS) is that particular phase of emergency cardiac care that prevents circulatory or respiratory arrest or insufficiency through prompt recognition and intervention. BCLS can and should be initiated by any person present when cardiac arrest occurs. The process begins with chest compressions to maintain circulation of the oxygen present in the circulatory system.[5] This is referred to as *hands only* CPR. In adults the compression depth should be at least 2 inches, followed by allowing the chest to fully recoil. In infants or children the compression depth should not exceed one-third the anterior-posterior diameter of the chest.

When the arrested patient is in the OR, anesthesia providers and other team members are present. In a witnessed arrest the carotid pulse is palpated. The carotid artery is located in the groove between the trachea and muscles of the side of the neck. Palpation of the femoral artery is an acceptable option. If pulse and breathing are not immediately restored, CPR is begun.

If ventricular fibrillation or tachycardia without a pulse is evident, countershock is delivered as soon as possible (DC 200 to 300 joules delivered energy in an adult; 2 joules/kg or 1 joule/lb in an infant or child). If this is unsuccessful, additional countershocks and medications are given as ordered or per protocol. In open heart defibrillation, between 5 and 40 joules is delivered, beginning with lower energy levels.

In infants and small children a hand is placed over the precordium to feel the apical beat or the brachial pulse is checked in lieu of a carotid pulse. The brachial pulse is on the inside of the upper arm midway between the elbow and the shoulder. The index and middle fingers are used to implement chest compressions. A precordial thump is not given to an infant or child. In infants and children, bradydysrhythmias and heart block lead to cardiac arrest more commonly than does ventricular fibrillation.

Ventilation

During general anesthesia either an oropharyngeal or nasopharyngeal airway or endotracheal tube may be in place to maintain a patent air passage. Oxygen (100%) can be delivered at once under positive pressure by manual ventilation.

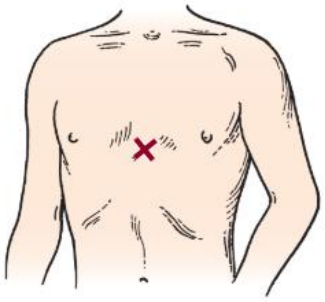
A cuffed endotracheal tube permits continuous delivery of high oxygen concentration without the hazard of stomach distention or aspiration. It facilitates adequate ventilation because with its use interposed breaths are not necessary, thereby permitting a faster, uninterrupted cardiac compression rate of 100 beats/min.[9] When ventilation is combined with cardiac compression, tissues receive oxygen. The ratio of compressions to ventilations is 30 to 2 for adult patients. In the OR the anesthesia provider manages ventilation. The following principles apply:

1. If attempts to ventilate the patient are unsuccessful despite proper opening of the airway, further attempts to remove the obstruction should be made. Laryngoscopy, cricothyrotomy, or tracheotomy may be indicated.
2. Tracheal suctioning should last no longer than 5 seconds at a time without ventilation, to prevent hypoxia.
3. If spinal injury is suspected or present, extension of the neck is avoided and a modified jaw-thrust technique is used. The head, neck, and chest are kept aligned.
4. Ventilation is assessed by seeing the chest rise and fall and hearing and feeling air escape during the patient's exhalation.

Circulation

This may be accomplished by external closed-chest cardiac compression: the rhythmic application of pressure over the lower half of the sternum above the xyphoid process (Figs. 31.4 and 31.5). Cardiac compression must be performed with knowledge and care. All physicians and patient care personnel must be trained and certified in CPR at least to the minimal BCLS level.

Because the heart occupies most of the space between the sternum and the thoracic spine, intermittent sternal compression of 2 inches raises intrathoracic pressure and produces CO. Blood is forced from the heart into the pulmonary artery and aorta. During relaxation of pressure, negative intrathoracic pressure causes venous blood to flow back into the heart from the pulmonary and systemic circulatory systems.



• **Fig. 31.4** Cross indicates correct spot to place hands for performing closed-chest cardiac compression: over lower half of sternum and above xyphoid process.

• **Fig. 31.5** Closed-Chest Cardiac Compression. Patient is supine on hard, flat surface. Resuscitator places heel of one hand over lower half of sternum with heel of other hand on top. Fingers are arched upward to avoid exerting force on ribs. Elbows are straight and locked, with shoulders straight over hands. Deliver thirty (30) compressions per two (2) breaths.

Basic principles are the same for infants and children. Differences in technique are related to the position of the heart in the chest and small chest size. The ratio of compressions to ventilation for pediatric patients is 15 to 2 in the OR.

CPR should not be interrupted for more than 5 seconds at a time except for endotracheal intubation. If intubation is difficult, the patient must be ventilated between short attempts. CPR is never suspended for more than 10 seconds, except during defibrillation (Fig. 31.6). Manual external cardiac compression causes fatigue, leading to variation in CO; therefore it is advisable to have additional relief personnel available.

Elevation of an adult's legs to a 60-degree angle aids venous return and augments circulation. Cardiac compression is successful only if the heart fills with blood between compressions and the resuscitator can move an adequate volume of oxygenated blood. The carotid or femoral pulse is checked every few minutes to indicate compression effectiveness or return of a spontaneous, effective heartbeat.

Complications of external compression are minimized by careful attention to detail. Compression must be performed with extreme caution to prevent injuries such as rib or sternal fracture, costochondral separation, fat embolism, laceration of the liver, lung contusion, pneumothorax, and hemothorax. To prevent fractures, the xyphoid process at the tip of the sternum is never compressed and pressure is never exerted on the ribs.

• **Fig. 31.6** The team in action during cardiac resuscitation.

Internal Cardiac Compression. Internal cardiac compression is instituted if the patient's chest is already open, such as during a cardiothoracic procedure. Thoracotomy may be performed and internal compression administered in instances in which external compression may be ineffective (e.g., internal thoracic injuries, such as penetrating wounds of the heart, flail chest, pericardial tamponade caused by hemorrhage, chest or spinal deformities). The advantages of internal compression are (1) more complete ventricular emptying with greater outflow of blood into the circulation and (2) rapid diastolic filling for a faster stroke rate than with external compression. Less blood flows in a retrograde manner. The disadvantages are (1) delay in compression, (2) potential trauma to the lungs and myocardium, and (3) possible infection.

Checking the Effectiveness of Cardiopulmonary Resuscitation

Signs suggestive of effective compression are constricted, reactive pupils; a palpable peripheral pulse; an audible heartbeat; and improvement in color of the mucous membranes, skin, and blood. Additional signs indicative of potential recovery are prompt return of spontaneous respiration and consciousness. Continuous compression is stopped when arterial BP remains above 70 to 90 mm Hg and a strong spontaneous pulse is resumed. CPR may be performed intermittently as necessary to assist the restored heart.

Persistent dilation of the pupils and lack of reaction to light are ominous signs usually indicative of brain damage. Cell destruction is also manifested by convulsions, hyperpyrexia, and persistent coma. Survival in relation to these symptoms is usually accompanied by tragic consequences such as decerebration or paralysis.

Advanced Cardiac Life Support

Advanced cardiac life support (ACLS) consists of definitive therapy intended to reinstitute spontaneous oxygenation. It includes BCLS, use of adjunctive equipment and special techniques for

establishing and maintaining effective ventilation and circulation, cardiac and supplemental monitoring, recognition and control of dysrhythmias, defibrillation, establishing and maintaining an IV infusion route, drug administration, and postresuscitation care. It requires the supervision and direction of a physician. It should be initiated immediately to improve long-term functional survival. Subsequent insertion of an arterial line supplies access for direct pressure monitoring and arterial blood gases. Capnography is used to measure the quality of cardiac compression and may be an indicator of returned circulation.

Intravenous Drugs

Compression is usually accompanied or followed by judicious use of drugs, administered IV, to manipulate cardiovascular variables, such as hypoxia and acidosis. These drugs may improve the patient's cardiopulmonary status by increasing the perfusion pressure during cardiac compression, stimulating spontaneous or more forceful myocardial contractions, accelerating the cardiac rate, and suppressing abnormal ventricular activity.

Oxygen, epinephrine, and atropine are the mainstays of pharmacologic management in CPR. Used in combination with basic life support, lidocaine, and defibrillation, they correct most CPR oxygen-delivery problems. Each additional drug serves as a vital adjunct in definitive therapy and postresuscitation care.

Crash Cart

An emergency arrest cart should be available at all times in all critical care areas (i.e., OR, emergency department [ED], PACU, and ICU). Specific drugs and equipment vary, depending on how well equipped the anesthesia provider is for emergencies. Equipment on a portable cart usually includes the following list:

- Oxygen and resuscitation equipment, including oxygen cylinder, tubing, mask, Ambu bag, or bag-valve-mask
- Capnography monitor
- Laryngoscope tray, blades, endotracheal equipment and tubes, assorted airways (oral and nasal), stylet, padded tongue blades
- Tracheotomy tray
- Sterile gloves, sterile gauze sponges, prep swabs, adhesive tape, tourniquets, sutures, armboard, drapes
- Suction machine, catheters, suction tips
- IV infusion solutions and sets, IV needles and catheters (14 and 16 gauge), tubing stopcocks, infusion pump, medication additive labels
- Equipment for intraosseous access
- Cutdown tray, venous cannulas, wire-guided catheters
- Assorted sterile syringes: 3, 5, 10, 20, and 50 mL
- Assorted sterile needles: 25 gauge × ⅝ inch; 20 gauge × 1½ inches; 18 gauge × 1½ inches; 20 gauge × 3 inches (intracardiac); spinal needles
- Arterial blood sampling kit with needles, heparinized syringes; arterial line tray
- Disposable scalpels, hemostats
- Emergency thoracotomy set, including scalpel with No. 20 blade, rib retractor, self-retaining retractor
- ECG monitor, leads, recording sheets
- Cardiac arrest board to provide a firm surface under the patient for compressions
- Defibrillator with paddles (adult, pediatric, external, internal), electrode jelly or paste, saline pads
- Cardiac arrest record for treatment documentation/flow sheets
- Cardiac pacemaker
- Drugs—mainly vasoconstrictors, cardiotonics, vasopressors, cardiac depressants, anticholinergics, cerebral dehydrating agents, pulmonary dehydrating agents (many frequently used emergency drugs are available in sterile, commercially prefilled syringes to avoid delay in preparation; they are routinely checked for expiration dates)
- CVP manometer
- Nasogastric tube and bulb syringe
- Flashlight and batteries for checking pupils

Personnel Responsibilities

During CPR, team members must remain calm but react quickly and act efficiently. Cardiac arrest in the OR during business hours may be more easily managed because more personnel may be on the premises. Codes after business hours are more complex and may involve minimal personnel who are required to perform multiple functions. The following outline is a suggestion of expected behaviors of team members during a code situation:

1. *Director of the code:* One person, the most knowledgeable in resuscitation efforts and patient physiology, usually the anesthesia provider, commands resuscitation efforts. He or she is assisted by surgeons, nurses, surgical technologists, and other available personnel. A cardiologist is usually summoned (if available). Resuscitation teams are multidisciplinary.

   The person in charge directs lifesaving interventions that entail minute-to-minute decisions such as medications and defibrillation. To avoid confusion the director of the code issues orders for others to follow. Every circulating nurse should be qualified and prepared to organize and assign tasks to members of the support staff in the event of cardiac arrest on the off-shifts.
2. *Circulating nurse:* Initiate the code and summon help.
   a. Start the time-elapsed clock (if available), and record the time of arrest.
      (1) Remain calm and support calmness in the team.
      (2) Documentation is performed according to facility policy. Most have preprinted code sheets.
   b. Activate the emergency alarm to alert the OR manager and summon assistance.
      (1) Several physicians and registered nurses should respond to form the code team.
      (2) Support staff should respond to become runners.
   c. Help reposition the patient as necessary into the supine position for CPR. Lower the OR bed and provide the resuscitator with a standing platform to facilitate cardiac compression. The circulating nurse must be able to perform chest compressions if an additional resuscitator is not immediately available.
      (1) Prone patient's transport cart should be immediately available.
      (2) A firm surface should be placed under patient's back.
      (3) If patient is on an irregular surface (i.e., fracture table), compressions may be difficult.
   d. Send a runner for the crash cart. Prepare necessary equipment from the crash cart, such as medications, the defibrillator, and the ECG if it is not already in use.
      (1) On the off-shift, the scrub person may have to break scrub and become the runner.
      (2) The circulating nurse remains in the room to assist the director of the code.
      (3) Record drugs, times, routes if a recorder has not been assigned.
   e. Control traffic. Exclude unauthorized personnel from the room. Students should either be instructed to stand back or enlisted to obtain supplies as able. Provide an optimal environment for successful resuscitation.

f. Help with and observe IV and monitoring lines, such as an arterial line. Assist in collection of blood samples.
g. Maintain accuracy of sponge, needle, and instrument counts and sterility to best of ability if wound closure progresses (but sterility is secondary to resuscitation efforts).
   (1) Counts may be aborted, but accountability remains important.
   (2) X-rays may be taken as patient condition permits.
h. Document all medications given, the time and amount, and the sequence of procedures performed. Documentation is important in guiding therapy and providing legal protection.
i. Supervise termination of the procedure as necessary.
   (1) Arrange for crash cart replacement.
   (2) Place restocked crash cart in the designated location for future use
j. In unsuccessful resuscitation, follow protocol regarding notification of family, care of the deceased, specimens to be saved, and forms to be filled out after a death in the OR.
   (1) Observe respect for the patient's dignity as possible.
   (2) The family may request to see the patient's body. A designated place should be available for this purpose.

3. Scrub person
   a. Remain sterile and keep the tables sterile if possible. If arrest occurs during a noncardiac surgical procedure, when the chest is not open, the surgical site is packed with saline-soaked sponges and covered with sterile drape, and the patient is repositioned as necessary for CPR. If the surgical site is in an area that can be closed rapidly during resuscitation, this may be done.
      (1) During regular business hours support staff should be the runners.
      (2) During off-shift times the support staff is minimal; it is necessary to break scrub and be the runner.
      (3) Obtain the crash cart.
   b. Keep track of sponges, needles, and instruments. Counts are completed as possible, and the surgical site is closed as soon as possible despite the outcome. In a life-threatening emergency the surgeon may order that counts be aborted. Follow the written institutional policy and procedure for counts during emergency situations.
      (1) Keep all unnecessary instruments and supplies off the field.
      (2) Push back table off to the side of the room. Move the Mayo stand away from the patient.
   c. Give attention to the field and the surgeon's needs. If the patient is hemorrhaging, keep suction tubing clear and tapes available.
   d. If the circulating nurse is performing chest compressions and no other support personnel are available, assist as required.
4. *OR manager (on duty during business hours):*
   a. Assign professional and assistive support personnel to augment the team (e.g., an extra circulating nurse, medication nurse, runners [personnel to obtain supplies or handle laboratory samples]).
   b. Notify the attending physician, if not present, and appropriate administrative personnel.
   c. Alert the ICU of a potential patient admission.
   d. Reassign subsequent patients' scheduling.
   e. Keep track of resuscitation progress.
   f. Evaluate the arrest procedure and emergency equipment; verify the documentation.
   g. Support the team as necessary. Keep the surgical suite running smoothly during the emergency. Order another fully stocked crash cart.

Duration of Cardiopulmonary Resuscitation

CPR may be done as long as necessary to restore circulatory function if adequate ventilation and a good peripheral pulse have been restored. It is not uncommon for a second arrest to occur after successful resuscitation. The time frame for survival is shortened drastically if the arrest is unwitnessed. When the patient's condition is adequately stabilized and the surgical site is closed, he or she is transferred to the ICU.

The decision to discontinue resuscitative efforts in the OR is made by a physician. The decision is based on assessment of cerebral and cardiovascular status. The end point of cardiovascular unresponsiveness is suggested as the most reliable basis for this decision.

Appropriate administrative personnel and services, such as the nursing unit, ICU, and clergy, as well as the patient's family, are notified of the cardiac arrest as required. In case of death, the surgeon notifies the family.

Postresuscitation Care

Postarrest supportive therapy depends on the cause and duration of arrest. Care centers on cardiac and cerebral preservation, maintaining circulation and ventilation, and minimizing sequelae such as cerebral edema. The patient must be carefully monitored and closely observed for 48 to 72 hours postarrest. In select patients, hypothermia may be used to reduce oxygen needs.

Vital signs, acid-base and electrolyte balances, and urinary output are closely watched. Seizures should be controlled to prevent further anoxia. The patient is observed for signs of embolism, pulmonary edema, fractured ribs caused by chest compressions, and hemopericardium. A chest x-ray is taken as soon as feasible after the arrest. An IV fluid lifeline must be left in place. If cerebral damage is evident, the prognosis is guarded.

Staff Education

Practice sessions of a cardiac arrest emergency and CPR with subsequent evaluation and revision are valuable to review the protocol and prepare the OR staff before need for implementation. Current CPR/BCLS certification for health care providers is required of all OR personnel. Many ORs require yearly BCLS review, with recertification every 2 years. ICU personnel are required to be ACLS-certified.

Fluid and Electrolyte Imbalances

Fluid and electrolyte imbalances may be caused by many different factors and may be manifested by numerous symptoms. Maintenance of correct balance, which greatly influences the outcome of surgical intervention, is a very relevant aspect of intraoperative and postoperative care.

Fluid loss is replaced by IV infusion. Usually normal saline or dextrose (5% or 10% in water or saline) solution is started initially.[8] Electrolytes may be added to the solution as needed. Two other IV solutions are commonly used to maintain balance:

1. *Mannitol:* An osmotic diuretic agent; has an effect on renal vascular resistance. Depending on the percentage of drug in solution, it can either increase or decrease renal blood flow. It may be given prophylactically to prevent renal failure. It is used also to decrease intracranial and intraocular pressure. It is rapidly excreted by the kidneys.

2. *Ringer's lactate solution:* A physiologic salt solution; may be infused when the body's supply of sodium, calcium, and potassium has been depleted or for improvement of circulation and stimulation of renal activity. Its electrolyte content is similar to that of plasma.

Changes in fluid and electrolyte balances affect renal function, cellular metabolism, and oxygen concentration in the circulation.[8]

Acid-Base Balance

For enzyme systems to function, a normal balance must be maintained between acidity and alkalinity of body fluids located within intracellular and extracellular compartments. The symbol pH represents the hydrogen ion concentration that determines acidity or alkalinity of a solution; neutral pH is 7, below 7 is acid, and above 7 is alkaline. Urine is usually acid, with a pH range between 4.6 and 8. Normal serum pH is 7.40, within a range of 7.35 to 7.45.

Hydrogen ions do not exist as separate electrolytes in body fluids but are maintained in balance with other electrolytes to ensure neutrality. Because most metabolic processes produce acids, chemical buffers interact with hydrogen ions. Carbonic acid and a hydrogen ion form bicarbonate (HCO_3)—the most important buffer. The kidneys and lungs regulate this system by excreting or retaining needed ions in body fluids. Abnormal acid-base balance results from the following factors:

1. Respiratory malfunction in handling carbon dioxide produced from carbonic acid
   a. *Acidosis:* pH less than 7.35 with carbon dioxide above 45 torr
   b. *Alkalosis:* pH more than 7.45 with carbon dioxide below 35 torr
2. Metabolic abnormality in balance between hydrogen and serum HCO_3
   a. *Acidosis:* pH less than 7.35 with HCO_3 less than 22 mEq/L
   b. *Alkalosis:* pH more than 7.45 with HCO_3 more than 26 mEq/L

Electrolytes

Compounds that separate into ions, which are charged particles capable of conducting electrical impulses, are essential in maintaining fluid and acid-base balance and regulating cell functions. The primary electrolytes in the body (Table 31.1) are as follows:

1. *Sodium:* A key regulator in water balance, sodium is necessary to the normal function of muscles and nerves. Large amounts are in extracellular fluid in concentrations of 136 to 145 mEq/L; intracellular concentration is 10 mEq/L. This balance is necessary for normal metabolism.
   a. Hyponatremia (insufficient serum sodium) usually accompanies excessive fluid loss or adrenal insufficiency. Muscle twitching, hypovolemia, hypotension, and tachycardia may be symptoms.
   b. Hypernatremia (elevated serum sodium) may be caused by hyperglycemia or administration of mannitol. Diaphoresis (sweating) may be the only obvious symptom. Convulsions can occur.
2. *Chloride:* Essential to electrochemical reactions for acid-base regulation, chloride is in extracellular fluids in large amounts. Chlorides are retained or excreted by the kidneys to offset HCO_3 excretion. Sodium tends to carry chloride with it.
   a. Hypochloremia (loss of chloride) may occur from vomiting, suctioning, sweating, and diuresis. It produces symptoms of metabolic alkalosis: slow, shallow respirations and muscle tightening.
   b. Hyperchloremia (excessive chloride) can result in renal failure. Acidosis develops, and breathing becomes labored.
3. *Potassium:* One of the main constituents of cell protoplasm, potassium is primarily (98%) in intracellular fluid. It is essential for electrochemical reactions for cellular functions.
   a. Hypokalemia (shift of potassium from the blood to the cells or depletion of potassium from the body) can be associated with metabolic alkalosis. Cardiac dysrhythmias can occur when the serum potassium level falls.
   b. Hyperkalemia (increase in serum potassium) may be caused by renal failure and may lead to respiratory and/or cardiac arrest. Metabolic or respiratory acidosis can occur.
4. *Calcium:* Essential to normal muscle physiology, calcium also is an integral part of the blood-clotting mechanism.
   a. Hypocalcemia (decreased calcium intake or absorption) may be a result of increased excretion. This can cause cardiac dysrhythmias.
   b. Hypercalcemia (increased serum calcium) may be a result of a shift of calcium from the bones to plasma, decreased excretion, or increased uptake and absorption. It causes neuromuscular depression and cardiac dysrhythmias.
5. *Magnesium:* Essential to electrochemical reactions for normal body functions, magnesium is primarily in intracellular fluid. An imbalance may be accompanied by calcium and/or potassium imbalances.
   a. Hypomagnesemia (low magnesium level) usually is associated with hypokalemia. This may be the most undiagnosed electrolyte deficiency in geriatric patients or those who have illnesses associated with malabsorption in the intestine or kidneys. It may cause cardiac dysrhythmias and nervous system and muscular irritability, and it may exaggerate drug toxicities.

TABLE 31.1 Normal Blood Chemistry Laboratory Values

Parameter	Normal Values for Adults
Alanine aminotransferase (ALT)	10-35 international units/L
Aspartate aminotransferase (AST)	4-36 international units/L
Base excess of blood	0 ± 2 mmol/L
Bicarbonate (HCO_3)	22-26 mEq/L
Bilirubin (total)	0.1-1 mg/dL
Blood urea nitrogen (BUN)	5-20 mg/dL
Calcium (Ca)	9-10.5 mg/dL
Carbon dioxide (CO_2) in serum	23-30 mEq/L
Chloride (Cl)	90-110 mEq/L
Creatinine	0.7-1.5 mg/dL
Creatine phosphokinase (CPK)	12-80 units/L
Glucose	70-115 mg/dL
Magnesium (Mg)	1.6-3 mEq/L
pH of serum	7.35-7.45
Phosphate (P)	2.5-4.5 mg/dL
Potassium (K)	3.5-5 mEq/L
Sodium (Na)	136-145 mEq/L

   b. Hypermagnesemia (elevated serum magnesium) can inhibit nerve and muscle responses. It may lead to respiratory depression and cardiac arrest.
6. *Phosphate:* Normally in intracellular fluid, phosphate allows electrochemical reactions for metabolic functions. Phosphate and calcium vary inversely; thus phosphate will buffer acidosis from a rising calcium level.
   a. Hypophosphatemia (low serum phosphate level) may produce tissue hypoxia.
   b. Hyperphosphatemia (increase in phosphate) usually occurs in renal failure. It is associated with hypocalcemia.

Disturbances in fluid and electrolyte balance can result from:

- *Acid-base imbalances associated with chronic disease or organ dysfunction:* Acidosis increases serum chloride, potassium, and calcium; alkalosis decreases chloride, potassium, calcium, and phosphate.
- *Cell destruction leading to hyperkalemia:* Cellular potassium is depleted, with serum potassium increase.
- *Shift of potassium from blood into cells, causing hypokalemia:* This may be caused by the effects of epinephrine, insulin, bicarbonate, hypothermia, or cardiopulmonary bypass.
- *Changes in blood lipids:* Calcium and magnesium are depleted by poor absorption.
- *Fever:* Metabolic rate is increased; water and electrolytes are lost.
- *Stress:* Glucose tolerance is diminished, and blood glucose and serum potassium levels are increased.
- *Gastric drainage:* Sodium and chlorides are lost.
- Fluid loss from drainage tubes, diaphoresis, vomiting, or diarrhea: Sodium, chloride, and potassium are lost.
- *Maxillofacial injury:* Oral intake is inhibited.
- *Radiation enteritis:* Magnesium and potassium are diminished.
- Disease of the bowel, liver, or biliary tract; intestinal tract obstruction; or gastrointestinal fistula: Calcium and phosphate are poorly absorbed.
- Loss of muscle mass as a result of preoperative malnutrition: Nitrogen loss is increased.
- *Drugs:* Metabolic balance can be adversely affected; losses of potassium, magnesium, and chloride from diuretics are examples.
- Inadequate oxygen/carbon dioxide exchange: Acid-base balance is disrupted.

Hypovolemia

Hypovolemia is a decreased circulating blood volume from loss of blood and plasma or a deficit of extracellular fluid volume commonly referred to as *dehydration*. When excessive fluid loss is greater than absorption of interstitial fluid into the circulation, the patient may go into hypovolemic shock.

Etiology

Etiologic factors include reduced fluid intake, hemorrhage, plasma loss (e.g., through extensive burns, wound drainage), and dehydration from loss of gastrointestinal fluids (e.g., by vomiting), or diaphoresis (caused by fever, from diuresis). Impaired renal function and metabolic acidosis are predisposing factors. Prolonged cardiopulmonary bypass can cause hypovolemic shock.

Signs and Symptoms

Signs and symptoms include dry skin and mucous membranes; depressed BP; elevated pulse; oliguria; decreasing CVP and blood volume determinations; and deep, rapid respirations.

Treatment

Hypovolemic shock resulting from hemorrhage or underestimated blood loss is most often seen in the OR. This is usually reversed by prompt restoration of circulating blood volume. The extent of hypovolemia will determine treatment, which may include the following:

1. *Fluid volume replacement:* Whole blood, plasma expander, or infusion of lactated Ringer's solution or other IV fluid is indicated to increase blood volume. Hypervolemia must be avoided in replacement.
2. *Position:* Elevation of the legs may aid venous return and CO except in severe oligemia (low total blood volume [TBV]).
3. *Temperature:* The patient is kept warm but not overheated. Perspiration increases fluid loss. Shivering can cause hypothermia.
4. *Oxygen:* Oxygen is administered when PO_2 is low because the circulation is not delivering enough oxygen to tissues.
5. *Drugs:* Drugs are administered as needed to maintain BP, correct acidosis, or protect the kidneys from failure.

Prevention

Decreased blood volume, if present preoperatively, increases surgical risk and morbidity. It should be treated, and the electrolyte imbalance should be corrected. Fluids, blood gases, and blood loss must be monitored intraoperatively.

Hypervolemia

Hypervolemia is an excess of extracellular fluid in the blood, commonly referred to as *fluid overload* and *edema*. IV infusions given too rapidly or in excessive amounts, especially isotonic saline solution, can cause hypervolemia. Prolonged administration of adrenocorticosteroids is also a predisposing factor. Hypervolemia may progress to pulmonary edema.

Dyspnea, coarse crackles, an elevated pulse and respiratory rate, and diminished urinary output are symptomatic of hypervolemia. Increasing CVP may indicate fluid overload with venous distention. Diuretics and fluid restriction ameliorate hypervolemia and prevent pulmonary edema.

Blood Volume Complications

Blood Loss Considerations

Some blood loss is inevitable whenever tissues are severed by intent or traumatic injury. Blood loss is computed as a percentage of total blood volume (TBV). TBV averages from 6% to 8% of total body weight. This equals about 75 mL/kg in the average healthy adult man and 60 to 70 mL/kg in the average woman. Calculation of TBV depends on the venous hematocrit value. Normal hematocrit, the volume of red blood cells expressed as a percentage of the volume of whole blood, is 42% to 52% in men and 37% to 47% in women. An infant reaches these blood volume levels at approximately 3 months of age.

An increase in hematocrit indicates a decrease in plasma volume, normally by dehydration and loss of sodium. A decrease in hematocrit indicates a decrease in the number of red blood cells, but this does not necessarily reflect blood loss; it may be caused by overhydration. Fluid and electrolyte balance are important for maintenance of blood volume. Inadequate fluid replacement can lead to a decrease in CO and cardiovascular collapse.

A decrease in red blood cells (erythrocytes) and in hemoglobin, the chief oxygen-carrying component of these cells, causes hypoxia

TABLE 31.2 Normal Values of Blood[a]

	Males	Females	Children
Red blood cells (RBCs)	4.7-6.1 million/mm^3	4.2-5.4 million/mm^3	3.8-5.5 million/mm^3
Hemoglobin (Hgb)	14-18 g/dL	12-16 g/dL	11-16 g/dL
Hematocrit (Hct)	42%-52%	37%-47%	31%-43%
Prothrombin time (PT)	11.0-12.5 seconds	Same	Same
Platelets	150,000-400,000/mm^3	Same	Same after 1 week of age
Partial thromboplastin time (PTT)	30-40 seconds	Same	25-35 seconds

[a]Values vary depending on calibration of testing equipment in the laboratory that services the health care facility.

if values fall below normal (Table 31.2). Therefore determination of intraoperative blood loss may be critical to physiologic functions.[10] The extent of blood loss will depend on the location and magnitude of the surgical procedure. Blood loss can be categorized as follows:

- *Minor:* Loss of 500 to 700 mL is about 15% of TBV.
- *Moderate:* Loss of 750 to 1500 mL is about 15% to 30% of TBV. A resultant decrease in pulse pressure and slight tachycardia (rapid heart rate) may progress to tachycardia, tachypnea (rapid breathing), and postural hypotension (reduced BP on position change).
- *Major:* Loss of 1500 to 2250 mL is about 30% to 45% of TBV. The BP drops, the skin becomes cold and clammy, and urinary output decreases.
- *Catastrophic:* Loss of more than 2250 mL is greater than 45% of TBV. Hypoxia (decrease in oxygen level) develops from loss of hemoglobin (red blood cells). Prolonged hypoxia leads to irreversible heart, brain, liver, and kidney damage.

Hemorrhage

Severe bleeding into or from a wound is a major contributing factor to intraoperative and postoperative morbidity and mortality. If bleeding is uncontrolled, exsanguination can occur. Massive hemorrhage may cause hypovolemic shock, ventricular fibrillation, or death as a result of marked decrease in CO. Common symptoms are arterial hypotension, pale or cyanotic moist skin, oliguria, bradycardia from hypoxia or tachycardia after moderate to marked blood loss, restlessness, and thirst in the conscious patient.[10]

In the OR, hemorrhage is readily visible. Meticulous hemostasis during every step of the surgical procedure and good nutritional status of the patient preoperatively are crucial to prevention. Preoperative evaluation of the patient's clotting time and history of bleeding (personal and familial), type and crossmatch of blood, and insertion of an IV line before incision are necessary precautions. In treating hemorrhage the surgeon locates the source of bleeding and applies digital compression to severed or traumatized blood vessels until noncrushing vascular clamps can be placed to occlude the vessel proximal and distal to the site of bleeding. The vessel is then ligated, clipped, electrocoagulated, or sutured. Circulating blood volume must be restored promptly.

If allogeneic blood is transfused, it must be fresh and warmed to limit electrolytic changes. Sodium bicarbonate may be given IV to reduce acidosis. Multiple IV infusion routes can be used, by cutdown if necessary, to infuse blood under pressure.[10] Lactated Ringer's solution or other plasma expanders are used when blood is contraindicated (e.g., for religious reasons). Oxygen is administered to combat hypoxia. Accurate measurement of blood and fluid losses intraoperatively, followed by adequate replacement, will help prevent hypovolemic shock. Autotransfusion may be feasible.

Hemorrhage can be detected postoperatively by observation of blood-soaked dressings. The patient must be checked frequently for both observable and nonobservable symptoms of hemorrhage. Slipping or sloughing of a ligature or the passage of clots from ligated or coagulated vessels can cause internal bleeding.

Estimation of Blood Loss

An accurate determination of TBV involves measuring plasma and red blood cell volumes separately and then adding these values together. This may be done rapidly by an electronic counting device. In lieu of this, blood loss is estimated in all surgical procedures in which a major loss is anticipated. This can be done by the following steps:

- Visual inspection of blood on drapes and the floor by the anesthesia provider.
- Estimation of blood in the suction container. Allowance must be made for the presence of other body fluids and irrigating solution, if used. The scrub person must estimate the amount of solution suctioned into the container through irrigation of the wound and/or tubing. This can be done by knowing the capacity of the irrigation syringe in use and keeping track of the number of times it is used. The circulating nurse subtracts these amounts to estimate the volume of blood in the container.
- Visual inspection of blood in sponges by the anesthesia provider.
- Measurement of blood in sponges by weighing them. Sponges are weighed after use as they are discarded from the surgical field.

Weighing Sponges

Some anesthesia providers and surgeons prefer to have sponges weighed to determine blood loss rather than visually estimating the loss (Box 31.1). A scale calibrated in grams is used. The dry and wet weights of each type of sponge must be known. Wet weight is that of a sponge soaked in normal saline solution and wrung out until almost dry. A chart of these weights should be available; often it is attached to the scale. The number of sponges being weighed is multiplied by the appropriate dry or wet weight.

Each type must be weighed separately, with the dry sponges separated from the wet ones. To allow for (i.e., by subtracting) dry

• BOX 31.1 Weighing Surgical Sponges

Use a scale that measures in grams. Always wear personal protective equipment (PPE). This method helps subtract the weight of the actual sponges and the container they are weighed in. One gram of weight equals one millimeter of blood (1 g = 1 mL).

Weighing Dry Sponges

1. Obtain a small plastic sponge basin and one pack of each type of sponge used for the procedure.
2. Weigh a complete unwrapped complement of each type of sponge in the plastic sponge basin (e.g., 10 unwrapped Raytec, 5 unwrapped laparotomy sponges of the correct size).
   - *Raytec:* Place the open pack of dry Raytec in the plastic sponge basin on the scale and set the dial to zero. This will account for the weight of the sponges and the basin without the blood.
   - Remove the dry sponges from the plastic basin and set aside.
   - Place the counted bloody sponges into basin.
   - Take the weight reading. The number of grams of weight is recorded.
   - *Laparotomy sponges:* Place the open pack of dry laparotomy sponges in the plastic sponge basin on the scale and set the dial to zero. This will account for the weight of the sponges and the basin without the blood.
   - Remove the dry sponges from the plastic basin and set aside.
   - Place the counted bloody sponges into the basin.
   - Take the weight reading. The number of grams of weight is recorded.

Weighing Sponges Premoistened with Saline

Repeat the previous steps with the following changes:

1. Dip the complete set of dry Raytec or laparotomy sponges into water and wring out all excess liquid. This will simulate the dampening of the sponges with the sterile saline.
2. Place the damp set into the plastic basin and set the dial on the scale to zero. This accounts for the weight of the damp sponges and the container.
3. Remove the moist sponges and replace them with the same number and type of bloody sponges.

or wet weights and the weight of a moisture-proof cover on the scale platform or a container, the scale is adjusted to register at zero. When blood-soaked sponges are weighed, the reading on the scale equals the blood loss; 1 g equals 1 mL. The scale is checked at each use for readjustment to zero. Some scales are controlled by a microprocessor that automatically makes calculations.

The circulating nurse must weigh sponges before they dry out. Blood loss is recorded each time sponges are weighed, adding new weight to previous ones to keep a current total. A tally board for this purpose may be mounted on the wall where the anesthesia provider and surgeon can read it. The estimated blood in the suction container can be recorded here also. Irrigation solutions used for moistening sponges should be carefully measured and documented.

Reduction of Blood Loss

When significant bleeding can be anticipated, several techniques are used to reduce red blood cell loss during the surgical procedure or eliminate blood transfusion requirements.

Hemodilution

Acute normovolemic or isovolemic hemodilution reduces red blood cells but maintains normal or equal blood volume. After induction of anesthesia, a physician, usually the anesthesia provider, withdraws blood through an arterial or venous catheter. The blood is drawn into bags containing anticoagulant, usually citrate. Citrate metabolizes rapidly, thus minimizing the risk for systemic anticoagulation when blood is reinfused. The amount withdrawn depends on the anticipated blood loss and the patient's estimated TBV and hematocrit.

A plasma volume expander is given by IV infusion while blood is removed, to restore blood volume. This hemodilution technique reduces red blood cell loss during the surgical procedure because the hematocrit has been lowered. The surgical procedure begins when the hematocrit is between 27% and 30%. Adequate intravascular volume and oxygenation are maintained. Urinary output must be measured.

Each bag of blood must be labeled with the patient's name and identifying number and the time of withdrawal. Blood may be stored at room temperature for 6 hours or in a refrigerator for 24 hours. At the conclusion of the surgical procedure, or sooner if indicated, the blood is reinfused IV to raise the hematocrit back to the preoperative level. Units are reinfused in reverse order of withdrawal (i.e., last one first) so that the unit with the highest concentration of red blood cells and coagulation factors is infused last. (More information is available at the website of the American Association of Blood Banks, www.aabb.org.)

Blood Volume Expanders

Crystalloid or colloid solutions are administered IV for fluid replacement and plasma volume expansion. They are not the sole replacements for blood loss. They must be used with caution. The following list comprises the most commonly used plasma volume expanders.

- *Dextran:* This crystalloid polymer of glucose acts by drawing fluid from tissues to decrease blood viscosity. It remains in circulation for several hours. It interferes with the crossmatching of blood; thus a blood sample for this purpose must be drawn before dextran is infused. It may be used until blood or blood products are available or for hemodilution. As a 6% or 10% solution, it may be mixed in water with glucose or sodium chloride.
- *Lactated Ringer's solution:* This crystalloid physiologic salt solution is infused for the improvement of circulation and stimulation of renal activity and in patients in whom the body's supply of sodium, calcium, and potassium has been depleted.
- *Hetastarch (Hespan):* This colloid polymer expands plasma volume slightly in excess of the volume infused. It approximates the action of serum albumin. Large volumes may alter coagulation factors. It can be used for hemodilution.

Pharmacologic Agents

The action of specific pharmacologic agents either stimulates or retards the coagulation mechanism. This action may reduce blood loss and help provide hemostasis in patients with hematologic disorders. Some of these disorders are associated with cardiovascular disease or end-stage renal disease. Others are congenital or acquired coagulopathies. Three types of agents affect bleeding.

Desmopressin Acetate

Desmopressin promotes hemostasis in patients with von Willebrand disease and shortens the bleeding time in patients with uremia. When given prophylactically, this synthetic vasopressin analog can decrease surgical blood loss in patients undergoing spinal surgery and reduce blood loss after cardiac surgery.

Vasodilators

Vasodilators lower systemic BP, thus decreasing bleeding. Sodium nitroprusside, nitroglycerin, and trimethaphan are the most commonly used.

Anticoagulants

Anticoagulants minimize the tendency of blood to clot, yet do not lead to excessive bleeding during or after the surgical procedure. These agents provide adequate anticoagulation with a minimum of hemorrhagic complications. They help prevent venous stasis to reduce the incidence of DVT and PE. They may be given orally (PO), subcutaneously (SQ), or IV, beginning preoperatively, especially in patients who have a history of thromboembolic disease. The action of each anticoagulant is different and is described as follows:

- Heparin acts to inhibit conversion of prothrombin to thrombin. This prolongs clotting time. It may be administered SQ to keep activated partial thromboplastin time in the high-normal range between 30 and 40 seconds. Given IV, heparin is effective immediately. It may be used as a flush to keep IV lines open or to flush the lumen of a blood vessel (1 mL of heparin in 100 mL of normal saline solution). Heparin does not dissolve a thrombus, but it will prevent a clot from becoming larger.
- Coumarin derivatives depress blood prothrombin and decrease the tendency of blood platelets to cling together, thus decreasing the normal tendency of blood to clot. They also interfere with action of vitamin K to prevent the synthesis of prothrombin and fibrinogen. Warfarin sodium is the most commonly used coumarin derivative.
- Low-molecular-weight dextran reduces platelet adhesiveness and aggregation to prevent sludge from forming in the bloodstream. It coats blood platelets to keep them from massing together.
- Aspirin diminishes clumping of platelets by inhibiting the release reaction of platelet factors and action of vitamin K.

Vitamin K enables the liver to produce clotting factors in blood, including prothrombin. To reduce the possibility of intraoperative hemorrhage, patients who have been receiving anticoagulant therapy and those who have faulty metabolism or absorption of vitamin K are given it preoperatively. It also is given to geriatric or debilitated patients before intraocular surgery, to newborns preoperatively, and to mothers just before delivery. The latter helps prevent postdelivery hemorrhage and ensures that the baby has an adequate prothrombin level until a sufficient amount is produced by the liver.

Hypotensive Anesthesia

In selected situations in which excessive blood loss is anticipated or encountered, arterial BP may be deliberately lowered to produce an essentially bloodless field. When induced, hypotension is carefully controlled by the anesthesia provider.

Hematologic Disorders

Some hemolytic and hemorrhagic disorders require special consideration during perioperative care to minimize risks of surgical intervention. Concern is for the maintenance of adequate tissue perfusion and oxygenation and for hemostasis and coagulation in patients at risk. Patients at risk for intraoperative bleeding or who have a known hematologic disorder should have a complete blood count, complete blood chemistry panel, and urinalysis done preoperatively. Hemoglobin, hematocrit, and red blood cell counts are critical determinants for blood replacement requirements preoperatively and intraoperatively.[10] Precautions can be taken to minimize the risks of surgical intervention with adequate blood replacement.

Anemia

Anemia is a symptom of a deficiency in either the quantity or quality of red blood cells (erythrocytes). Hemoglobin, the chief component of these cells, delivers oxygen to tissues. Normal hemoglobin values are 14 to 18 g/dL of blood in males, 12 to 16 g/dL in females, and 11 to 16 g/dL in children. These values are lower in anemic patients. Thus anemia may result in tissue hypoxia. The various types of this disorder may be caused by the following factors:

- Blood loss from massive bleeding (e.g., from a traumatic injury) or chronic blood loss (e.g., from a gastric or intestinal ulcer): This blood loss can be replaced by transfusion of blood products.
- Dietary deficiency of sufficient iron, protein, vitamins, and minerals to form red blood cells or produce hemoglobin: Dietary supplements are given to correct the deficiency.
- Diseases or drugs that inhibit the bone marrow from producing blood cells, such as tumors or chronic renal disease: The cause must be diagnosed and treated.
- Destruction of red blood cells (**hemoglobinopathy**) by an overactive reticuloendothelial system in the spleen or liver: A splenectomy may be indicated for hypersplenism or hereditary spherocytosis, for example.
- Destruction of red blood cells by foreign substances entering the circulatory system (e.g., through an incompatible blood transfusion): Neonatal anemia may necessitate an exchange transfusion.
- Abnormal blood cells produced by the bone marrow: These are usually caused by genetic or hereditary factors.
- Myelodysplastic syndromes in which the bone marrow fails to produce blood cells in sufficient numbers: Bone marrow suppression can be the result of disease or treatment of disease. Some patients have the genetic disposition for bone marrow failure known as trisomy 8 that develops in the older adult. It is manifest by low hemoglobin concentration, marked decrease in red cells, and significantly low platelet formation.

The average normal life span of red blood cells is 120 days. In patients with any one of the many forms of hemolytic anemia, red blood cells have a shortened life span. Hemolytic anemias may be acquired or inherited. All must be adequately assessed preoperatively.

Sickle Cell Hemoglobinopathies

A severe, chronic, inherited hemolytic disorder, sickle cell anemia is most prevalent among blacks of African descent. It may be found in other ethnic groups, particularly people of Mediterranean descent. Pairing of identical abnormal recessive genes causes substitution of a single amino acid for glutamic acid in the polypeptide chain, which alters the hemoglobin. These abnormal cells, known as hemoglobin S, become distorted in shape when exposed to low oxygen tension in the venous circulation. Dehydration, cold, infection, and physical or emotional stress may precipitate crisis periods that vary in duration and intensity when sickling occurs.

A crisis may also occur spontaneously without apparent cause. The resultant sickle-shaped red blood cells occlude the microcirculation through the capillaries, arterioles, and venules. Occlusion results in blood stasis, hypoxia, vasospasm, ischemia, and necrosis, which cause pain and ultimately permanent damage to tissues and organs. Stasis ulcers and biliary tract disease are common complications that may require surgical intervention. Elective surgical procedures are performed when the patient is not in crisis, but these patients are always at risk for crisis.

Sickle cell trait is present when one abnormal gene is inherited. The red blood cells have both hemoglobin A (normal) and hemoglobin S (sickle cell). People with this trait usually are asymptomatic and tolerate routine anesthesia and surgical intervention well. However, when they are stressed by hypothermia, acidosis, or

hypoxemia, local or regional sickling can occur during the surgical procedure. Sickle cells have a life span of 15 to 30 days.

The severity of the hemolytic process is proportional to the amount of hemoglobin S in the blood. Hemoglobin in patients with sickle cell anemia usually ranges from 6 to 9 g/dL, with a hematocrit of 25% to 30%. Patients of African descent and other susceptible people should be tested preoperatively. Electrophoresis is the standard laboratory test for hemoglobin S. Consideration must then be given to the following in the perioperative management of patients with sickle cell anemia or sickle cell trait:

1. Transfusion of whole blood, packed cells, or low-molecular-weight dextran may be administered preoperatively, especially if the patient's hemoglobin is 5 g or less.
2. Urea may be given PO or IV prophylactically to prevent a sickle cell crisis. It also may be used to reverse a crisis.
3. Systemic antibiotics are initiated preoperatively, because these patients are susceptible to postoperative infection.
4. Normal body temperature must be maintained. Any lowering increases the requirement for oxygen. The patient must be kept warm to avoid hypothermia.
   a. Add extra blankets during transport to the OR suite.
   b. Avoid drafts from the air-conditioning system in the holding area, OR, and PACU.
   c. Cover the patient's head for warmth.
   d. Raise the temperature in the OR to 80° F to 85° F (27° C to 29° C).
   e. Place the patient on a hyperthermia blanket on the OR bed.
   f. Monitor the patient's temperature intraoperatively with an electronic probe.
   g. Place warm blankets over the patient before transfer to the PACU.
5. Oxygen is administered during induction of anesthesia, intraoperatively, and after extubation to prevent deoxygenation of the sickle cells and subsequent ischemic infarction in tissues.
6. Blood gases are monitored to avoid hypoxia, acidosis, hypotension, and hypovolemia. Fluid and blood replacement intraoperatively reduces the risk for crisis from dehydration.
7. Scheduling an elective surgical procedure early in the morning minimizes dehydration after a period of nothing by mouth (NPO).

Hemorrhagic Disorders

Patients with a disorder in the mechanism of blood coagulation have abnormal bleeding tendencies. These may be related to the following:

- Hemorrhagic diseases, such as a type of purpura in which spontaneous bleeding occurs under the skin, through mucous membranes, or in the gastrointestinal tract, that is idiopathic (cause unknown) or secondary to a systemic or an infectious disease or to exposure to chemical agents
- Platelet deficiency in the blood, such as thrombocytopenia as a result of decreased production of platelets by bone marrow or excessive destruction of platelets in the peripheral circulation
- Abnormal clotting factors, such as in hemophilia and von Willebrand disease, which are inherited genetic disorders

A baseline of blood values should be established preoperatively. The baseline consists of a complete blood count, including platelets, plasma clotting time, bleeding time, prothrombin time, and partial thromboplastin time. Adequate blood replacement of the deficient factors must be available during the surgical procedure and postoperatively.

Hemophilia

The term *hemophilia* refers to a group of genetic bleeding disorders characterized by abnormal clotting factors.

Hemophilia A, the classic disorder, is caused by a deficiency of functional factor VIII, the antihemophilic globulin in plasma. Hemophilia B, also known as Christmas disease, is caused by a lack of functional factor IX—the plasma thromboplastic cofactor. A carrier mother transmits to her son this sex-linked recessive trait of the specific clotting factor. Hemophilia occurs most commonly in males of Russian-Jewish descent.

The severity of the disorder depends on the percentage of functional versus nonfunctional factor in the blood. Partial thromboplastin times or thromboplastin generation times are the standard tests for this determination. These patients have normal vasculature and platelets (150,000 to 400,000/mm^3 of blood); thus bleeding time (1 to 3 minutes by the Duke method) and prothrombin time (11 to 12.5 seconds) test results are normal.

Severely affected hemophiliacs have spontaneous bleeding episodes into the skin, muscles, and joints, most commonly the ankles, knees, wrists, and elbows. If untreated, joint deformities can result. Bleeding will be excessive from even a minor wound such as a bruise or cut.

For hemostasis during a severe bleeding episode, replacement therapy must be initiated to raise the clotting factor to between 60% and 100% (normal individuals have clotting factor levels of 60% to 120%). In hemophiliacs, fibrin clots do not form and bleeding continues. The missing clotting factor must be raised temporarily to control hemorrhage. This is started preoperatively for elective surgery. Concentrates available for replacement therapy include the following:

1. Factor VIII for hemophilia A
   a. Lyophilized concentrate products, such as Hemofil CT and Koate HT or HS reconstituted with diluent provided by the manufacturer
   b. Cryoprecipitate
   c. Fresh-frozen plasma or concentrate
2. Factor IX for hemophilia B
   a. Lyophilized concentrate products, such as Konyne and Profilnine reconstituted with diluent provided by the manufacturer
   b. Fresh-frozen plasma
3. Lyophilized concentrate with inhibitors to neutralize the antibody that prevents clotting

Lyophilized concentrates are made from pooled normal human plasma obtained by plasmapheresis, a process of separating red blood cells by centrifugation. The circulating nurse should obtain factor concentrate from the blood bank and must be familiar with how to prepare it. The dosage for factor deficiency is calculated on the basis of the plasma volume, half-life of the factor, and percentage of the deficit. It is given by IV infusion intraoperatively and postoperatively.

Blood Loss Replacement

Despite meticulous hemostasis and methods to reduce blood loss, blood replacement is necessary during many extensive surgical procedures, particularly cardiovascular, orthopedic, organ transplantation, and trauma surgery. Surgeons limit the use of transfused blood whenever possible. However, to compensate for blood loss of more than 1200 mL or a hematocrit value below 30% and to prevent shock, transfusions of whole blood, fresh-frozen plasma, packed red blood cells, platelets, serum albumin,

or blood substitutes must be carried out according to policy. Transfusions may be allogeneic, autologous, or a blood substitute. Informed consent should be obtained before blood loss replacement methods are selected.

Allogeneic Blood

Allogeneic blood is that drawn from one individual for transfusion into another. It must be compatible (i.e., not cause a reaction). Therefore blood typing and crossmatching are essential to determine compatibility between donor and recipient. The four main blood types are A, B, O, and AB. In addition, many subgroups of antigens exist in red blood cells. Also, agglutinogens, known as Rh factor, may be present (i.e., Rh positive or negative). If these are not present in red blood cells, the blood is Rh negative.

A recipient must receive donor blood of the same type and Rh factor. In extreme emergency situations, O-negative blood, referred to as universal donor blood, may be given until the patient's blood can be typed and crossmatched or until compatible blood can be obtained. Conversely, type AB is considered to be the universal recipient, being compatible with A, B, O, and AB.

A transfusion of the wrong blood type can be fatal. Transmission of hepatitis B or C, human immunodeficiency virus (HIV), and other viruses and infections is a potential danger, even with current testing of all donor blood. According to the American Association of Blood Banks, in 1998 the Transmissible Spongiform Encephalopathy Advisory Committee of the U.S. Food and Drug Administration (FDA) recommended deferral of potential donors who have traveled to or resided in the United Kingdom. This exclusion is intended to prevent the risk for new-variant Creutzfeldt-Jakob disease (nvCJD) transmission. Other diseases that require deferral of blood donation include the following:

- Syphilis
- Hepatitis B, C
- HIV
- Human T-lymphotropic virus (HTLV) 1 and 2
- Cytomegalovirus (CMV)
- Malaria
- Babesiosis
- Toxoplasmosis
- Chagas' disease
- Lyme disease
- Creutzfeldt-Jakob disease (and patients who have had injections of human pituitary hormone or human dura mater tissue implants)

Consequently, because of many transmissible disease subjects, many patients prefer "directed donors." When blood replacement is anticipated before a surgical procedure, a family member or friend with a compatible blood type can be asked to donate blood to be held in the blood bank for the patient. Directed donations are not necessarily safer than nondirected voluntary donations supplied from the blood bank, however.

When multiple units of blood must be transfused, packed cells, fresh-frozen plasma, and platelets usually are given to supplement units of whole blood. These components are not part of whole blood replacement.

All established measures must be strictly observed for the patient's safety. The following basic rules apply to the transfusion of all allogeneic blood products:

1. Blood products are obtained from the blood bank by a person responsible for signing them out to a specific patient.
2. To have blood nearby, a refrigerator with controlled temperature may be installed in the OR suite. Blood products for transfusion are kept at a constant temperature between 34° F and 43° F (1° C to 6° C), verified by a recording thermometer on the outside and a standard one inside. Both audible and visible alarms are activated if a dangerous temperature is reached. Fluctuations in temperature cause red blood cells to deteriorate.

   Microorganisms can multiply in unrefrigerated blood. If blood is brought into the OR and then not needed, it should be returned immediately to the refrigerator in the suite or blood bank. Do not allow whole blood or its derivatives to stand unrefrigerated in the OR. Before use, each blood product should be checked for the expiration date. Each product has a specific shelf life (Table 31.3).
3. Blood products are administered by a physician or nurse after a careful comparison of the label on the bag with the identity of the patient. A second professional person confirms the data. The label stays on the container while the blood product is being transfused.
4. Cold, refrigerated blood may induce hypothermia. Blood should be warmed as it is transfused by immersion of administration tubing in a controlled water bath or through coils in a temperature-modifying device. The temperature must be maintained between 89° F and 105° F (32° C to 41° C). Hemolysis may occur if the temperature exceeds 110° F (43° C).
5. Another solution may be infused immediately before a blood product is administered. In changing to the blood product, avoid the possibility of air entering the tubing. A blood filter must be used for transfusion. The filter should be changed after the second or third unit of whole blood to avoid the filter becoming clogged with microaggregates.
6. The anesthesia provider records on the anesthesia record the following information for each unit transfused:
   a. The name of the person who started the transfusion.
   b. The type and amount of product transfused (i.e., whole blood, plasma, packed cells, platelets, albumin).
   c. The time started and drops per minute.
   d. Information on the label, including the blood group, Rh factor, and number.
7. The patient is observed closely for any type of reaction. This probability increases in direct proportion to the number of units transfused. The most common type of reaction is allergic; febrile is almost as common, and hemolytic reactions are possible. Transfusion reactions with the patient under anesthesia may be accompanied by profound hypotension, temperature change, blood in urine, and/or skin rash. The common physical

TABLE 31.3 Shelf Life of Blood Products According to the American Association of Blood Banks

Blood Products	Shelf Life
Red blood cells	42 days refrigerated
Frozen red blood cells	10 years
Platelets	5 days at room temperature
Fresh-frozen plasma	1 year
Cryoprecipitated antihemophilic factor	Frozen 1 year
Granulocytes	Transfuse within 24 hours of collection

reactions and chills are not seen in an anesthetized patient. If any suspicious reactions occur:

a. Stop the transfusion. Keep the IV line patent with IV solution as directed by the physician.
b. Return unused blood to the blood bank along with a sample of the patient's blood.
c. Send a urine sample to the laboratory as soon as possible.
d. Take vital signs (temperature, pulse, respirations, BP) every 5 to 10 minutes until the patient is stable.
e. Have emergency medications and resuscitation equipment available.
f. Document on the patient's chart the type of reaction, action taken, patient's response, and other documentation as required by the institution.

Autologous Blood

Autologous blood is blood recovered from the patient and reinfused. Referred to as autotransfusion, this process is the preferred method of replacement for either elective or emergency procedures. The patient's own blood is the safest form of transfusion; it eliminates concerns about compatibility/reactions and transmission of exogenous organisms. Autologous blood is equal or superior in quality to allogeneic blood. It may be obtained preoperatively from patients and returned to them intraoperatively or postoperatively as needed.

Some patients who, because of religious beliefs, will not accept allogeneic blood may accept autotransfusion in the form of cell salvage, red cell fractions, plasma fractions, white cell fractions, or platelet fractions. Jehovah's Witnesses, for example, believe that receiving blood or blood products violates a biblical prohibition against consumption of blood.[11] They have the right to refuse transfusion, and that should not be interpreted as a death wish. Some will accept blood fractions as a personal decision. Informed consent should be obtained from all patients for whom autotransfusion or administration of blood fractions is contemplated.

Preoperative Blood Donation

One or more units of whole blood or blood components can be obtained by phlebotomy from the patient preoperatively and stored in the blood bank. Blood may be donated as often as every seventh day for a period of 6 weeks if the hemoglobin remains at least 11 g/dL or the hematocrit is 33%, with the final unit donated no less than 72 hours before the scheduled surgical procedure. If two or more units are donated, a PO or IM iron supplement may be prescribed because as much as 10% of iron stores are lost with each donation. Epoetin alfa, a glycoprotein, can be administered SQ or IV for up to 6 weeks preoperatively to stimulate red blood cell production. Red blood cell stimulation can be continued postoperatively and is effective if iron stores are adequate. The patient's body replenishes the fluid lost in donation within 24 hours.

Autologous blood is usually stored in a liquid state as whole blood or packed red blood cells. Whole blood with anticoagulant can be stored for 35 days, and red blood cells with preservative for 42 days. Red blood cells and plasma can be frozen for prolonged storage. The same protocol is used in the OR for reinfusing autologous blood as described for allogeneic transfusions. If the patient does not need reinfusion, the blood is discarded. The blood is not given to another patient.

Intraoperative Autotransfusion

Recovery of blood as it is lost requires sterile equipment that suctions blood from the surgical site, filters and anticoagulates it, and contains it for IV reinfusion to the patient with minimal damage to cells. Intraoperative blood salvage is widely used when potential blood loss may exceed 20% of the patient's blood volume. Blood can be suctioned directly from a body cavity or the wound. Any plastic devices, including suction tubing and pouches, used for blood recovery must be approved by the FDA.

Blood is not salvaged if microfibrillar collagen (Avitene) has been used for hemostasis. This may not wash out when red blood cells are processed and can predispose the patient to DIC or ARDS. In addition, blood contaminated with enteric organisms or amniotic fluid is not salvaged. If a malignant tumor can be resected intact, autotransfusion may benefit the patient with cancer. Most cancer cells will filter out of processed blood. Autologous blood is not collected from patients with known systemic infections or from open traumatic wounds. Other patients, of all ages, are candidates for autotransfusion.

The autotransfusion unit must be easily and quickly assembled because it may be lifesaving for a trauma patient in an emergency situation. All fluid paths should be disposable and must be sterile. Three basic systems are used for intraoperative autotransfusion, as follows:

1. *Automated cell salvage processor:* Blood is suctioned through double-lumen tubing. An anticoagulant solution of heparinized saline or citrated dextrose mixes with blood at the tip end of the tubing. The aspirate passes through a 140-mm filter before entering the collection reservoir. This filter removes fat and debris.

   When a sufficient quantity to be processed has accumulated, the blood is pumped into a centrifuge bowl. The centrifugal force separates red blood cells from plasma, platelets, white blood cells, and other debris, including anticoagulant. These red blood cells are washed with normal saline solution. A suspension of red blood cells in saline solution is pumped into a reinfusion bag. Each bag contains about 250 mL of washed packed red blood cells with a hematocrit of 50% to 55%, ready for IV reinfusion. The entire cycle takes 3 to 7 minutes.

   Some autotransfusion units have automatic, programmed cycles, including process air and foam detectors; others operate manually. Platelet-rich plasma suitable for autotransfusion can be sequestered from some units.
2. *Canister collection method:* Blood is suctioned and anticoagulated as described for the cell processor. From the tubing, the blood collects in a reservoir with a disposable liner. When the reservoir becomes full, or at the end of the surgical procedure, the liner is removed. The contents are washed in a standard red blood cell washer before being reinfused.

   This equipment may be located in the blood bank. The liner must be labeled with the patient's name and identifying number if it leaves the OR for washing. Autologous blood obtained using this technique has a high hematocrit level and is nearly free of protein, anticoagulant, and debris.
3. *Salvage collection bag:* An anticoagulant, usually citrate, is added to blood collected directly into a single-use, self-contained transfusion bag. The blood is not washed but reinfused through a blood filter. This simple method is most appropriate when profuse bleeding occurs in areas that form pools that can be easily suctioned, such as the abdominal or chest cavities.

All three methods are safe when used according to the manufacturer's instructions. The automated cell salvage devices are the most sophisticated and complex. Only properly trained personnel should operate them. OR personnel may be trained to set up the sterile suction and containers.

Postoperative Autotransfusion

Autologous blood may be collected, processed, and bagged during a surgical procedure for reinfusion postoperatively. Bags must be labeled with the name and identifying number of the patient and the time of processing. Autologous blood also can be salvaged postoperatively from a drainage tube placed into the surgical wound, most commonly a chest tube. The tube may be connected to a cell washer in a portable unit that attaches to wall suction in the PACU or ICU.

Another method collects wound drainage by suctioning it directly into a filtered collection bag. With both of these methods, blood is anticoagulated. It may be collected for a maximum of 6 hours. The concentrated red blood cells, either washed or unwashed, are reinfused IV. Whether obtained intraoperatively or postoperatively, unwashed blood can be kept at room temperature for 4 hours and washed blood can be kept for 6 hours at room temperature or refrigerated for 24 hours at 39.2° F (4° C).

Blood Substitutes

Oxygen-carrying blood substitutes offer another alternative for transporting oxygen. Since the 1970s, researchers have sought to develop hemoglobin-based oxygen carriers to serve as blood substitutes for emergency use. The ideal blood substitute has not been developed that satisfies clinical testing and safety for patient use. Chemically modified hemoglobin from outdated human blood or bovine blood has been used in the research effort.

Oxygenation of body tissues is a serious subject when the patient's blood volume or hemoglobin level is decreased because of blood loss. These substitutes might be used in anemic patients, in people who refuse blood or blood products for religious reasons, or when compatible allogeneic blood is not available. A number of blood substitutes were under investigation as of 2014, but not approved by the FDA. As of 2018, most of those blood substitutes were postponed during clinical trials due to safety issues and adverse reactions. Several blood substitutes are being studied and used outside the United States. The FDA approved one product for use in veterinary medicine.

- *Fluorovent:* Oxygen-carrying perfluorocarbon (PFC) can be used for preterm infants with underdeveloped lungs and in both adults and children with ARDS. It is a liquid instilled directly into the lungs to act as a surfactant. It encourages the exchange of oxygen and carbon dioxide. Patients with COPD may benefit from its use as well. Clinical trials were postponed for safety reasons.
- *Oxycyte:* This IV form of PFC carries five times the amount of oxygen carried in hemoglobin. The oxygen-hemoglobin exchange ratio is extremely efficient, because the molecules are 1/70 the size of a red blood cell and can reach tiny capillary surfaces. It can be stored at room temperature and requires no crossmatching. It was rejected for FDA approval, more studies are needed.
- *Hemopure:* This bovine hemoglobin–based polymer solution has been used in clinical trials in the United States and Europe.[12] It is stable for 3 years at room temperature and requires no crossmatching. It is given by IV infusion and is compatible with all blood types. The phase II clinical trial was put on hold in the United States for safety reasons.
- *PolyHeme:* Human polymerized hemoglobin is processed from outdated human red blood cells. The product is screened for infectious disease, pasteurized, and polymerized. It is safe for use with any blood type. The shelf life is 12 months. It was rejected for FDA approval.
- *Oxyglobin:* This red blood cell alternative for veterinary services is compatible with all blood types. It was approved by the FDA for use in animals.

Complications of Blood Loss or Replacement

The patient is constantly monitored to detect any complications that might be developing as a result of blood loss or replacement or as a compromise of the cardiovascular system. Hemorrhage can cause shock and DIC. Earlier PFC emulsions caused pulmonary complications, such as hyperinflated, noncollapsible lungs. Traces of older PFC emulsions can persist systemically and cause the threat of accumulation in fatty tissue. Accumulation could compromise developing neonatal nervous tissue, which has a high fatty content.

Early blood substitute products have been associated with gastrointestinal problems, myocardial infarction, stroke, coagulopathies, kidney and liver dysfunction, fever, and vasoconstriction.

Research is being done on growing red blood cells in a laboratory from adult donor cells. Small amounts of red blood cells have been successfully bioengineered and could be a safer alternative to treat blood loss in the future.

Shock

Shock is a state of inadequate blood perfusion to parts of the body. If untreated, it will become irreversible and result in death. George W. Crile (1864–1943), one of the founders of the Cleveland Clinic, was the first surgeon to systematically study physiologic shock and its relationship to hypotension in the surgical patient.

Hemorrhagic shock results from a decrease in circulating blood volume caused by loss of blood, plasma, or extracellular fluid. Fluid loss is excessive when it is greater than compensatory absorption of interstitial fluid into the circulation. Shock resulting from hemorrhage or inadequate blood volume replacement, as seen in the OR and PACU, usually is reversed by prompt restoration of circulating blood volume.

Shock is a complex phenomenon, a life-threatening condition in which circulation fails for one or several reasons. Loss of circulating blood volume, loss of the pumping power of the heart, or loss of peripheral resistance can result in insufficient flow of blood for adequate tissue perfusion or oxygenation. If it is prolonged, inadequate organ blood flow with deficient microcirculation profoundly depresses vital processes. Because the objective of circulation is achieved in the capillaries, defective cellular metabolism derived from shock interferes further with the body's inherent defenses, and metabolic acidosis occurs.

Normal defense mechanisms are reflex vasoconstriction and increased pulse rate, which tend to redistribute the flow of blood to the heart and brain at the expense of the other vital organs. If shock is promptly recognized, treated, and reversed, permanent damage is avoided. If it progresses to irreversibility, death ensues from cellular dysfunction and organ hypoperfusion.

Multiple types and causes of shock present problems in relationships among the heart, circulatory system, and blood volume. Circulatory inadequacy may originate from a marked decrease in CO, venous return to the heart, or peripheral vascular resistance. All forms of shock carry high mortality rates. The best treatment is prevention. Shock is classified according to the cause of inadequate tissue perfusion.

Hypovolemic and Traumatic Shock

Fluid loss is greater than compensatory absorption of interstitial fluid into the circulation. The vascular capacity is low, causing a decrease in diastolic filling pressure. Damage to the capillaries caused by soft tissue trauma increases capillary permeability, with loss of blood volume into the tissues and decreased urine production. This state is aggravated by pain, which inhibits the vasomotor center, leading to vasodilation and hypovolemia. Toxic factors associated with intravascular coagulation lead to pulmonary, renal, and/or multiple organ failure.

Hemorrhagic Shock

Shock results from hemorrhage or inadequate blood volume replacement. This is characterized by significant blood loss, more than can be replaced for physiologic equilibrium. The loss of blood causes the BP to decrease to levels too low to perfuse vital organs.

Cardiogenic Shock

The pumping action of the left ventricle is insufficient to pump enough blood to vital organs. Cardiogenic shock may be precipitated by congestive heart failure, myocardial contusion or infarction, coronary air embolism, mechanical venous obstruction, or hypothermia. In addition to drugs, various mechanical devices may be used, such as an auxiliary ventricle or counterpulsation with an intraaortic balloon pump (IABP) to temporarily increase left ventricular function.

Neurogenic Shock

Loss of vasomotor tone in peripheral blood vessels leads to sudden vasodilation and pooling of blood. Vasodilation produces hypotension. Peripheral resistance is too great for compensation by increased CO, increasing the risk for congestive heart failure and PE. Causes may be brain damage, deep anesthesia, emotional trauma, vagal reflex from pain or surgical manipulation, or spinal cord injury.

Vasogenic Shock

Anaphylaxis and septic shock (toxic shock) from infection are the most common types of vasogenic shock. CO decreases as the heart muscle weakens and the CVP is unstable.

Metabolic Crises

Convulsions

Convulsions occur most often in patients with a hyperactive metabolic rate, especially in dehydrated or febrile children. Anoxia and death can occur.

Etiology

Etiologic factors include severe hypoxia and carbon dioxide retention, hypernatremia, hyperthermia, overdose of regional anesthetic drugs, air embolism, and epilepsy.

Symptoms

Symptoms include muscular twitching, dilated pupils, rapid snorting respirations, rapid pulse, grimacing, and cyanosis.

Treatment

Oxygen is administered to maintain respiration, and diazepam (a rapid-acting barbiturate) or a neuromuscular blocker is given to stop muscular activity. Mechanical ventilation may be needed for apnea or to support circulation.

Prevention

Metabolic crises are prevented by maintaining normal body temperature and fluid and electrolyte balance.

Inadvertent Hypothermia

A decrease in the patient's core body temperature to below 96° F (35° C) can affect vasoconstriction and vasodilation, CO, and renal function. Depending on the degree of body heat loss, hypothermia is categorized as follows:

- Mild (down to 90° F [32° C])
- Moderate (down to 85° F [29° C])
- Deep (down to 80° F [27° C])

If core temperature falls below 68° F (20° C), brain activity ceases. Patients can emerge from anesthesia with a body temperature below normal. Inadvertent hypothermia occurs spontaneously intraoperatively; it is not to be confused with induced hypothermia. Age-extreme, thin, and debilitated patients are most susceptible, as are patients undergoing neurosurgical, cardiovascular, thoracic, and abdominal procedures.

Etiology

Anesthesia inhibits the protective reflexes that generate body heat (i.e., shivering). It also depresses the thermoregulatory center in the hypothalamus, decreases the basal metabolic rate, and increases vasodilation for heat loss by radiation and conduction. Core body heat is lost by exposure to a cool external environment (e.g., during skin preparation) and through the surgical incision.

Other factors include preoperative sedation, use of general versus regional anesthesia, adjunctive drugs, the length of the surgical procedure, blood and fluid loss and replacement, the room temperature, and evaporative loss through the skin and respiratory tract.

General anesthesia commonly causes a 1° F to 1.5° F decrease in core temperature during the first hour, extending the action of propofol by 30%. The greatest risk for hypothermia is in the patient who has had combined general and epidural anesthesia. Protective central inhibition of the thermoregulatory center in the hypothalamus and peripheral nervous system is delayed.

Symptoms

Hypothermia can cause adverse cardiovascular, hematologic, immunologic, metabolic, and neurologic effects.[13] Cardiac dysrhythmias, hypoxia, metabolic acidosis, hyperglycemia, and dilated pupils may be a result. A depressed central nervous system, which can lead to coma, may not be evident until the postoperative period.

Shivering, impaired speech, muscle rigidity, peripheral or central cyanosis, a weak pulse, falling BP, and dysrhythmias seen in the PACU may be symptoms of hypothermia. The incidence of ventricular tachycardia is doubled, causing an increased incidence of postoperative myocardial infarction.

Treatment

The hypothermic patient must be rewarmed as soon as possible. However, postanesthesia shivering during the rewarming process can be hazardous. Shivering is an involuntary rhythmic contraction

of muscle groups with irregular and intermittent relaxation. This physiologic response to cold is activated when the hypothalamus senses that the core temperature has dropped. Some postanesthesia shivering is caused by anesthetic agents. Untreated shivering leads to increased oxygen consumption as a result of muscular activity and to increased cardiac stress as a result of hypoxia.

In the PACU a forced-air skin surface warmer or an ultraviolet or infrared heat lamp directed at the lightly covered patient is an effective means for raising the body temperature. A temperature-regulating hypothermia/hyperthermia machine, set at 104° F to 107° F (40° C to 42° C), may be used with a heated blanket beneath the patient. Any warming device placed under the patient should be closely monitored to prevent burns and used according to the manufacturer's instructions. If mechanical warmers are not available, heated blankets placed over and underneath the patient should be changed at 15-minute intervals. Blankets can be heated to 105° F (40.5° C) for an adult or 100° F (38° C) for a small child or infant. The patient should wear a cap. Warmed, humidified oxygen and warm IV fluid should be administered. Coniine (an alpha$_2$-adrenergic agonist) or analgesics such as meperidine or morphine derivative may suppress shivering.

Prevention

Prevention of hypothermia is the best treatment. Prevention begins before the patient arrives in the OR and continues during the procedure:

1. Place a hypothermia/hyperthermia mattress or reflective blanket on the OR bed. A radiant heat source can be placed over an infant.
2. Check the room temperature and humidity.
3. Apply warmed blankets as soon as the patient arrives in the OR and immediately after drapes are removed.
4. Limit skin exposure during positioning and skin preparation (i.e., keep the patient covered as much as possible).
5. Minimize the time of exposure between skin antisepsis and draping.
6. Keep the sheet under and the drapes over the patient and around the surgical site dry to provide insulation, prevent heat loss, and maintain asepsis. Dry the area after skin preparation.
7. Warm antiseptic, irrigating, and IV solutions, including blood, before administration. Anesthetic gases, including oxygen, can be warmed also.
8. Monitor body temperature.
9. Leave a cap on the patient; a plastic head covering retains more heat than do other materials.

Malignant Hyperthermia

Malignant hyperthermia (MH) is a hypermetabolic crisis in susceptible people. It is triggered by potent halogenated anesthetic agents and depolarizing skeletal muscle relaxants. MH, a potentially fatal complication of inhalant anesthesia, is characterized by uncontrolled acceleration of muscle metabolism accompanied by tremendous oxygen consumption and production of heat and carbon dioxide.

Elevated body temperature is a later sign of an MH crisis. The body temperature can rapidly rise at a rate of 1.8° F (1° C) every 5 minutes if MH is untreated. A temperature as high as 117° F (47° C) has been recorded, but 111.2° F (44° C) is probably the highest with survival. The survival rate with appropriate treatment is between 80% and 90%. The mortality rate without appropriate treatment is around 90%; thus MH is of significant concern.

Etiology

The exact cause of MH is unknown. It is understood that certain patients are susceptible and some anesthetic agents may trigger this **metabolic crisis**.

Susceptible Patients

A familial genetic transmission exists as an autosomal dominant trait with variable multifactor inheritance patterns. The genetic defect manifests by increasing calcium levels in skeletal muscles. The crisis results from a hereditary inability of the sarcoplasmic reticulum, a skeletal muscle cell membrane, to control intramyoplasmic levels of calcium.

Skeletal muscle undergoes contraction as a result of release of calcium ions in response to drugs or stress. A rapid increase of calcium in muscle fiber leads to generalized **catabolism** of the cells, an interruption of normal **anabolism**. As biochemical reactions occur, the body produces heat and carbon dioxide.

Susceptible patients also include those with any type of myopathy or acquired muscle disease, such as ptosis, strabismus, hernia, muscle weakness or hypertrophy, or muscular dystrophy. The incidence of MH is higher in children than in adults. Patients, especially children, with rheumatoid arthritis are particularly susceptible to MH. MH may occur in a patient's first exposure to anesthesia or in a later one; one third of reported cases of MH have occurred in a second or subsequent anesthesia.

Triggers

Succinylcholine, halothane, enflurane, desflurane, and isoflurane are the main triggers of MH in susceptible individuals.

Symptoms

Clinical signs and symptoms occur according to the swiftness of onset. The onset may be rapid, occurring immediately after induction, or may occur after several hours of general anesthesia or even in the postoperative recovery period.

Spasm of the jaw muscles with rigidity of the masseter muscles (trismus) or severe fasciculation after succinylcholine administration may suggest MH development to the anesthesia provider, although this activity is not uncommon in pediatric patients.

The most common presenting sign of MH is unexplained ventricular dysrhythmia, primarily tachycardia or PVCs.[6] This is associated with an unexplained increase in end-tidal carbon dioxide, tachypnea, cyanosis, skin mottling, and unstable BP. Blood in the surgical field may appear dark as a result of central venous desaturation.

When a sudden, generalized hypermetabolic state is produced, the temperature rises rapidly as more heat is produced than the body can eliminate. This is not a first sign. Elevated temperature may be a late sign or may be absent in MH syndrome. Fever, hot skin or tissues, and diaphoresis are symptoms of heat buildup. A favorable prognosis decreases when excessive heat in the tissues is noted through the surgeon's gloves or when the anesthesia provider senses heat in the reservoir bag or soda lime canister on the anesthesia machine. The body tries to adjust by vasodilation and increased CO.

If rapidly increasing tissue demands are not met, hypoxia, central venous hypercapnia, and severe respiratory and metabolic acidosis occur, progressing to cardiovascular collapse. Blood tests will reveal increased serum levels of potassium, magnesium, creatine phosphokinase (CPK), and myoglobin. Excessive myoglobin release caused by rapid muscle destruction (rhabdomyolysis) can cause renal failure and lead to anuria.

Late clinical findings include hyperkalemia; acute renal failure; left-sided heart failure; DIC; skeletal muscle swelling or necrosis from hypoxia and acidosis; pulmonary edema; neurologic sequelae, including paraplegia and decerebration; and coma from ischemia secondary to hypoxia. Recurrence of MH crisis can occur 24 to 72 hours postoperatively.

Monitoring

Parameters and studies to be monitored routinely in patients at risk for MH who undergo general anesthesia are heart rate and rhythm, BP, core temperature by esophageal probe, pulse oximetry, capnometry, nerve stimulation to measure the level of muscle relaxation, and precordial stethoscopy. A rise in temperature greater than 0.5° F per hour should raise suspicion for MH.

Treatment

Success is contingent on complete preparedness (preplanned action, written protocol, immediate equipment supply), early diagnosis, and vigorous therapy. The following treatment outline is the suggested protocol established by the Malignant Hyperthermia Association of the United States (MHAUS). (Emergency therapy wall charts can be ordered online at www.mhaus.org.) Institutional policies and procedures should be in place as follows to guide the perioperative team in caring for a patient in MH crisis:

1. Discontinue inhalant anesthesia and stop the surgical procedure immediately. The anesthesia provider immediately institutes hyperventilation with 100% oxygen at a high flow rate of at least 10 L/min. Research has shown that the breathing circuit and anesthesia delivery machine need not be changed because the high concentration of oxygen delivery clears the machine of anesthetic gases very rapidly. If the surgical procedure cannot be interrupted, safe agents may be used to maintain anesthesia during the stabilization period.
2. Immediately start drug therapy. Administer:
   a. Dantrolene sodium (Dantrium, Revonto, Ryanodex), 2 to 3 mg/kg in an initial IV bolus and repeat every 5 to 10 minutes until the maximum dose of 10 mg/kg is given or the MH episode is controlled. Large volumes are needed; therefore a central line is necessary.

      Patients generally respond to the drug quickly. The onset of action is usually 2 to 3 minutes. Occasionally doses higher than 10 to 20 mg/kg are needed.

      Dantrolene is a specific drug for treatment of MH. It directly blocks accumulation of calcium within the muscles by preventing its release from the sarcoplasmic reticulum and by uncoupling excitation-contraction, thus relaxing skeletal muscle. It has no effect on cardiovascular or respiratory functions. Calcium channel blockers may not be given with dantrolene because they may cause hyperkalemia, myocardial depression, and cardiovascular collapse. Verapamil is contraindicated.

      Given IV, Dantrium and Revonto are supplied in 65-mL vials as a sterile, lyophilized powder that contains 20 mg of dantrolene and 3 g of mannitol. Each vial must be reconstituted before use with 60 mL of sterile water for injection without a preservative agent. The large quantities of sterile water that are needed would contain the preservative agent in toxic amounts. A semiautomatic fluid-dispensing syringe expedites mixing. If this is not available, additional personnel should help with the reconstitution process because large quantities of the diluted drug will be needed and each vial will require vigorous shaking to mix. A central line is the best route for administration of large quantities of the drug. Peripheral vessel constriction can make IV administration difficult. In extreme circumstances the drug may be given through a filter to remove particulate from the solution.

      Ryanodex is a rapidly prepared formulation of dantrolene sodium supplied in 250 mg vials with 125 mg mannitol. This form of the drug requires 5 mL nonbacteriostatic sterile water to reconstitute the solution in 20 seconds. This allows rapid administration to stabilize the patient with minimal risk for fluid overload. A central line may not be needed if the peripheral veins are patent. Reconstituted Ryanodex and other forms of dantrolene must be used within 6 hours of mixing and must be protected from direct sunlight. Dantrolene sodium solution will be yellow-orange when mixed. More information can be found at www.ryanodex.com/.

      If other IV solutions have been running, the line should be flushed with sterile water before dantrolene is injected; this will prevent precipitation. Do not use lactated Ringer's solution, because it will increase the level of acidosis. An additional IV site should be established to infuse iced normal saline solution at the rate of 15 mL/kg every 15 minutes for at least 45 minutes.

      Dantrolene is continued postoperatively at a minimum of 1 mg/kg every 6 hours for 24 to 72 hours postepisode. After the initial 48 hours, 1 mg/kg every 6 hours may be given orally for 24 hours. No serious side effects have been reported with short-term use, but muscle weakness may be evident for 24 to 48 hours after administration. A few isolated reports of nausea, vomiting, and fatigue have been documented. Prolonged administration may lead to hepatotoxicity.
   b. Procainamide (Pronestyl), 15 mg/kg diluted in 500 mL physiologic saline solution IV over 60 minutes. Procainamide treats cardiac dysrhythmia if required.
   c. Sodium bicarbonate, 1 to 2 mEq/kg IV stat and repeat as guided by blood gas analysis. An alkali, sodium bicarbonate raises pH temporarily. It combats acidosis and antagonizes hyperkalemia by lowering the plasma potassium level. It can cause rebound acidosis. Monitoring of arterial pH and Pco_2 is necessary to determine subsequent doses.
   d. Regular insulin, 10 units in 50 mL of 50% dextrose in water IV. Insulin offsets the high glucose metabolic demands and improves glucose uptake. It shifts potassium back into the cells to help treat hyperkalemia. Blood glucose and potassium levels must be monitored.
   e. Calcium chloride, 2.5 mg/kg, to treat severe cardiac toxicity caused by hyperkalemia.
   f. Mannitol, 0.25 g/kg IV, and furosemide (Lasix), 1 mg/kg IV, up to four doses each. These drugs dislodge myoglobin from the renal tubules and sustain urinary flow. Urinary output greater than 2 mL/kg/hr must be maintained to prevent renal failure. The dose is calculated in consideration of the mannitol contained in the dantrolene sodium solution.
3. Begin active cooling. Administer refrigerated or iced normal saline IV. Lavage the stomach and rectum. Avoid irrigating the bladder if at all possible, because accurate measurement of urinary output and urinalysis are important. If the peritoneal or thoracic cavity is open, cool sterile saline may be poured into the opening.

Cool the body surface by placing the patient on a plastic sheet and applying ice bags and ice water, or use a hypothermia blanket. If readily available, use extracorporeal perfusion apparatus for partial (femoral-to-femoral) cardiopulmonary bypass to cool the viscera. Body temperature must be carefully monitored to avoid accidental cooling to dysrhythmic levels. Medication may be given to limit shivering, normally a heat-retaining mechanism that also increases oxygen consumption. Surface cooling is considered more effective in children because of their high ratio of surface area to body volume. Cooling that is too vigorous can result in inadvertent hypothermia and cardiac arrest. To avoid hypothermia, cooling should be discontinued when the core temperature reaches 100° F (38° C).

4. Correct the electrolyte imbalance on the basis of blood sampling of electrolytes, pH, and blood gases. After the presumed onset of MH, an arterial line must be established if one is not already in place. Blood samples are taken at 10-minute intervals for pH, Pco_2, Po_2, sodium, potassium, chlorides, calcium, magnesium, and phosphate. Hypocalcemia and hyperkalemia followed by hypokalemia may be expected.

   Also measured are CPK, aspartate aminotransferase (AST, formerly serum glutamic-oxaloacetic transaminase [SGOT]), alkaline phosphatase, and lactate dehydrogenase for indication of muscle destruction. Blood urea nitrogen (BUN) for kidney function, bilirubin for liver function, coagulation studies, blood lactate and pyruvate, and serum thyroxine levels may be ordered.
5. CVP should be monitored. A CVP line may need to be inserted if one is not already in place.
6. Urinary output is monitored via an indwelling Foley catheter. In addition to the measurement of volume, urine is sampled for hemoglobin and myoglobin. The urine may be brown as the amount of hemoglobin and myoglobin increases.

Supplies for Malignant Hyperthermia

Supplies should be kept in a specific location and must be immediately available for both adult and pediatric patients. A cart marked for use in MH is convenient. Supplies that may be needed include the following:

1. Monitors, including ECG, electronic temperature probes, recorder
2. IV equipment, including blood administration sets and pumps; CVP line setup; IV solutions—12 bags, 1000 mL each, of physiologic saline kept in a refrigerator
3. Arterial line setup
4. Intubation equipment
5. Ice chips and plastic bags, hypothermia blankets
6. Gastric lavage set, three-way indwelling catheter for insertion into the rectum, 50-mL syringes
7. Blood sampling and arterial blood gas equipment
8. Indwelling Foley catheter, urometer bag
9. Drugs:
   a. Thirty-six 20-mg vials of dantrolene sodium (the quantity needed to treat and stabilize a 70-kg adult)
   b. Thirty-six 60-mL vials of sterile water without a preservative agent to reconstitute dantrolene (the quantity needed for a 70-kg adult is 2100 mL)
   c. Five 100-mL prefilled syringes of sodium bicarbonate 5%
   d. Six 1-g ampules of procainamide
   e. Ten 50-mL vials of 20% mannitol
   f. Four 2-mL (20-mg) prefilled syringes of furosemide
   g. One 100-unit vial of regular insulin
   h. Two 50-mL vials of 50% dextrose in water
   i. Three 1000-unit vials of heparin
   j. Ten 250-mg vials of hydrocortisone sodium succinate (Solu-Cortef)
10. Associated needles and syringes
11. Extracorporeal perfusion apparatus if available
12. Defibrillator machine and electrodes

Prevention

Identification of susceptible patients is the best prevention. The preoperative history should routinely include questions about the patient's previous anesthesia experiences, unexplained incidents or death of family members who underwent anesthesia, and known muscular abnormalities or episodes of heatstroke in the patient or relatives. Hereditary predisposition has been detected in three generations; however, the patient's family history frequently is not known.

The most prominent clue to identification of a patient susceptible to MH is a family history of unexplained death while under general anesthesia. Genetic counseling of the patient and family is advised. Although the crisis usually occurs when the patient is under general anesthesia, it can occur during periods of emotional or physical stress. Susceptible people should wear a Medic-Alert bracelet or tag.

Diagnosis of susceptibility to MH can be accomplished by preoperative muscle biopsy. A 1-g specimen of skeletal muscle is excised from the thigh with the patient under local anesthesia. The specimen is removed from the muscle as a strip and outstretched between the prongs of a double-tipped clamp. Evaluation of the muscle response to caffeine-induced contracture during exposure to halothane reveals sensitivity. Although a local anesthetic is used to obtain the muscle biopsy, dantrolene should be readily available in the unlikely event of an episode of MH.

The blood CPK level may be elevated in susceptible patients, but it also can be influenced by alcohol consumption or strenuous exercise. A normal CPK level does not ensure absence of the MH trait. Nuclear magnetic resonance imaging using phosphorus also may detect susceptibility, but it is not always a reliable indicator.

Prophylaxis

Dantrolene may be given preoperatively to susceptible patients. The suggested dose is 1-mg/kg increments every 4 to 6 hours PO up to a total dose of 4 mg/kg, followed by 2.5 mg/kg IV 30 minutes before induction of general anesthesia. Intraoperative monitoring is mandatory. When nontriggering anesthetic agents are used, prophylactic dantrolene therapy may be unnecessary. Each patient should be evaluated individually. Some indications for dantrolene prophylaxis may include:

- Previous history of suspected MH episode
- Family history of MH (actual or suspected)
- Known MH susceptibility
- Prolonged procedure anticipated in an MH-susceptible patient
- Underlying disease or physiology causing suspicion of MH susceptibility

Nontriggering anesthetic agents should be administered to MH-susceptible individuals. Barbiturates, benzodiazepines, narcotics, and opioids are considered safe. Nitrous oxide by inhalation or IV propofol or ketamine hydrochloride can be administered for general anesthesia. Most of the synthetic nondepolarizing neuromuscular blockers are safe muscle relaxants. Amino amide and ester agents can be used safely for local anesthesia.

Postoperatively the patient should be continuously monitored in the ICU for 24 to 48 hours. If the vital signs remain stable

during this time, the patient may be discharged. (More information is available from MHAUS at www.mhaus.org.)

Iatrogenic Injury

Physiologic injuries are many and varied. The anesthesia provider may inadvertently loosen teeth or damage dental work during endotracheal intubation. Nerves can be injured from faulty positioning, such as hyperabduction or extension of the arm. Pressure sores may develop on poorly padded areas. Fingers and body parts can be pinched in OR bed flexures. Careless handling of an anesthetized patient can result in paralysis, fractures, or postoperative pain.

Eyes can be injured from irritating anesthetics or facemasks or from drying or scratching of the cornea if the eyelids are not closed. Patients with protruding eyes, faces covered by drapes, or those in prone positions are at high risk for eye injury. Use of an ocular lubricant protects the cornea from drying, and taped eyelids prevent corneal abrasions.

Extravasation, thrombophlebitis, and air emboli are associated with IV infusions. IV cannulas should be visible and not entirely hidden beneath drapes; infusions should be checked frequently. Precaution is the best prevention of injuries.

32 Endoscopy and Robotic-Assisted Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Describe the difference between rigid and flexible endoscopy.
- List the eight essential elements necessary for all endoscopy.
- Identify three potential hazards of puncture endoscopy.
- List three considerations for patient safety during endoscopy.

KEY TERMS AND DEFINITIONS

Endoscopy Examination of a body part or cavity with an optical system in a tubular structure.
Insufflation Act of filling with gas. Laparoscopy is performed with carbon dioxide gas (CO_2).
Laparoscopy Endoscopic examination of the peritoneal body cavity through a percutaneous access portal, placement of expansion medium to create a working space, and manipulation of intraabdominal organs.
Percutaneous Puncture through the skin.
Pneumoperitoneum The peritoneal cavity is filled with CO_2.
Trocar Surgical instrument that consists of a sheath with a sharp pyramidal or blunt conical obturator used to puncture or penetrate multiple layers of tissue. The sheath remains in place as the obturator is removed. Additional instrumentation is passed through the sheath.
Veress needle Spring-loaded needle that delivers CO_2 for the creation of a pneumoperitoneum.

Eight Essential Elements of Endoscopy

Endoscopic technology, regardless of whether it is performed with a rigid scope or a flexible scope, has the following eight elements in common (Box 32.1):

1. Access portal
2. Working space
3. Illumination
4. Vision
5. Manipulation
6. Capture
7. Evacuation
8. Closure

These essentials of **endoscopy** are described in more detail in the following sections.

Access Portal into the Body

1. Natural orifice or functional stoma
   a. Oral, nasal, aural, vaginal, anal, urethral. Some rigid scopes have an obturator (a blunt-tipped rod placed through the lumen) to permit smooth insertion of the instrument, such as into the anus.
   b. Natural Orifice Transluminal Endoscopic Surgery (NOTES).[1] This is a form of incisionless surgery.

      The surgical procedure is performed by entering the mouth, vagina, or anus. The endoscope is passed into the passage and traversed to a point where an incision can be made into an organ wall to access a structure within the peritoneum. Target structures include the stomach (obesity procedures and fundoplication), adjacent structures, and

• BOX 32.1 Eight Essentials of Endoscopy

1.	Access portal	Natural orifice or percutaneous puncture
2.	Working space	Fluid, gas, or positional expansion to accommodate instrumentation
3.	Illumination	Fiberoptics or incandescent bulb
4.	Vision	Direct or indirect viewing with lens or camera
5.	Manipulation	Tissue grasping, debulking, and dissection
6.	Capture	Collection of specimens
7.	Evacuation	Remove gases, plume, or fluid
8.	Closure	Suturing, stapling, or minimizing the access portal

appendectomy. Research is under way for diaphragmatic pacing wires, pancreatic biopsy, and percutaneous endoscopic gastrostomy (PEG) tube revision.

The surgeon can enter the mouth and pass the endoscope into the stomach, where an incision is made through the gastric wall. The working instruments are used to excise the gallbladder and remove it from the body through the mouth. One point of concern is the closure of the gastrotomy and the potential for bleeding and leakage.

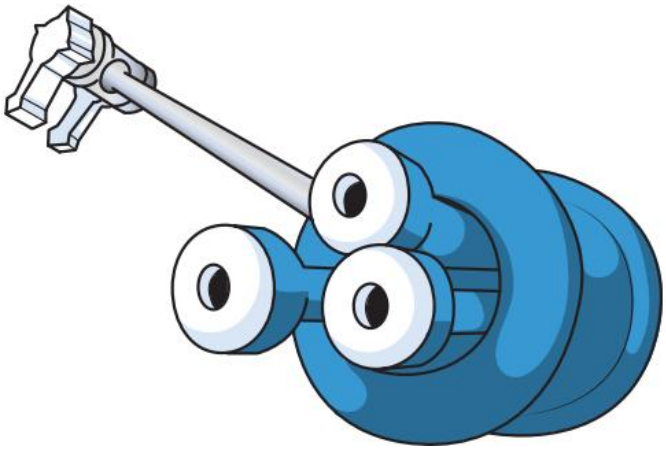
For gynecologic procedures the endoscope can be inserted through the vaginal wall to perform a hysterectomy or tubal and ovarian procedures. Women with previous hysterectomies may have adhesions and may not be candidates for a transvaginal approach to the peritoneal cavity. Previous surgery of any kind may be a problem for NOTES endoscopists.

Other procedures can be performed transrectally, but there are concerns for bowel contents entering the peritoneal cavity. Research is being done on the feasibility of transesophageal NOTES to enter the thoracic cavity for node staging without an external incision.

c. Ear canal: Small specula are used to perform procedures within the ear.

2. Puncture or incision: Placement of the initial devices to introduce the expansion medium for creation of the working space requires interruption of the body's intact surface. Some surgeons use preemptive analgesia with a local anesthetic injection at the port sites at the start of the laparoscopic surgical procedure. Some surgeons inject local anesthetics at the end of the case.
   a. Multiple sites based on the type of cavity or space and the location of landmarks and blood supply.
      (1) *Open method:* An incision is made into the skin, and a 5 to 10-mm blunt Hasson trocar and sheath are placed into the cavity or space. No Veress needle is used. Expansion medium (carbon dioxide [CO_2]) can be placed through a port into the cavity or space. This procedure may be used for the patient who has many adhesions or has had multiple previous surgeries.

      Single-port **laparoscopy** (single-incision laparoscopy [SILs], single-port access [SPA], one-port umbilical surgery [OPUS], and laparoendoscopic single site [LESS])[2]: One periumbilical incision is created, and a semiflexible port platform with three or four lumens is inserted. **Insufflation** is performed through accessory tubing attached to the device. The laparoscope and instrumentation are used through the lumens in the multilumen platform (Fig. 32.1).



• **Fig. 32.1** Single site laparoscopic port.

The single-site multilumen platform can be used in robotic applications.[3] The instrumentation styles are curved or articulated and permit triangulation of placement and two-handed manipulation of internal structures. Robotic procedures can incorporate single-port incisions.

(2) *Closed method:* A tiny nick is incised into the skin, and a Veress spring-loaded insufflation needle is placed through the skin into the peritoneal cavity for the delivery of an expansion medium such as CO_2 gas.

The surgeon can test placement of the **Veress needle** in three ways. The first way is the *manometer* test. The surgeon inserts the Veress needle and begins insufflation. If the needle is not completely in the peritoneal cavity, the manometer reading on the gas machine reads high. The gas is turned off, and the needle is advanced until the flow of the gas is unobstructed. The second method of Veress needle placement testing is by the *hanging drop* method. A small drop of sterile saline is placed at the opening of the Veress needle and is "sucked" in by the negative pressure of the peritoneal cavity. The third method of Veress needle placement is the *aspiration* test. The Veress needle is inserted with a syringe attached at the end. The surgeon attempts to aspirate through the needle. If the syringe does not permit aspiration, the placement is correct. If any fluid, blood, or other material enters the syringe, the needle has entered a viscus or vessel.

   b. Access devices for insufflation and creation of a working space.
      (1) *Veress needle:* A tiny 1 to 2-mm nick is made with the scalpel at the inferior edge of the umbilicus. The Veress needle is inserted by blind puncture **percutaneously** (through the skin) into the abdominal cavity. This needle has an exterior sharp bevel and an interior spring-loaded ball-tip obturator that retracts as it passes through tissue.

      The valve key on the top should be closed for insertion. As the sharp bevel passes through the tissue layers, the rounded obturator snaps forward to guard against inadvertent punctures of nontarget tissue.

      Slight popping noises are made by the needle and spring mechanism as the needle passes through each layer. The last sound is the peritoneal perforation.

The CO_2 tubing is connected for insufflation of a working space when the surgeon is reasonably assured that the Veress needle tip is in the correct space. The gas flow is started at 1 L/min and increased to 2 L/min. The intraperitoneal pressure should remain at 15 mm Hg for the average adult patient. Methods of placing the Veress needle into the peritoneal cavity include:

(a) *One-hand placement:* The surgeon grasps and lifts the lower abdominal (hypogastric) segment midway between the umbilicus and the superior margin of the pubis. As the abdomen is raised, the surgeon directs the Veress needle through the tissue layers until the peritoneal cavity is entered. A towel clip may be used at the infraumbilical midline to grasp and raise the abdominal wall.

(b) *Two-hand placement:* The surgeon and the first assistant grasp the abdominal tissue on either side of the umbilicus and lift. Some surgeons use Allis forceps or perforating towel clips to grasp the sides of the umbilicus. The surgeon introduces the Veress needle through the abdominal wall into the peritoneal cavity. In the average patient the needle is inserted at a 45-degree angle. In obese patients a 90-degree angle can be used.

(2) *Trocar and sheath (sleeve):* A **trocar** consists of a sharp or blunt obturator and a sheath or sleeve. The primary sheaths have ports with key valves for instillation of fluids or gases. The trocars are inserted with the key valve closed to prevent evacuation of the expansion medium used to create the working space. In arthroscopy the medium is fluid. In laparoscopy the expansion medium is CO_2. The primary access portal will be the appropriate size in millimeters to accommodate the laparoscope.

(a) Sharp trocar

(i) *Pyramidal or conical tip:* Describes the configuration of the tip.

(ii) *Shielded:* A spring-loaded shield drops down and protects the sharp tip of the trocar when it is not actively cutting through tissue. Studies have shown that this mechanism does not necessarily reduce the incidence of iatrogenic trocar-induced punctures.

(b) *Blunt trocar:* The trocar tip is rounded. The blunt trocar and sheath (Hasson) are introduced through a small infraumbilical incision in the open technique. The tissue layers are retracted with S-shaped retractors. Silk traction sutures are placed at the level of the fascia and brought out through the skin incision. The sheath has graduated threads that permit the device to create a seal when placed through the abdominal layers. The traction sutures are tied to the sheath to stabilize and seal the **pneumoperitoneum**. Insufflation with CO_2 for creation of a working space is performed through the key valve. A Veress needle is not used.

Another style of blunt trocar has a distal balloon that is inflated to anchor the trocar in place. It is placed using the open technique. A small foam collar seals the external portion of the incision.

(c) *Dilating sleeve:* The initial trocar/obturator and primary sleeve are small diameter (between 1.9 and 2.1 mm) and are introduced through a small nick in the inferior aspect of the umbilicus. The trocar is rigid, and the sheath is a flexible plastic meshwork with a stopcock for insufflation of the pneumoperitoneum.

As the initial trocar is removed, larger diameter instrumentation can be introduced through the radially dilating sleeve, causing it to dilate or "step up." The texture of the sleeve expands to accommodate a variety of diameters, such as 5, 7, 10, 11, and 12-mm instrumentation.

The skin puncture stretches and forms a seal around the access portal, anchoring it in position. The fascial puncture can be stretched to accommodate 12-mm instrumentation. The wounds measure around 4 mm when the sleeve is withdrawn and rarely need closure with suture.

c. Secondary insertion of accessory trocars for manipulation within the working space can be inserted under direct vision after the laparoscope is inserted into the primary port. Additional trocars and sleeves may be used in a triangular position around the umbilicus or primary trocar. Instrumentation for manipulation and capture is placed though these ports.

Working Space within the Body

1. Structural working space
   a. Abdominal lift device for creation of a gasless, tent-shaped working space. No expansion media used. The working space is somewhat smaller than that created from gas insufflation. The bowel is not compressed and may be distended. Visualization is affected by the small working space. Care is taken when placing the abdominal lift hooks so as not to snare the omentum or bowel.

   The lift devices are sometimes difficult to remove without ensnaring abdominal contents. Trocar insertion is sometimes difficult because there is no back pressure or resistance to the force of placement. Blind puncture is not commonly used.

   An expandable balloon can be used to bluntly dissect and separate the abdominal wall from the abdominal contents for instrumentation placement. It takes some of the pressure off the actual lift device as it pulls upward on the abdominal wall.

   (1) Linear lift requires a frame such as an arc above the patient that attaches to a cable system placed through the patient's abdominal wall. The shape of the working space may be irregular.

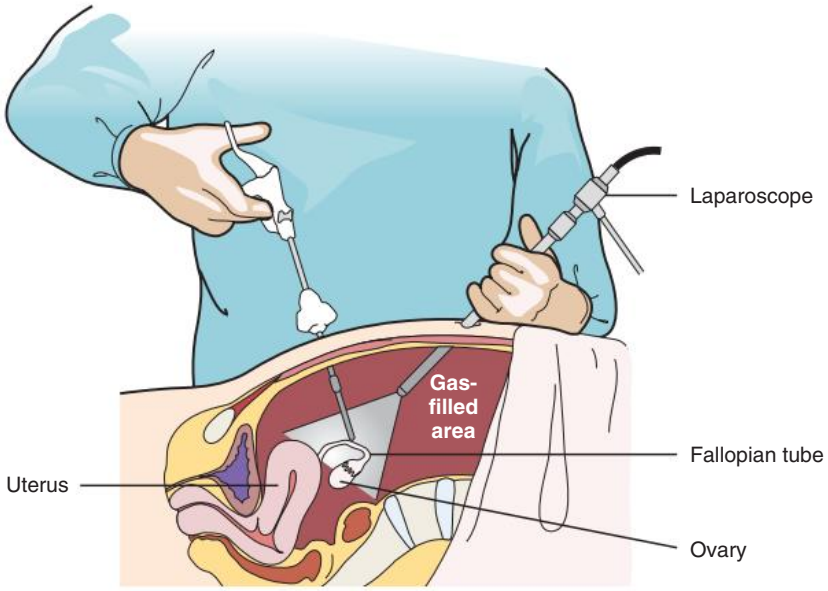
   (2) Planar lift uses a corkscrew-like hook or a fanlike retractor that is placed through the abdominal wall and suspended from an articulating arm attached to a frame on the OR bed. The shape of the working space is more trapezoid than domed like a pneumoperitoneum.

   b. Physiologic muscularity or structural framework, such as cartilage in the trachea and bronchus for upper aerodigestive flexible or rigid endoscopy.

   c. Speculum support between muscular layers such as the vaginal speculum or anoscope.

2. Expansion media
   a. *Fluid:* The bladder, uterus, and joint spaces can be expanded with fluid to create a working space.

   b. *Gas:* The peritoneal cavity is filled with CO_2 gas, creating a gas lake called a pneumoperitoneum, before a laparoscope



• **Fig. 32.2** Surgeon working with laparoscopic instruments within a CO_2-filled pneumoperitoneum.

is inserted into the primary trocar through the abdominal wall. The pneumoperitoneum expands the abdomen and provides a working space (Fig. 32.2).

With the tip of a No. 11 or 15 scalpel blade, a small incision (1 to 2 mm) is made into the abdominal wall at the infraumbilical margin. The spring-loaded 14-gauge Veress needle measuring 70 to 120 cm (average) to 150 cm (obese) is inserted through the tiny incision at the thinnest portion of the abdominal wall. Great care is taken when a Veress needle is used for blind puncture. The major vessels of the abdomen are at risk for injury.

Some surgeons will check for entrance into the peritoneal cavity with a syringe. Some surgeons will aspirate to check for blood or bowel contents, and others may use a saline-filled syringe to introduce a few milliliters into the opening of the Veress to check for obstruction of the needle.

The CO_2 tubing is attached to the Veress and the gas is delivered by an insufflator, which is a specially designed machine that allows a metered flow of gas at a controlled pressure of between 12 and 18 mm Hg depending on the patient's body size and health condition. Pressure gauges on the machine will indicate if the flow is commencing appropriately.

The gas passes through sterile disposable tubing with an inline, single-use hydrophobic filter that prevents particulate matter and condensation from the gas tank from entering the abdominal cavity.

The insufflation tubing filters particulate as small as 0.2 micron. The insufflator should be positioned higher than the patient's abdomen for maximum performance. If the cylinder is placed below the level of the patient, the pressure gradient on the patient's side increases, causing a backflow of biologic contaminants into the insufflator. As a result, the internal aspect of the insufflation machine can become biologically contaminated. This can be the source of cross-contamination between patients.

The CO_2 gas itself is not sterile and is delivered to the body cold, around 73.4° F (23° C) when not passed through a heating and humidifying element. Studies have shown less hypothermia in patients when the gas is delivered at temperatures between 86° F and 95° F (30° C and 35° C). The patient is at risk for hypothermia if core body temperature is less than 36° C. Studies have shown a decrease of 32° F (0° C) body temperature for each 50 L of CO_2 cycled through the patient.

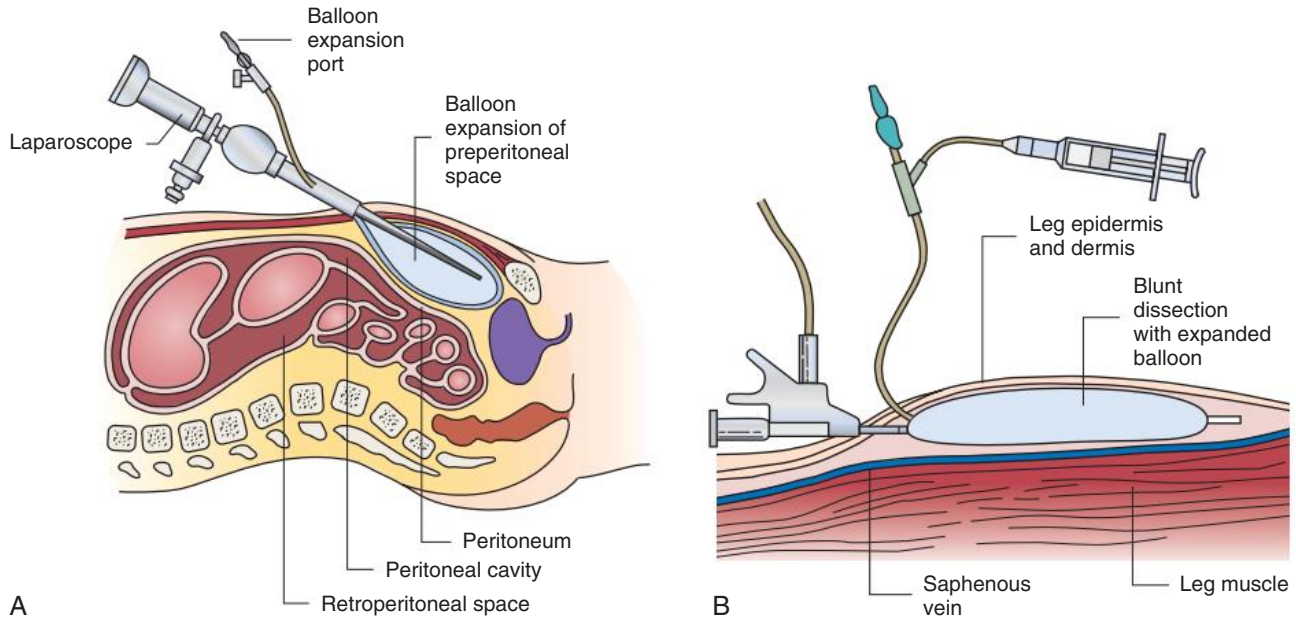
Once the pneumoperitoneum is established, a 10 or 12-mm trocar is inserted and the insufflation tubing is attached to a port on the side of the trocar sleeve. The average adult can accommodate 5 to 6 L of CO_2 in the peritoneal cavity to create the working space. A secondary 5 or 7-mm trocar with a gas port will be inserted.

c. *Air:* Ambient room air can be delivered into a natural body orifice by a hand pump bulb or machine to expand the lumen of the bowel for sigmoidoscopy or colonoscopy.
d. *Balloon expansion between tissue planes:* A balloon device can be inserted between tissue layers and expanded with saline to separate and bluntly open the preperitoneal plane of dissection. After blunt dissection and expansion, the balloon is deflated and withdrawn. The space is then insufflated. This is useful for extraperitoneal laparoscopic hernia repair procedures. Saphenous vein harvests and spinal surgery can be performed using this method (Fig. 32.3).

Illumination of the Working Space

Illumination within the body cavity is essential for visual acuity. The light source may be through a fiberoptic bundle or, rarely, from an incandescent lightbulb. The light carrier may be an integral part of the viewing sheath, as in flexible scopes and rigid telescopes, or it may be a separate light carrier accessory to a hollow rigid scope. The power source is usually electricity, but some handheld rigid scopes can use batteries.

1. *Fiberoptic light:* With fiberoptic lighting, an intense cool light illuminates body cavities, including those that cannot be seen with other light sources. Light is conducted through a bundle of thousands of coated glass fibers encased in a plastic sheath



• **Fig. 32.3** Balloon expansion of surgical planes. **A,** Preperitoneal expansion. **B,** Saphenous vein harvest using balloon dissection technique.

attached to a light source generator. Each fiber is drawn from optical glass into a strand 10 to 70 mm in diameter that is coated to minimize loss of light by reflection. Light entering one end of the fiber is transmitted by refraction through its entire length.

The light produced through the bundle of fibers is nonglaring and evenly distributed on the area to be visualized. Although it is of high intensity, the light is cool. A minimal rise of temperature in the tissues exposed to it may occur. Although the light inside the patient is cool, the cable should not be allowed to lie on the drapes because it is a potential source of ignition and fire.

Both ends of the fiberoptic cable must have the correct fittings to attach to the lamp and to the endoscope or removable light carrier. The diameter of the cable varies from 2 to 5.5 mm to be compatible with the aperture for the light source. Cable lengths also vary from 6 feet (183 cm) to 9 feet (274 cm), so the projection lamp can be positioned at a distance from a sterile field.

Before use, the fiberoptic cable should be checked for damage. One end of the cable is held toward a low-power light, such as the overhead operating room (OR) light. With a magnifying glass, the opposite end is examined. Broken fibers in the cable will appear as dark spots like pepper, even to the naked eye. The cable should be replaced if more than 20% of the area appears dark. Newer light cables have a clear sheath for easier visualization of broken fibers.

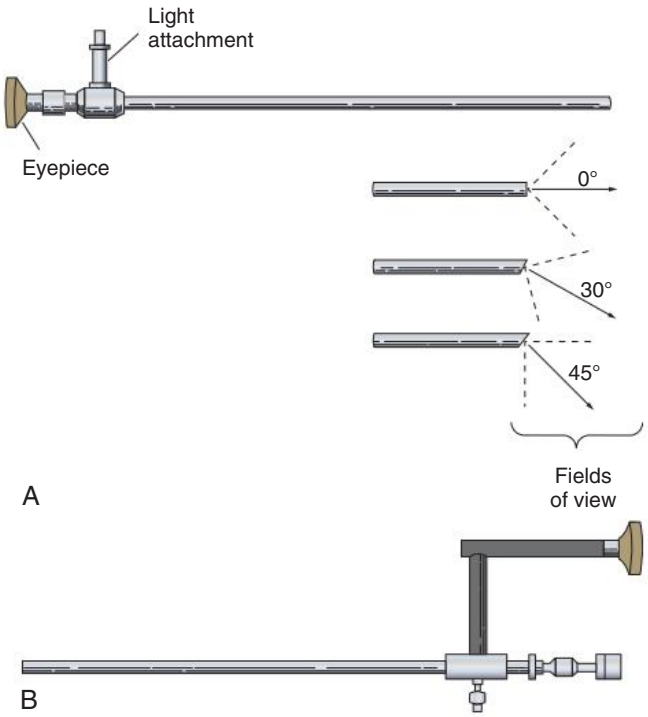
A xenon, quartz-halogen, mercury, or halide lightbulb provides an intense light source for transmission of light through a fiberoptic bundle to the distal end of the scope. Usually a portable, compact, self-contained unit, the light has an intensity that may be regulated from 400 foot-candles to as much as 5200 foot-candles, and up to 5500 Kelvin daylight in some illuminators.

2. Other
   a. Incandescent bulbs screw into the fitting at the end of a removable light carrier or at the end of a built-in lens system. Electric current is conducted through a single-filament wire to illuminate the tiny incandescent lightbulb. Very few instruments use this lighting system. Older-model rigid laryngoscopes are an example.
   b. Indirect lighting is used with specula, such as vaginal, nasal, or anal.

Vision within the Working Space

1. *Scope:* The length of the scope varies but is appropriate to reach the desired structure. The surgeon views anatomic structures through a telescopic lens. The diameter of the scope varies from the 1.7-mm needle fetoscope to the 5 mm or less of the arthroscope to the 10 to 12 mm of a laparoscope.
   a. *Rigid:* A rigid scope is a telescopic rod-lens system that permits viewing in a variety of directions, such as a cystoscope. The direction of a telescope lens can be straightforward (0 degrees) or angled (30, 45, 90 degrees). Laparoscopes are made in two styles—diagnostic and operative. The diagnostic laparoscope is a single telescopic rod-lens with no accessory ports (Fig. 32.4, *A*). The operating laparoscope has the rod-lens system with one working channel (see Fig. 32.4, *B*). Operating laparoscopes have been in use since the 1970s and were the first scope to use an umbilical single incision approach. Gynecologic surgeons used the operating laparoscope for tubal ligation and exploratory procedures.

      Rigid telescopes are metal and use fiberoptic illumination. Disposable models are available. The rigid telescope used in laparoscopy is placed into the body through the primary trocar sheath.
   b. *Rigid hollow:* Disposable plastic sigmoidoscopes, anoscopes, and otoscopes are available. Illumination is from a separate light carrier rod. Rigid bronchoscopes have additional side ports for administration of oxygen or anesthetics. These scopes are used through a natural body orifice.



• **Fig. 32.4** Basic rigid endoscopes. **A,** Standard rigid endoscope. **B,** Single-puncture laparoscope with working channel.

• **Fig. 32.5** Flexible endoscope.

c. *Flexible:* Flexible scopes have a directional adjuster dial that contours the lensed tip into and around anatomic curvatures to permit visualization of all surfaces of the wall of a hollow structure, such as the upper and lower gastrointestinal tract (Fig. 32.5).

The user can look directly into the eyepiece, or an attachment can be placed over the eyepiece to project the image onto a video screen. Flexible endoscopes have working channels that permit the manipulation of flexible biopsy forceps and laser fibers. A separate suction channel is on the opposite side. Two trumpet valves located near the eyepiece control suction and insufflation with air to create a viewing and working space. The covering of flexible endoscopes is made of silicone-plastic material and is usually latex-free.

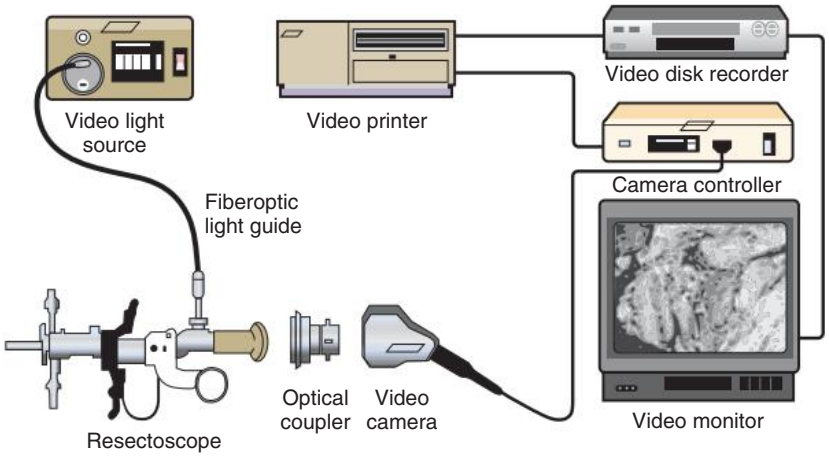
2. *Camera:* A camera can be mounted to the eyepiece of the endoscope. Some cameras are used sterile, and others are high-level disinfected and covered with a sterile camera drape. The camera consists of a coupler that attaches to the eyepiece of the endoscope, a camera head, a connecting cable, and a connector to attach the camera to the camera controller box (Fig. 32.6).
   a. *Video:* Endoscopes may be attached to a still or video camera so that organs or lesions can be photographed during a procedure. Video cameras with recorder/player/printer equipment require high-powered light sources for photographic applications and video documentation.

   By viewing high-resolution monitor(s), the endoscopist can manipulate instruments for diagnostic examination or to perform a therapeutic procedure. Video documentation can be obtained by recording the examination or procedure on a flash drive or to a CD. Microcomputer imaging systems with a printer can reproduce these images into still photographs. This equipment is either kept on a mobile cart or permanently placed in ceiling-mounted articulated booms (Fig. 32.7).
   b. *Monitor:* More than one video monitor is recommended for ease of viewing the image transmitted by the endoscope by the entire team. Placement of the monitors in the direct line of vision of the surgeon and the first assistant eliminates the need to turn the head away from the field and prevents stiff neck and fatigue.

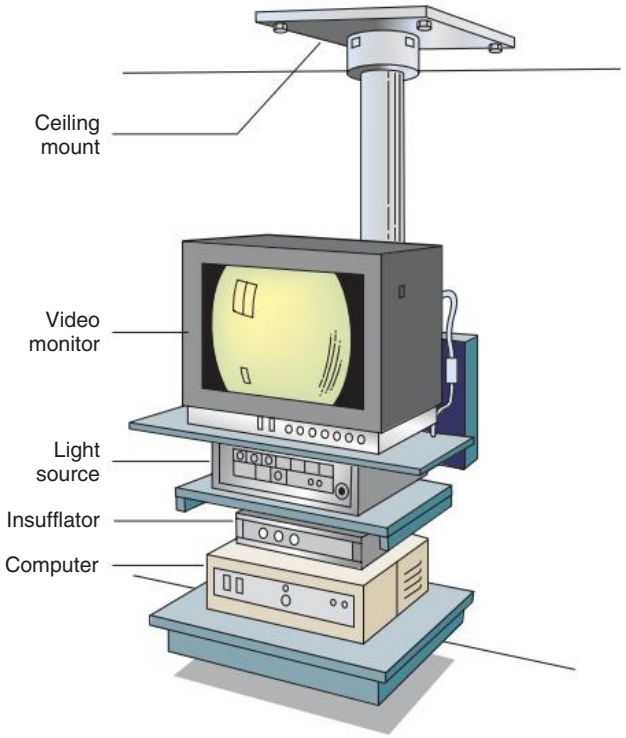
   Flat-panel monitors can be suspended from the ceiling on articulated arms that permit the user to place the viewing plane in a position of function.
   c. *Wireless capsule endoscopy:* An endoscopic camera can be ingested to visualize the small bowel. The camera weighs around 4 g and measures 11 mm—about the size of a jellybean.

   The endoscopic capsule contains four light-emitting diodes (LED) and a color camera. It travels by peristalsis through the small bowel, taking up to 50,000 images over an 8-hour period. The patient wears adhesive reception pads that transmit to a small receiver worn on a belt. No food may be consumed for 4 hours; however, liquids can be taken 2 hours after swallowing the capsule. The capsule endoscope is excreted naturally in the feces after a few days. If the capsule is not expelled, an x-ray should be taken to rule out a stricture causing entrapment of the device.

   The diagnostic capabilities have proven effective even when a negative finding was noted by other means. This method of video endoscopy is useful for patients who weigh more than 20 kg and children older than 10 years.
3. *Microscopic attachments:* The optical system of some endoscopes can be attached to a specially designed operating microscope such as the colpomicroscope (colposcope). The illumination of the endoscope and binocular magnification of the microscope permit study of abnormal tissues and/or therapeutic procedures in areas otherwise inaccessible without an open surgical procedure. Many microscopes have manipulators or "joysticks" that permit the use of laser during the procedure.
4. *Ultrasonic imaging:* A high-frequency ultrasound transducer at the end of a fiberoptic endoscope provides visualization of the heart, liver, pancreas, spleen, and kidneys. Interventional use during diagnosis of mediastinal, retroperitoneal, and gastrointestinal disease is enhanced by the use of endoscopic ultrasound scopes.
   a. *Radial echoendoscope:* Provides rotational ultrasonic imaging between 270 and 360 degrees of circumference at the tip of the endoscope. The radial scope has no access port for fine needle aspiration.
   b. *Linear array endoscope:* Provides straightforward imaging. It has a working channel for fine needle aspiration and a Doppler for sensing vascular structures.
   c. *Single ultrasound probes:* Provides vision similar to the radial ultrasound endoscope, but is introduced through a regular fiberoptic endoscope.



• **Fig. 32.6** Camera and video setup for endoscopy.



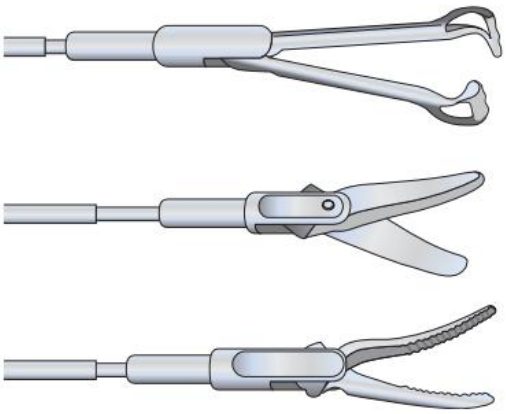
• **Fig. 32.7** Ceiling-mounted endoscopic equipment.

5. *Radiographic assisted:* Fluoroscopy may be preferred to video images for visualization of certain procedures such as radioactive implantation.
   a. *Contrast media:* Radiopaque contrast can be injected into the lumen of the biliary system or other structure to observe for patency or obstruction.
   b. *Radioisotopes:* Radioisotopes can be injected and traced with sensitive detector probes.

Manipulation and Maneuverability within the Working Space

For puncture endoscopy, one or more 5 to 12-mm secondary trocars are inserted through the abdominal wall under direct video visualization at strategic points. This is to create working access portals for graspers, cutters, dissectors, staplers, and suturing devices for tissue manipulation. These accessory instruments can be passed through channels in the endoscope to, for example, remove fluid or tissue; coagulate or ligate bleeding vessels; or inject fluid, contrast media, or dye to distend cavities. The accessories will be determined by the type of endoscope and purpose of the procedure.

1. *Instrumentation:* Dissectors, graspers, hooks, spatulas, snares, clamps, needle holders, specimen catch bags, and probes are available for tissue manipulation through the endoscope (Fig. 32.8). The length and diameter are appropriate to the type of endoscope in use. The handle and shaft of the instrument can be rigid or flexible for procedure-specific maneuverability.
   Laparoscopic tip designs include duckbill (flat straight), dolphin (pointed straight), Babcock (tubular grasper), and Maryland (curved). Most have ring handles. Some handles lock and others simply grasp. The surface of the jaws can be smooth, serrated, or toothed and can be articulated, single action, or double action. Some of the jaws rotate. Special dissectors such as a peanut or Kittner are available on long probes for use in blunt dissection.
2. *Suturing, stapling, and clipping instrumentation:* Laparoscopic suturing instruments have one fixed and one mobile jaw. The handles lock to securely hold the needle for complex intracorporeal stitches. Knot pushers slide the knot into place. A special suturing device that shuttles the needle back and forth



• **Fig. 32.8** Examples of instrumentation used in endoscopes.

through tissues can be operated with one hand. To reverse the direction of the needle the surgeon presses a lever. LAPRA-TY clips can be used to secure sutures without tying a knot.

Endoscopic gastrointestinal anastomosis (GIA) linear stapling and cutting instruments require a 12-mm port.[2] The jaws have markings to help the surgeon line up the tissue for manipulation and stapling. Linear staplers are available to create 3 to 4 row staple lines without cutting. These can be used to close an enterotomy. Care is taken not to staple across a second staple line or incorporate Ligaclips in the dissection plane.

Laparoscopic clip appliers require a 10 or 12-mm access port. Most disposable styles have a rotating jaw and a self-loading mechanism. Clips range in size from 6 to 11 mm.

3. *Functional energy-driven devices (laser, ultrasonics, suction, irrigation, electrosurgery):* A laser beam can be focused through some endoscopes. Argon, potassium titanyl phosphate (KTP), holmium:yttrium aluminum garnet (Ho:YAG), and neodymium:yttrium aluminum garnet (Nd:YAG) lasers will pass light through a fiber. The CO_2 laser can be directed through a rigid endoscope or the interior mirror system of a multiarticulated arm of the operating microscope. The beam is then focused through the endoscope, which is usually held in a self-retaining device.

   A distal smoke-evacuation suction device clears plume to maintain visibility through the scope and at the site of lasing. The endoscopes are specifically designed for adaptation to the articulated arm of the CO_2 laser (e.g., the CO_2 laser laparoscope and CO_2 laser bronchoscope).

   Ultrasonic waves can be used through an endoscope to disassociate tissue or materials such as stones for removal from the body via suction or retrieval devices. Other forms of ultrasonic dissection are found in the harmonic scalpel, which moves at more than 50,000 vibrations per second to denature protein without heat. It seals small vessels by coagulation as it incises.

   An active electrode connected to a monopolar electrosurgical unit (ESU) may be used through an endoscope for surgical procedures or a resectoscope for transurethral surgery in urology. A variety of electrodes, both disposable and reusable, are available in many lengths and configurations. They must have adequate insulation and be inspected for defect before use. Care is taken not to activate the ESU tip when it is touching any of the metal staples or hemostatic clips because they may conduct the energy causing tissue injury.

   Electrical energy transfers by capacitance from the activated electrode through intact insulation into other nearby conductive materials. Unless a safe path is provided for current to return to ground, the current induced by capacitance might cause an unintentional burn on nontargeted tissue.

   Direct coupling occurs when the activated electrode touches other metal instruments, particularly the laparoscope. An all-metal trocar/cannula system allows accidental contact to dissipate through the abdominal wall. The surgeon should avoid activating the electrode unless it is in direct contact with the tissue.

   A shielding and monitoring system is commercially available for monopolar endoscopic electrosurgical electrodes. Bipolar instruments, including dissectors, scissors, and graspers, eliminate the potential hazard of stray currents with monopolar electrodes.

4. *Adjunct organ displacement:* A uterine manipulator such as a tenaculum can be placed through the vagina to the inside of the uterus or attached to the cervix. This manipulator can be reusable or disposable and may have a channel for the instillation of colored dye for chromopertubation or radiopaque contrast medium to observe for uterine configuration and tubal patency by x-ray. The uterus can be displaced into the desired position by moving the exterior portion of the device cephalad, laterally, anteverted, or retroverted to view the pelvic structures. Some devices have a disposable patient intrauterine cannula with a reusable handgrip (e.g., Rumi or Humi).

   Retractors can be placed through the laparoscope to provide additional exposure or displacement of organs in the endoscopic field. The expanding styles (fan-type) have hinged joints so they can be passed through the trocar sheath into the peritoneal sac and then opened widely to retract organs.

5. *Robotics:* A voice-actuated articulated arm can be used as a steady camera-holding device. The surgeon uses a programmed voice card to instruct the arm where to position and reposition the camera. Adjunct robotic manipulators can be used by a surgeon seated at a control panel manipulating joysticks to activate instrumentation inside the patient.

6. *Hand-assisted access sleeves:* Larger organs may require a tactile sense for diagnosis or excision that cannot be attained by endoscopic instruments alone. The surgeon can make a small 3-inch incision and insert a sterile inflatable or gel sleeve through which he or she can insert a hand into the abdomen without losing the pressurized field.

   After sleeve assembly is placed in the incision, pneumoperitoneum can be established. Organs can be palpated or grasped by hand and removed. This method is particularly good for laparoscopic splenectomy and any specimen greater than 5 to 8 cm. Darker gloves are suggested for less light reflection on the video monitor.

Capture of Specimens within the Working Space

1. Graspers and snares can be used through an endoscope to remove tissue specimens through the same access portals as the trocars. Some specimens are too large to pass through the trocar sheath, so the sheath is removed and the specimen is withdrawn through an enlarged incisional puncture or hand-assist portal site.

   Instrumentation used in tissue capture can be used through all forms of endoscopes. Some instruments of this type have electrosurgical capabilities to provide hemostasis in the process.

2. Pouches with drawstrings can be introduced through the trocar sheath to capture an entire specimen for delivery to the surface via the access portals created for the trocars. Larger pouches can entrap specimens for morcellation. Pouches are available in many sizes, including capacity for a 2-kg specimen.

Evacuation of Gases, Fluids, and Solids from the Body

1. Gases, fluids, and solids can be evacuated through an endoscope. Suction irrigators are commonly used. Ultrasonic dissectors use this principle for the evacuation of tissue through the suction port on the endoscopic instrument. The substances are biohazardous because they contain blood and body fluids.
2. Containment is used when evacuating CO_2 after the procedure is completed. The gas should not be evacuated into the room air, because it contains biologic particles.

Closure or Minimizing of the Access Portal(s)

1. Closure of target internal organs with suture or other media such as staples and clips can be performed through the endoscope. Intraabdominal ligation is achieved with loops of chromic or plain surgical gut (Endoloop ligatures). After the applicator is passed through the scope, the loop is placed around the tissue and pulled taut. An endoscopic swaged needle-suture is passed in a needle holder for suturing. Intracorporeal (inside body) and extracorporeal (outside body) knotting techniques are used to secure sutures. Endoscopic ligating clips and staples also are used for ligation and tissue approximation.
2. External punctures and incisions are closed. In adults, incisions of 5 mm are closed at the subcutaneous level; however, 10-mm incisions are closed at the fascial level to prevent herniation. In pediatric patients, 5-mm incisions are closed at the fascial level proportionate to body size.
3. Natural closure by physiologic structures such as muscular sphincters requires no intervention by the surgeon. Rigid tubular anatomy, such as bronchi, is unaffected and requires no specific closure.

Knowledge and Skill for a Safe Endoscopic Environment

Attributes of the Endoscopic Team

Each member of the endoscopic team has an important role in the performance of the surgical procedure. The intricacies of the instrumentation and the limits of the visual field require strict attention to detail and awareness of each step in the endoscopic process. The attributes of the team members complement each other within their own scope of practice. Together, they provide the knowledge and skill necessary for the safe and effective performance of an endoscopic procedure. Each member anticipates the needs of the other and is prepared to convert to an open procedure at a moment's notice.

Attributes of the Surgeon

The surgeon must have an expert knowledge of anatomy and physiology. Landmarks can look distorted and unusual through an endoscope. An inexperienced person would not be able to recognize physiologic structures in this visual context. Manual dexterity is critical for all phases of the procedure. During a puncture laparoscopy, major vascular and digestive structures are in significant jeopardy if an insufflation needle is blindly placed or if a trocar is aimed in the wrong trajectory.

Eye-hand coordination is essential for specimen capture and tissue suturing. The inability to directly view target structures with the naked eye may present some distortion of the field. Working from a monitor screen instead of using direct vision can be awkward because the eyes are not directed to the area of manipulation.

Types of Endoscopic Procedures

Not all endoscopic procedures are performed as sterile procedures; some are aseptic (high-level disinfection). An endoscope is introduced into the gastrointestinal tract through the mouth or anus. It touches only intact mucous membranes. The gastrointestinal tract normally harbors resident and transient microorganisms. Although the procedure is not considered sterile, patients and personnel are protected from cross-contamination.

Endoscopes are thoroughly cleaned and terminally sterilized or undergo high-level disinfection after use. The Spaulding classification recommends sterilization for semicritical items, including endoscopes. Accessories or instrumentation such as biopsy forceps that come into contact with nonintact tissue should be sterile. High-level disinfected flexible endoscopes should be hung from a rack after terminal processing. They should not be stored in an enclosed case, because the working channels could harbor and grow microorganisms. Instruments should be stored according to the manufacturer's recommendations. Many endoscopic procedures are performed in an endoscopy unit rather than in the OR.

Endoscopy is performed as a sterile procedure if body tissue will be incised or excised or if a normally sterile organ or body cavity is entered, such as the bladder or uterus. Ideally, the endoscope and all accessories should be sterile regardless of the point of entry. Consider the entry of the vascular system when taking biopsies and the possibility of microbial contamination.

Control of scheduling endoscopic procedures and adequate instrumentation will help provide sterile endoscopes for every patient. Written policies and procedures must specify accepted practices for patient care and infection control. AORN (The Association of periOperative Registered Nurses) has developed recommended practices for the use and care of endoscopes to be used as a guide in establishing processing procedures.

Only sterile endoscopes and accessories should be used on patients with suppressed immune systems, such as from chemotherapy or steroid therapy or human immunodeficiency virus (HIV)-related diseases.

Routine practices should be established to reduce the risk for potential patient injuries and complications. These practices include but are not limited to the following:

- Training for and demonstrating competence in the use and care of endoscopic equipment by surgeons and perioperative personnel
- Providing complete sets of properly prepared, functional instruments
- Monitoring the patient for changes in physiologic status (e.g., development of hypercapnia and/or hypothermia can be caused by CO_2 insufflation)

All patients should be prepped and draped for conversion to an open procedure when warranted because of recognized or potential complications. Instrumentation and supplies for an open procedure should be readily available. The surgeon should inform the patient preoperatively of this possibility and should obtain an informed consent.

Laparoscopic Procedure

After the patient has been anesthetized, intubated, prepped, catheterized, and draped, the OR bed may remain flat or be tilted approximately 5 to 10 degrees into a slight Trendelenburg's position. A Veress needle, blunt Hasson trocar, or single-port access device is inserted into the peritoneal cavity through a small infraumbilical incision to create the primary access portal. The anterior abdominal wall is thinnest and less vascular at the lower edge of the umbilicus, along the linea alba, which makes this area easiest for penetration of a single layer of fascia and peritoneum with minimal interruption of skin and dermal blood vessels.

The average adult peritoneal cavity is insufflated with CO_2 to an intraoperative pressure of 12 to 15 mm Hg to create the working

space. Obese patients may need higher insufflation pressures to counteract the weight of the abdominal wall. The circulating nurse monitors this pressure during insufflation; it should not fall below 8 mm Hg or rise above 18 mm Hg.

After sufficient pneumoperitoneum is established, the patient is placed in a slight reverse Trendelenburg's position to shift abdominal contents caudad for upper gastrointestinal procedures. A padded footboard should be in place to prevent the patient from sliding downward on the OR bed. Moderate Trendelenburg's position is used for lower pelvic procedures to shift abdominal contents cephalad.

If a Veress needle is used to create the working space with CO_2 gas, it is replaced by a trocar and sheath, which is inserted into the peritoneal cavity. The insufflation tubing is disconnected from the Veress needle and attached to the inlet port of the trocar sleeve. The sharp obturator is then removed from the trocar sheath. A rigid 7 or 10-mm, 0-degree laparoscope with a light cable is introduced into the abdomen through the trocar sheath. The sheath matches the size of the laparoscope.

If the Hasson blunt trocar is used, the trocar is placed percutaneously through the abdominal wall. The surgeon will make an incision and enter the peritoneal cavity. The edges of the deeper tissue will be held with silk traction sutures or S-retractors as the trocar is introduced. Once in position, the Hasson will be attached to the insufflation tubing and used to insufflate, creating the working space without the blind puncture technique. Once the working space is established, the blunt obturator will be removed and the laparoscope is inserted. The use of a Hasson trocar is referred to as *open laparoscopy.*

The cold CO_2 gas flowing through the primary access portal sleeve may cause the lens to fog as the scope enters the warm peritoneal cavity. Some surgeons use a sterile antifog solution on the laparoscope lens. Commercial scope warmers that look like a thermos canister may be used. The container should contain only warm sterile water. Saline use can be corrosive to instrumentation. Disposable active charcoal scope warming sleeves are available. They are easy to use and convenient.

If a single-port device is not used, one or two secondary 5, 7, or 10-mm trocars are inserted through the abdominal wall under direct vision through the laparoscope. Placement of multiple secondary trocars will form a triangular pattern on the abdomen for insertion of multiple instruments. The CO_2 insufflation tubing can be connected to a secondary port inlet to minimize the effect of the cold gas against the laparoscope lens that could cause fogging inside the warm body of the patient.

If 10-mm trocars are used, sizing caps or lumen reducers can be used to reduce the opening of the sheath for the use of smaller endoscopic instruments and probes. The use of size-reducing caps prevents the escape of pneumoperitoneum.

A sterile camera attached to the laparoscope transmits images on video monitor(s). Two monitors, one on each side of the OR bed, generally are used. Without straining their necks, the surgeon and the team can view the manipulation of instruments inserted through secondary ports in the direct line of vision.

At the conclusion of the procedure, the CO_2 should be evacuated through the suction port on the trocar into the vacuum system and not expelled directly into the room air. The expelled gas contains plume, blood, and body fluids that cause airborne contamination. Personal protective equipment, such as masks and eyewear, should be worn by all personnel in the room.

Some surgeons prefer to use a gasless method for displacing and expanding the abdomen during laparoscopy. A device referred to as an *abdominal lift* can be used to elevate the abdominal wall for minimal access procedures without the use of CO_2. Shorter instrumentation can be used, because the internal organs are closer to the surface.

Pediatric Endoscopy

Pediatric endoscopy is gaining favor as a method of diagnosis and treatment. Procedures such as appendectomy, pyloromyotomy, fundoplication, orchiopexy, nephrectomy, ureteral procedures, and cancer staging are examples of endoscopic surgery performed successfully in children. Robotic approaches are generally successful; however, the procedural time may be increased. One advantage is the robotic instrument tips are much smaller than the surgeon's hands and can accomplish delicate maneuvers relatively easier.

Procedural Considerations for Laparoscopy in Children

Anatomic differences between children and adults are most pronounced between the ages of birth to 8 years. Infants have large umbilical vessels that are easily damaged and may even be permeable to CO_2. The processus vaginalis at the inguinal ring may be weak and easily inadvertently opened by a pneumoperitoneum. The aortoiliac axis is nearer the surface and may be punctured by the trocars or instrumentation. The left epigastrium or the right hypochondrium is a good site for initial insufflation. A 1-year-old child may accommodate a 1-L working space. Smaller, shorter instruments and scopes should be used.

The visual field is limited by the small size of the child, sometimes as small as 4 to 5 mm. Hasson trocars and sheaths may be preferred to other methods if CO_2 insufflation must be used. In some circumstances, abdominal wall lift devices are more appropriate for a safe and effective procedure.

General anesthesia is used, and the child should have an empty bladder. The bladder is higher in the abdomen than it is in adults. A Foley catheter and a nasogastric tube are useful for decompression of internal structures before a laparoscopy. After the skin prep and sterile draping, the infraumbilical incision is made. A mosquito hemostat is inserted into the incision and opened to stretch the wound slightly.

Some surgeons prefer to use an open laparoscopic method as opposed to a blind puncture. A radial dilating trocar can be placed in the tiny incision and can be sequentially enlarged with instrumentation to the desired size. It can be secured with suture to prevent dislodgment. Pneumoperitoneum is established with CO_2 insufflation at 8 mm Hg to the desired level. Pressure should not exceed 8 mm Hg for infants and 12 mm Hg in children to 8 years of age. Smaller telescopes are usually adequate with a 0 to 30-degree viewing angle. Secondary trocars are inserted sharply under direct vision of the laparoscope.

Endoscopy and the Pregnant Patient

Endoscopy is rarely performed on pregnant patients. The usual risks for laparoscopy are present with addition of the risk to the fetus and the potential for preterm birth. The team must keep in mind that two patients are involved with the procedure. The risk for spontaneous abortion is ever present. If the fetus is viable, the team must be prepared for a surgical preterm delivery.

The most common laparoscopic applications include appendectomy, cholecystectomy, and ovarian procedures. Newer procedures include laparoscopic cerclage of the uterine cervix for patients with cervical insufficiency (formerly known as cervical

incompetency). The isthmus of the cervix can be banded with Mersilene tape before the 13th week of gestation.

Laparoscopy during the first trimester potentially increases the risk to the developing fetus as a result of the anesthetic. The severity of the mother's disease such as infection or preeclampsia plays a role. Second-trimester laparoscopy increases the risk for nontarget organ or vessel damage because the typical landmarks are distorted. Visceral displacement by the enlarging uterus changes the landscape of the internal structures.

Recommended techniques include using the open laparoscopic method employing the Hasson trocar and minimizing operative times. The patient should have her right side slightly elevated to displace the uterus from the inferior vena cava and a Foley catheter to keep the urinary bladder empty.[4] Antiembolic hose should be applied to decrease the risk for deep vein thrombosis (DVT). If x-ray will be used, the fetus should be completely shielded. Uterine manipulators are not used.

Placement of the primary trocar depends on the height of the fundus. The open technique using a Hasson trocar is a safe method. A Veress needle can be used under ultrasound guidance. A subxyphoid approach between 2 and 6 cm above the umbilicus is a common location. An alternative site is Palmer's point in the left upper quadrant, 2 cm below the costal margin at the midclavicular line. The secondary trocars can be placed under direct visualization. Single incision ports have been used with some success.

End-tidal CO_2 should be monitored closely and maintained between 25 and 30 mm Hg to prevent fetal acidosis. The intraperitoneal pressure should be between 12 and 15 mm Hg. If the fetus is of viable age (around 24 weeks) a transvaginal ultrasound should be used. Any sign of fetal distress indicates the need to release the pneumoperitoneum immediately. If the fetus is not of viable gestational age, a Doppler should be used to document heart tones preoperatively and postoperatively. More information about pregnant patients and endoscopy can be found at www.sages.org.

Hazards of Endoscopy

Endoscopy is not without its hazards. Minimally invasive surgery requires appropriate credentialing. Surgeons who wish to perform laparoscopy and other endoscopic techniques should be credentialed through the medical staff department. Personnel who are responsible for scheduling endoscopic procedures should confirm the surgeon's practice privileges. Serious complications of endoscopy include the following:

1. *Perforation:* Perforation of a major organ or vessel is a constant cause for concern when sharp trocars and rigid scopes are used. Flexible fiberoptic endoscopes have decreased this danger, but it remains a potential complication. Patient positioning from supine to Trendelenburg's position shifts the intraabdominal anatomy, causing elevation of the major vessels of the lower abdominal cavity. Care is taken to prevent inadvertent injury to these structures while holding cameras or other devices situated in intraabdominal trocar sleeves during repositioning of the OR bed.

   The sharp obturator should be examined briefly after it is withdrawn from the trocar sleeve. The presence of gross blood, stool, bile, or other unidentified substance may indicate perforation of an intraabdominal organ.
2. *Bleeding:* Bleeding can occur from a biopsy site, pedicle of a polyp, or other area where tissue has been cut. Endoscopic sutures or clips can become dislodged. Care is taken to observe for pooling of blood in the body cavity that may indicate venous oozing or other vessel disruption.
3. *Hypothermia:* CO_2 is colder than body temperature. The patient may experience moderate to severe hypothermia if other warming measures, such as forced-air warming or heating blankets, are not used. Hypothermia can alter the effects of propofol and increase the incidence of hypothermic coagulopathy.
4. *Preperitoneal insufflation:* If the Veress needle was not inserted completely into the peritoneal cavity, the CO_2 can be insufflated into the preperitoneal tissues. The trocar can be inserted and the gas evacuated through the inlet side port. The gas is a biocontaminant and should be evacuated via the suction.
5. *Gas embolism:* Gas in the vascular system can cause a cardiovascular collapse. Signs include dysrhythmias, tachycardia, cyanosis, and pulmonary edema. Treatment includes stopping the CO_2 flow, placing the patient in a left lateral position, elevating the right side slightly, hyperventilating with 100% O_2, and the anesthesiologist can pass a right CVP catheter to aspirate blood from the right atrium (Durant's procedure).
6. *Incidental iatrogenic injury:* Robotic attachments or frames attached to the OR bed can cause pressure against the patient's body. Brachial plexus injury can occur after laparoscopic or robotic procedures caused by placement of the equipment. Stirrups and other table positioning devices can cause iatrogenic injury if not used safely.

Electrical systems used with endoscopy must conform to the standards and be subjected to the routine maintenance procedures prescribed by the National Fire Protection Association code for electrical safety. Two major electrical hazards associated with endoscopy are as follows:

1. *Improperly grounded electrical equipment:* If the surgeon will be using a monopolar ESU, place the return electrode on the patient with adequate skin contact to allow return of electric current. Only solid-state generators, and preferably bipolar active electrodes, should be used, to avoid variances in voltage. A new return electrode should be placed if the patient is repositioned from a lithotomy to supine position for an open abdominal procedure. The return electrode may gape and lose sufficient contact with the skin when the legs are moved. Pads should not be removed and repositioned. The adhesive may have weakened after the first application.
2. *Unsuspected current leaks:* Corrosion or accumulation of organic material can inhibit flow of current across the screw fitting between the light carrier and the bulb. Current can leak through the instrument to the patient. Ideally, endoscopes should not contain electrically conductive elements or metals that can corrode. Corrosion can be caused by repeated exposure to body fluids, hard water, or chemical agents.

Microorganisms, such as *Mycobacterium tuberculosis,* can be transmitted from one patient to another via a bronchoscope. *Streptococcus pneumoniae, Pseudomonas aeruginosa, Clostridium* organisms, and bloodborne pathogens also present potential hazards of cross-contamination. Personnel are exposed to potentially infectious body fluids and blood from aerosols, splashes, and contact with contaminated instrumentation. Gloves, masks, protective eyewear, gowns, and/or aprons are worn during endoscopic procedures and cleaning of equipment. Personnel should use standard precautions during endoscopic procedures and when handling and processing contaminated endoscopes and accessories.

Care of Endoscopes

Endoscopes are delicate and expensive instruments. Rough handling, jarring, or bending of parts should be avoided. They should never be piled on top of each other or mixed with other instruments. Endoscopes should be cleaned and flushed at the point of use with the manufacturer's recommended cleaning solution. Contaminated endoscopes should be transported to the processing area in a biohazard container. Facility policies should be in place for handling contaminated endoscopes for personnel safety.

All parts of endoscopes and accessories are thoroughly disassembled, mechanically cleaned, and terminally sterilized or subjected to high-level disinfection after use. The primary causes of infection, such as herpes, hepatitis, or condylomata transmitted endoscopically, are inadequate cleaning and disinfection or sterilization of endoscopic equipment.

Cleaning

All parts of the endoscope should be cleaned as soon as possible after use while organic debris is still moist. Mucus, blood, feces, and protein-type residue can become trapped in the channels of the scope. This material is difficult to remove if it dries and may render the scope useless.

Endoscopes should be washed in warm, never hot, water and a neutral, nonresidue liquid-detergent solution. A pipe cleaner or small brush may be used to clean inside the lumens of all channels. The stopcocks on some scopes should be thoroughly disassembled for cleaning, too, because dirty valves will stick. Stopcocks are opened for cleaning; they should never be forced but can be loosened with a drop of solvent or lubricant.

Particular attention should be paid to lens cleanliness, or viewing will be obstructed. Debris can be carefully removed from around the lens with a fine toothpick. Special lens paper is used on the lens itself. Lensed instruments should not be cleaned with any substance that could dissolve cement around the lens. Consult the manufacturer's recommendations.

The endoscope is rinsed thoroughly and dried well. If scopes are to be sterilized in ethylene oxide gas, they must be thoroughly dry. Ethylene oxide combines with water on items that are damp to form ethylene glycol. Alcohol on cotton can be used on a wire stylet or a pipe cleaner to dry insertion tubes. Air can be forced through channels to dry inside them. Because organisms will multiply in a moist environment, all parts should be dry during the interval before further processing or storage.

An endoscope processor is available to clean long, flexible fiberoptic scopes, such as a colonoscope. It has two modes of operation to process the scope and its channels: a wash-and-dry cycle and a cycle of wash, disinfectant soak with activated glutaraldehyde solution, rinse, and dry. Some endoscopes are cleaned with a solution of hydrogen peroxide and peroxyacetic acid.[5] This equipment is an automated washer/disinfector.

Accessories are scrupulously cleaned. All debris is removed to ensure adequate steam sterilization. Disposable, single-use biopsy forceps and cytology brushes are recommended because the configurations of these accessories are particularly difficult to clean. Some trocars, scissors, and forceps have disposable or replaceable points or tips on reusable shafts or handles. These combination instruments facilitate cleaning and ensure a sharp cutting edge with each use.

Scopes and accessories should be inspected for damage after cleaning. Preferably, all endoscopic equipment should be terminally sterilized; otherwise it should be high-level disinfected after thorough mechanical cleaning.

Sterilization

After cleaning and drying, each endoscope with all of its parts disassembled is placed in a well-padded perforated tray of convenient size. Some endoscopes, such as an arthroscope, are supplied in a perforated case lined with foam cut to fit each disassembled part. The tray or fitted case is wrapped for sterilization. Instruments should be wrapped and sterilized by the method recommended by the manufacturer.

Some parts of endoscopes can be safely steam sterilized and therefore should be. Hollow, rigid metal sheaths, such as a sigmoidoscope, can be terminally steam sterilized after use but then may be stored to keep clean rather than sterile for a surgically aseptic procedure. Some fiberoptic cables also can be steam sterilized. Reusable biopsy forceps should be steam sterilized.

Parts with lenses and some fiberoptic carriers, such as a colonoscope, cannot be steam sterilized. High temperature and moisture will soften the cement holding lenses or fiberoptic fibers in place. The flexible shafts of some accessory instruments may erode when steam sterilized. These parts should be sterilized in ethylene oxide gas, hydrogen peroxide plasma, or soaked in a chemical sterilant solution if ethylene oxide or hydrogen peroxide is not available.[5] The lumens must be completely dry before sterilization.

The manufacturer may recommend that the pressure not exceed 5 lbs during ethylene oxide sterilization of a fiberoptic lighting system. The manufacturer's instructions for handling, using, cleaning, and sterilizing these items should be followed. Aeration is necessary after ethylene oxide sterilization. Ethylene oxide is a vesicant if it comes into contact with skin. It also can cause eye irritation.

If endoscopes and accessories are immersed in activated glutaraldehyde or acetic acid, a plastic tray should be used without a towel in the bottom. Prolonged use of a stainless steel tray may create an electrolytic action between the metals and can cause metallic deposits on instruments. Scopes and all accessories should be well rinsed in sterile distilled water before they are used, to prevent tissue irritation from solution.

Peracetic acid, another chemical sterilant in solution, is commercially available for sterilizing endoscopes for immediate patient use. The STERIS system has specialized tray assemblies for endoscope processing. These tray assemblies are not intended for long-term storage of sterilized instruments, but for immediate patient use.

Storage

If endoscopes are not wrapped for sterilization and storage, they are terminally sterilized by chemical means or at least undergo high-level disinfection before being returned to their respective storage cabinets. Clean, dry, unwrapped rigid instruments should be stored on a soft material such as plastic sheeting or foam. Towels hold a residue of laundry detergent that can tarnish metal. Flexible endoscopes with detachable parts should be stored disassembled, hung in a vertical position with the distal end pointed downward. Accessories also may be hung. The lumens should be flushed with alcohol to facilitate fluid evaporation.

The scope should be subjected to high-level disinfection or peracetic acid sterilization before use in patient care.

Considerations for Patient Safety

Endoscopy through a natural body orifice is usually performed on a patient who is not under general anesthesia. The following considerations should be included in the plan of care:

1. The patient should be monitored for signs and symptoms of reaction to drugs. Endoscopy is frequently performed with the use of sedatives and a topical or local anesthetic agent or with no anesthetic at all. The patient is awake during these procedures. Drugs such as midazolam (Versed), diazepam (Valium), opioids, and narcotics such as meperidine hydrochloride (Demerol) may be administered intravenously as an adjunct to other preoperative sedation to produce relaxation and cooperation during the procedure and amnesia afterward. Respiratory depression and transient hypotension can occur. Antagonistic drugs should be available to reverse narcotic depression. Emergency resuscitation equipment should be available.
2. A topical agent is frequently applied to nasal or oral and pharyngeal mucosa before introduction of an endoscope into the tracheobronchial tree or gastrointestinal tract. A topical agent may be instilled into the urethra before introduction of a cystoscope.
3. The teeth, gums, and lips are protected if the endoscope is introduced through the mouth. Dentures are removed. A mouthpiece is inserted.
4. Hydrogen and methane gases are normally present in the colon. These gases are flushed out with carbon dioxide (CO_2) before laser surgery or electrosurgery through the colonoscope to avoid the possibility of explosion within the colon.
5. Power sources and lights should be tested before each use and after cleaning. They should be kept in working order.
6. The heat generated from the projection lamp of a fiberoptic illuminator is dissipated. It should not be enclosed in drapes because the heat could set them on fire. If the unit contains a fan for heat regulation, the direction of airflow should be away from the patient and the sterile field to minimize airborne contamination.
7. Endoscopes should be smooth, with no nicks on the surface. A scratch on the sheath could injure tissue or the mucous membrane lining of an orifice. Metal endoscopes should be individually wrapped and sterilized to prevent surface scratches from contact with other metallic instruments. Metallic endoscopes should be handled only with gloved hands.
8. Extreme care should be taken to observe patients after endoscopic procedures for effects of respiratory or circulatory system distress caused by gas absorption, trauma, or medication.

Many flexible endoscopic procedures are performed on ambulatory outpatients. The patients must not leave the facility until vital signs are stable and side effects have passed. Follow-up phone calls are suggested within 24 to 48 hours to monitor patient progress and answer questions. Any patient concerns should be directed to the surgeon. Additional follow-up phone calls may be necessary.

Duties of the Assistant for Flexible Endoscopy

Often only a circulating nurse assists the surgeon with a minimally invasive procedure. The assistant's duties are as follows:

1. Set up the supplies and equipment as much as possible before the patient and surgeon arrive. Consult the procedure book. Remember that sterility must be maintained for a sterile procedure.
2. Explain the steps of the procedure to the patient as appropriate. It is important that the patient know the reasons for any discomfort that may be experienced so that symptoms of discomfort will be recognized as normal.
3. Explain the position and need for it before positioning the patient. The position the patient must assume during the procedure is often uncomfortable.
4. Drape the patient properly to prevent unnecessary exposure.
5. Adjust room lighting. The surgeon may want the room in semidarkness. A dimmer on the room light is helpful, but if one is unavailable, the x-ray view boxes may be illuminated to provide indirect lighting.
6. Divert the patient's attention as much as possible during the procedure. The patient may complain of pain more than is justified as a way of expressing displeasure at the invasion of the endoscope or the position required during the procedure. The circulating nurse should stay with the patient to offer reassurance and emotional support. Suggest that slow, deep breaths may help relaxation and lessen the discomfort. Soft music may help the patient relax. The surgeon may allow the patient to watch the procedure through a viewing attachment on the endoscope or on a video monitor.
7. Evaluate the patient's level of discomfort, and inform the surgeon of unusual reactions. The circulating nurse also monitors the patient's respiratory status, blood pressure, and pulse. Pulse oximeter and automated blood pressure devices may be used routinely. Vital signs should be documented before the procedure begins, every 15 minutes during the procedure, and again at the conclusion. Additional vital signs should be recorded when medication is given or tissue samples are excised.
8. Know how to assemble the different scopes and their accessories and how to operate them. When passing the suction tube or biopsy forceps, place the tip directly at the lumen of the scope so the surgeon can grasp the shaft and insert it without moving his or her eyes from the scope.
9. Care for surgical specimens as appropriate.
10. Take care not to drop endoscopic instruments; they are delicate and expensive. Fiberoptic bundles are glass; do not kink or bend them.

Endoscopic procedures are considered minimally invasive except for ophthalmoscopy, because the scope is placed into a body orifice or cavity. Many require one or more small skin incisions for insertion of the scope and accessories. Endoscopy is used for many diagnostic and surgical procedures.

AORN has developed recommended practices for endoscopic minimally invasive surgery.

Robotic-Assisted Endoscopy

The first robotic-type system available in the United States, AESOP (Automated Endoscopic System for Optimal Positioning), provides a stable laparoscopic telescope/camera holder with a bed-mounted articulated arm controlled by a voice-actuated computer.[6] The device is voice actuated by the surgeon who wears a microphone headset during the procedure to verbally direct the aim and direction of the laparoscope. The robot discerns verbal commands because a voice card trained with the surgeon's spoken word is inserted into a microprocessor housed in the base of the unit. Each command causes the sterile-draped articulated arm to respond by assuming the exact position requested by the surgeon.

Intuitive Surgical later developed Navigator to hold the laparoscope/camera assembly steady and to change the visual field from micro to macro without causing the sensation of "seasickness" in the team as they visualize the surgical site on the monitor. The Navigator regulates the temperature of the laparoscope to prevent fogging.

Robotic technology has revolutionized the endoscopic approach to surgery. The devices currently found in operating rooms around the world range from simple camera holders to full room control at the command of the surgeon. Examples of contemporary robotic-integrated components include the following:

- Environmental control computer platform
- Functional peripheral equipment
- Instrument manipulating robot
- Master control console

Environmental Control by Robotics

Environmental control robotic systems are built into a computer-directed platform in which the surgeon verbally controls other computer-generated activities such as lights, bed motion, and other devices during the surgical procedure.

Environmental control systems have been developed by which peripheral equipment such as the ESU, lights, OR bed, insufflator, light source, and other mechanized devices in the OR are voice controlled by the surgeon. The surgeon can address the system through his or her headset and request a preloaded computed tomography (CT) scan to appear on a computer monitor.

Real-time verbal and video documentation is recorded for the permanent record. The surgical report is generated by electronic media, and a hard copy is printed simultaneously. Many companies such as STERIS, Skytron, Stryker, Storz, Olympus, Medtronic, Ethicon Endosurgery, CONMED, and Berchtold have coordinated with several robotic companies to develop compatible devices.

Functional Peripheral Equipment

Machines used during the surgical procedure can be controlled by the environmental control computer platform. All the endoscopic equipment such as light source, insufflator, electrosurgery unit, irrigator, aspirator, image recorder, and video monitor can be activated, adjusted, and directed by the surgeon's touch on a foot pedal or command into his or her headset. Other devices in the room such as the spotlights and OR bed respond in kind to the direction given by the surgeon. Casual conversation is ignored by the computer.

Instrument Manipulating Robot and the Master Console

Surgical robots are hands-free systems wherein the surgeon sits at a master console several feet away from the field (Fig. 32.9). The surgeon remotely manipulates three to four articulated arms with joysticks while observing each precision action with a three-dimensional (3-D) binocular laparoscope and a 3-D digital camera on a 3-D high-definition video touch screen with full depth of field (Fig. 32.10). The camera system can work with low levels of light.

Early robotic features included a double console with a communication intercom that permits two surgeons to collaborate and work simultaneously. The system offered the surgeons more control over the video, audio, and customized ergonomic settings. Surgeons in training find this technology engaging and efficient for learning robotic technology. The foot pedals permit the primary surgeon to switch between energy modalities. Other features include a multi-image viewer that can tile the images for comparative views. The one-piece drape for the robot streamlines the setup procedure.

Most robots offer magnified 3-D high definition with true depth perception. The design allows for freedom of robotic cart positioning over all four quadrants of the patient. The daVinci Xi does not require draping, focusing, white balancing, or other calibration before use.

The surgeon has 1 cubic foot of comfortable space wherein to work the controls and switch views in real-time action. The daVinci robot will not operate if the surgeon's forehead is not seated inside the face port viewer. The unit will lock and remain immobile until the surgeon's head is again placed in the correct position (Fig. 32.11).

The backup battery will run for 20 minutes in the event of a power failure. The robot runs on a dedicated circuit and requires 24 hours to recharge the battery. Each robot has an emergency stop button in the event of malfunction. There is an override switch to continue the surgery if the fault is a false alarm.

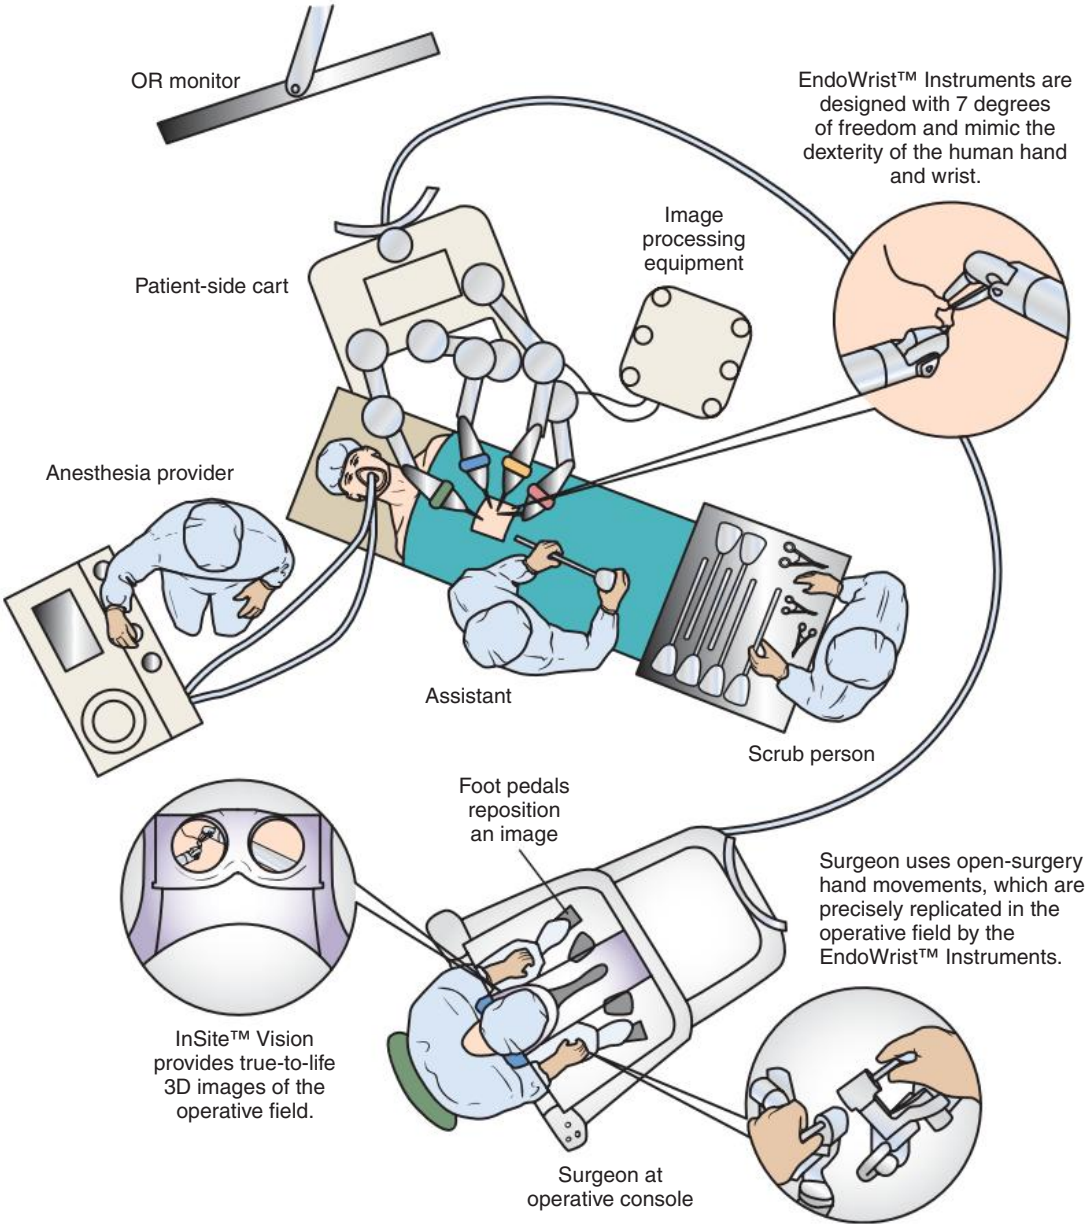
Each instrument is specially designed with a microchip that communicates with the computer to log each use. The computer tracks the function of the instrument and reports when it needs to be changed or repaired. Only instruments made by Intuitive Surgical or created by agreement with specific permissions work with the daVinci robot (i.e., harmonic scalpel, dissectors). Reposable instruments are available and should be cleaned with sterile water, never saline because of the corrosion potential. Most reposable instruments are good for 10 uses and may be marked with a permanent marker to document each use. Sterile wrenches are included in the instrument set in case of emergency conversion to an open procedure. The articulating arms can be disengaged at the field without contamination.

The system is voice actuated and may be controlled by a surgeon who is many miles away by telecollaboration, although this is not the intent of current technology. Many cardiac, prostatic, gynecologic, and general surgery procedures have been successfully performed by the surgeon using robotic technology. The articulated arms perform the procedure using a three- or four-arm laparoscopic system that offers a circumferential 360-degree wrist-like movement for precision grasping, manipulation, dissection, clamping, and suturing of tissues. Hand tremor is eliminated, and ambidextrous movement is facilitated with natural hand-wrist motion.

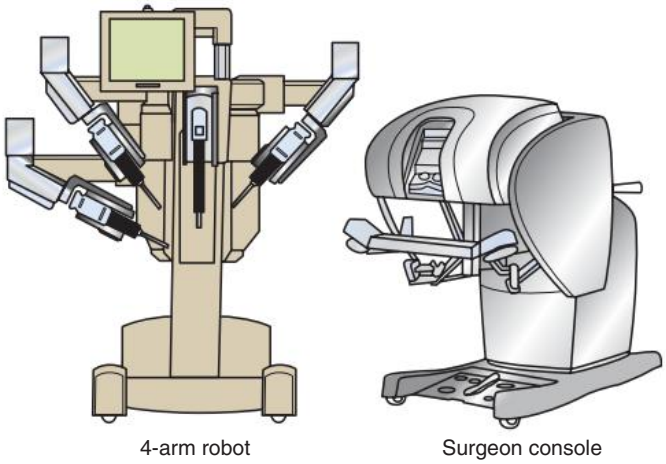
Motions are described in geometric terms aligned with 7 degrees of freedom in human wrist and arm-articulated motion. These motions are described as follows:

- Roll—rotation or circumduction
- Pitch—up and down
- Yaw—side to side
- Grip—open and close
- Insertion—back and forth
- Clockwise
- Counterclockwise

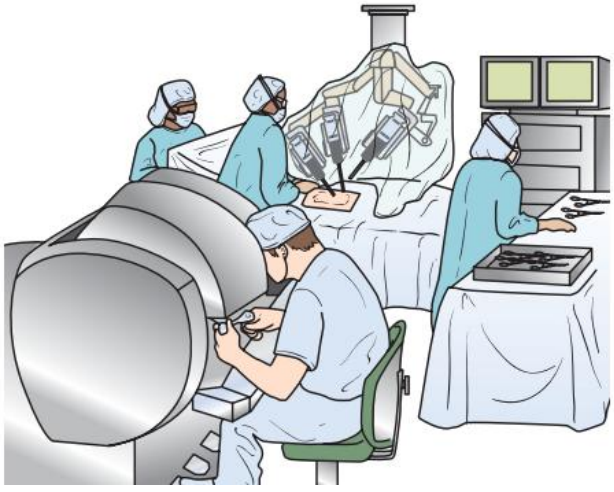
Specialty services such as orthopedics and neurosurgery have used robotics such as ROBODOC, ORTHODOC, and Neuromate by Intuitive Surgical. ROBODOC is a computer-controlled robot that drills bones for prosthetic implants and can remove old bone cement. ORTHODOC displays CT images for preoperative planning for hip arthroplasty. Neuromate is a surgical robot to assist with stereotactic brain surgery.



• **Fig. 32.9** Layout of a robotic system. *3D,* Three-dimensional; *OR,* operating room.



• **Fig. 32.10** Robotic components.



• **Fig. 32.11** Surgeon at robotic console.

The Mako robotic arm system by Stryker uses CT preoperative scans for planning, intraoperative cutting technology, and joint balancing for total knee, partial knee, and total hip arthroplasty.[7]

PROBOT assists with urologic surgery for prostatectomy. Instrumentation used through the access portals includes monopolar and bipolar electrodes, ultrasonics, sharp and blunt dissectors, graspers, clip appliers, and needle holders. Numerous robotic companies have designed robots with technology for use in specific surgeries such as ENT, spine, vascular, and cardiovascular surgery. The Magellan robotic system is designed for vascular catheterization. Emerging robotic systems can reach challenging areas with clear visualization and precise movement.

Virtual Reality

Research is being done to develop virtual reality training for surgeons and operators of complex technologic equipment. Virtual reality is the computer science of simulating real-life motion, time, and space. Computer-generated images mimic real-life situations. The surgeon-in-training practices a procedure without touching a real patient. The surgeon dons a specialized headset/visor and sensor gloves and selects the training scenario to be practiced. The computer displays a 3-D video of human anatomy in the headset/visor. The sensor gloves signal motion, direction, and pressure to a computer and in turn create a sensation of touch for the surgeon. The entire activity looks, feels, and responds as if the surgeon were performing surgery on an actual patient. This investigative technology can allow for "practice surgery" while evaluating the skill and dexterity of the surgeon.

The possibilities for integrating advanced technologies to simplify surgery and make it less painful and safer for patients seem endless as surgeons develop and refine innovative techniques. The challenges for all members of the OR team are to learn about technologic advances and monitor the quality of patient care in their application. Engineering performance (i.e., clinical application of biotechnology) is measured by reliability, safety, maintenance, and effectiveness of equipment. Clinical performance is measured by the skills of users to achieve desired results—a successful outcome for the patient.

Human Intervention during Robotic-Assisted Procedures

A sterile team is at the sterile field to guide tiny 1 to 2-cm incisions through the skin, place the Veress needle or trocars, and perform typical activities, such as draping, sponging, and dressing the surgical site.

The FDA requires the manufacturers to provide training for surgeons. Facilities using robotics require credentialing before the surgeon can schedule procedures. The surgeon should be mentored for 15 or more procedures before operating solo.

Although referred to as *robotic,* the procedures performed using machines require the surgeon's hands to manipulate the joysticks so the articulated arms and tips can mimic his or her motions on a microscopic level. None of these devices have the power of decision making, and cannot run without human intervention.

Advantages and Disadvantages of Robotic-Assisted Surgery

Advantages of robotic-assisted techniques include greater precision than the human hand can provide alone and greater freedom of motion, without the tremor and fatigue associated with maintaining a position for a long period.

Disadvantages of the computerized systems include startup costs, the learning curve, and time in training. Long-term studies need to be done to establish the full range of uses and efficacy. Many standardized procedures will need revision in order to be suited to the new technology. Additional consideration should be given to the size and positioning of the robotic arms and oversized console units. Each component is draped. Computerized technology requires adequate space for the additional machinery and team members. Ceiling-mounted booms may provide consolidation of essential endoscopic machinery, thereby reducing the floor space used by the large pieces of equipment. The use of the room is limited for other surgical procedures when the mounted equipment cannot be easily rotated out of the field.

Some surgeons state that the "haptic sense" is lacking, meaning that the tactile sense, or touch, of tissues is not as sensitive as working inside an open patient for some procedures.

General Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Describe the pertinent surgical anatomy of the breast.
- Describe the surgical procedures used to diagnose breast cancer.
- Identify the pertinent anatomy of the abdominal organs within the peritoneal cavity.
- Discuss the differences between laparoscopic and open cholecystectomy.
- List the types of anastomoses used for intestinal surgery.
- List several surgical diagnostic procedures used to evaluate abdominal trauma.
- Differentiate between direct and indirect inguinal hernia.
- Discuss the psychologic effects of limb amputation on the patient under regional anesthesia.

KEY TERMS AND DEFINITIONS

-itis Inflammation of an organ or part.
-ectomy Removal of an organ or part.
-otomy Opening into an organ.
-ostomy Creation of an opening in an organ or part intended to remain open permanently or for an extended time.
-orrhaphy Repair and fixation of an organ or part.
Anastomosis Surgically joining two lumens to create a patent passage.
Laparotomy Surgically opening the abdomen for an exploratory or definitive surgical procedure.
Resection Removal of a segment of an organ or part.
Stoma A surgically created opening in an organ that forms an exit from the body.

Special Considerations for General Surgery

The discipline of general surgery provides the fundamentals for surgical practice, education, and research. The definition of general surgery agreed on by the American Board of Surgery and the Accreditation Council for Graduate Medical Education (ACGME) serves as the basis of graduate education and certification as a specialist in surgery.[1] The following principles are inherent in general surgery:

- A central core of knowledge and skills common to all surgical specialties (e.g., anatomy, physiology, metabolism, pathology, immunology, wound healing, shock and resuscitation, neoplasia, and nutrition)
- The diagnosis and preoperative, intraoperative, and postoperative care of patients with diseases of the alimentary tract, the abdomen and its contents, breast, head and neck, endocrine system, and vascular system (excluding intracranial vessels, the heart, and vessels intrinsic and immediately adjacent thereto)
- Responsibility for the comprehensive management of trauma and critically ill patients with underlying surgical conditions

In a community hospital, the practice of general surgery usually encompasses many aspects of surgical care. In larger teaching facilities, general surgery services are commonly specialized (e.g., breast, biliary tract, gastrointestinal, or colon and rectal surgery). The introduction of surgical specialties was the outgrowth of increased knowledge of the etiology of disease and specialized treatment of all parts of the body. General surgery, the basis for all specialties, has decreased in breadth as specialization has increased. The anatomic parts not specifically delegated to specialists have remained in the realm of the general surgeon. Other surgical disciplines depend on general surgeons for clinical collaboration in reconstruction involving the gastrointestinal and vascular systems.

The scope of this chapter focuses on procedures commonly categorized as general surgery. Technologic advances characterize many aspects of surgical practice. The general surgery team of today should be familiar with endoscopic techniques for diagnosis and treatment. Electrosurgery, lasers, and surgical staplers are part of the setup for standard general surgery. Patients are best cared for when the entire perioperative team understands the principles of available technologies and has clinical experience in the safe use of these technologies. The following are examples of technologic applications and the associated aspects of patient care:

1. Malignant lesions, especially those of the breast, thyroid, and gastrointestinal tract, account for a large percentage of surgical interventions. The extent of the surgical excision of a lesion may be determined only after thorough exploration during a surgical procedure, sometimes scheduled as a diagnostic laparoscopy or biopsy and frozen section.
   a. Although the patient has been informed preoperatively of an anticipated procedure, the unknown factor is cause for apprehension. The circulating nurse should provide comfort while the patient is awake. A biopsy or endoscopic procedure may be performed with the patient under local anesthesia and with or without moderate sedation.
   b. A definitive open or laparoscopic surgical procedure may be performed on the basis of results of the biopsy and frozen section or endoscopic examination while the patient is under anesthesia. The scrub person should be prepared with two draping and instrument setups, depending on the diagnosis established and the surgeon's plan for the surgical procedure. Anticipated equipment and supplies should be available without delay.
2. The types of anesthesia administered are as varied as the types of surgical procedures. Blood pressure, pulse, respiration, electrocardiogram (ECG), and pulse oximetry should be monitored for all patients, regardless of the anesthetic used. Personnel responsible for monitoring patients should be qualified to interpret data, assess the patient, and effect corrective action in the event of an untoward reaction.
3. Patients are placed in the supine position for many general surgical procedures. Extra padding and accessory positioning aids should be available for other positions. The average operating room (OR) bed can accommodate 350 lbs of body weight. Obese patients require a suitable bed capable of managing body weight.
4. Draping for abdominal incisions is usually standardized. Modifications are necessary for other sites, such as the breast or neck.
5. Instrumentation is quite varied and suited to function in a specific anatomic area. For example, gastrointestinal procedures require crushing clamps (e.g., Pean clamps to occlude the intestinal lumen before **resection**) and atraumatic clamps (e.g., Bainbridge clamps to protect delicate tissues). Included in all procedures are instruments for exposing, dissecting, grasping, clamping, suctioning, and suturing. For atraumatic retraction, various lengths of umbilical tape, hernia tape, or vessel loops may be placed around vessels or other structures to retract them. These materials should be included in the count.
6. Some procedures require minimal access and are adaptable to ambulatory surgery; others are extremely extensive. More complex procedures, such as colectomy and cholecystectomy, are often performed endoscopically and require less in-house hospitalization.
7. The electrosurgical unit (ESU), argon beam coagulator, laser, endoscope, laparoscope, and/or ultrasound transducer may be used during the procedure.
8. In complex open and laparoscopic abdominal and pelvic procedures, the following should be noted:
   a. Indwelling Foley or ureteral catheters may be inserted preoperatively to decompress the urinary bladder and monitor urinary output. Some surgeons may request the placement of ureteral catheters to stent and outline the ureters for complex dissection of abdominal organs. This will require a sterile cystoscopy setup, stirrups, and a urologist before the general surgery procedure of the abdomen begins.
   b. Nasogastric (NG) tubes may be passed before or during the surgical procedure to decompress the stomach and bowel. The anesthesia provider inserts the NG tube after the induction of anesthesia. The NG tube may be removed at the end of the surgical procedure.
   c. After the abdominal cavity is entered, single free 4 × 4-inch sponges should be removed from the field. They are used only while folded and secured on a sponge stick. Wet or dry laparotomy sponges are used in the abdominal cavity. A small dissector (peanut, cherry, or Kittner) is always clamped in a forceps before being handed to the surgeon.
   d. Before the peritoneum is incised, suction should be available and ready for immediate use, especially in biliary or intestinal procedures or when fluid or blood may be anticipated in the peritoneal cavity. If a cell saver is used for blood salvage, the suction tip for blood is kept separate from the suction tip for other fluids.
   e. Drains may be exteriorized through a stab wound in the adjacent abdominal wall before closure. A nonabsorbable monofilament suture on a small cutting needle will be used to secure the drain to the skin. Drains are discussed in Chapter 29.
   f. Contaminated items, such as those used to dissect and/or anastomose intestinal segments, are isolated in a basin on the back table.
   g. Before closure, the wound is irrigated with warm, sterile, normal saline solution to remove blood and debris.
   h. Retention sutures may be used to give additional strength to wound closure. Rubber or silicone bumpers or a wound bridge may be used to protect the skin from tension exerted by the adjunct wound closure sutures. Wound closure is discussed in Chapter 28.
9. Assorted sizes of drains, tubes, drainage bags, and wound suction systems should be available. Care is taken to ensure that the patient is not latex sensitive.
10. Irrigating solutions should be body temperature (not to exceed 110° F [43° C]) when they are used. All radiopaque contrast media, anticoagulants, and solutions on the instrument table and their delivery devices are clearly labeled to avoid any error in administration. Hypodermic syringes with needles are not recapped by hand. Care is taken to monitor the volumes of fluid used for irrigation.
11. Blood loss and urinary output are recorded on the perioperative record. Anesthesia personnel document the amount of intravenous (IV) solution and medications administered during the case.
12. Specimens are carefully labeled and sent for processing as appropriate. Care of specimens is discussed in Chapter 22.

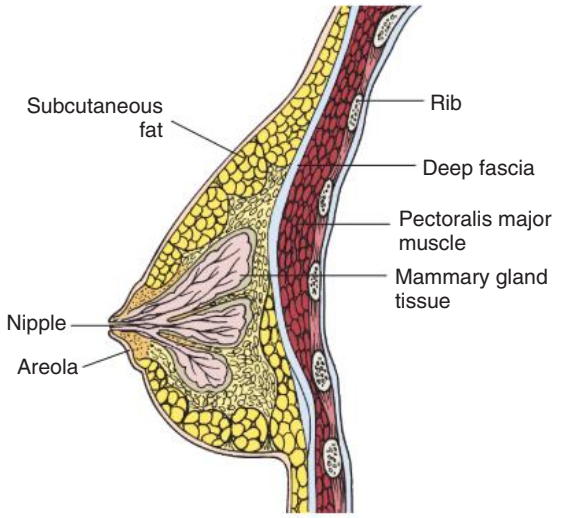
Breast Procedures

The mammary glands are bilateral organs (modified sweat glands) lying in the superficial fascia of the pectoral area (Fig. 33.1). They are attached to the underlying muscles by loose areolar tissue and suspended by Cooper ligaments. The breasts extend from the border of the sternum to the anterior axillary line (tail of Spence) and from approximately the first to the seventh ribs.

The breasts are highly vascular. The blood supply is derived laterally from the thoracic branches of the axillary, intercostal, and internal mammary arteries (Fig. 33.2). Venous drainage forms an anastomotic circle around the base of the nipple, with branches draining the circumference of the gland into the axillary and internal mammary veins. Lymphatic drainage follows the same path as the venous system and empties into the thoracoabdominal and lateral thoracic vessels. Innervation arises from the anterior and lateral cutaneous nerves of the thorax.

General surgery on the breast for males and females includes diagnostic procedures and those performed for known pathologic disease, such as cancer. Diagnostic techniques include mammography, ultrasonography, fine needle aspiration (FNA), computed tomography (CT), magnetic resonance imaging (MRI), and the traditional tissue biopsy.

The desired surgical procedure should be determined on an individual basis after careful diagnostic studies and histologic diagnosis.[2] Size, location, and type of diseased tissue and stage of malignancy are important considerations. No single surgical procedure is suitable for all patients.



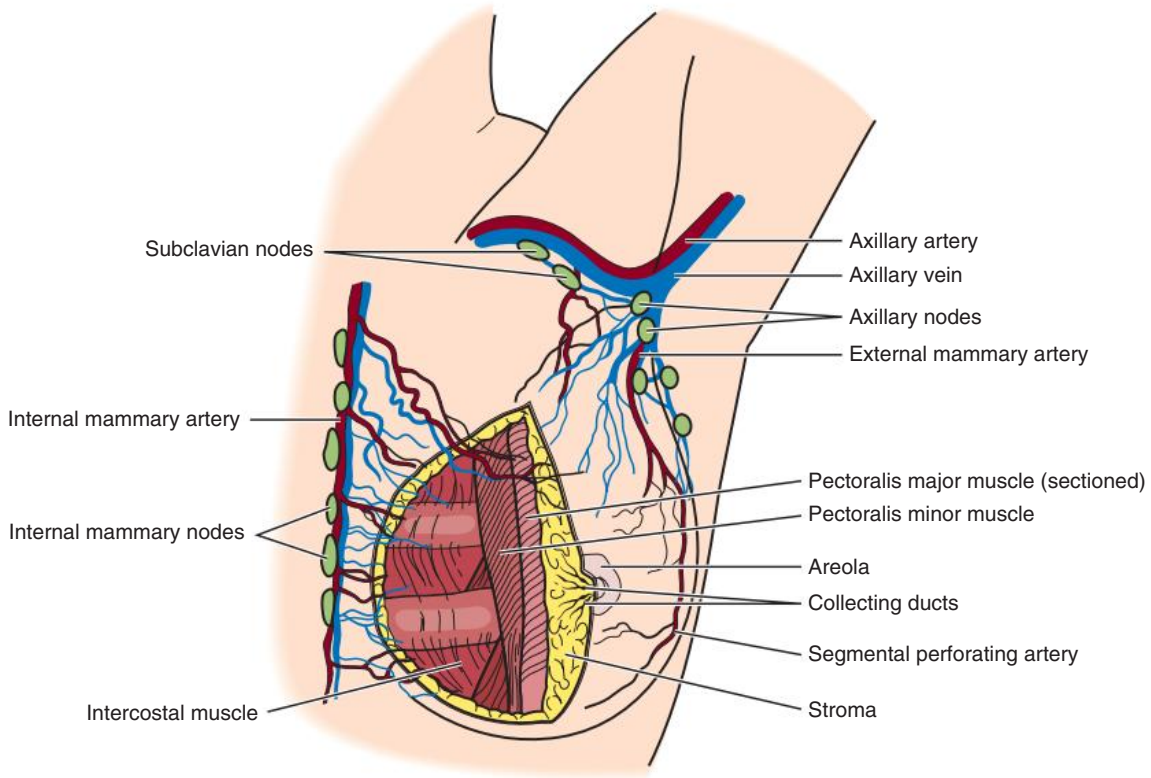
• **Fig. 33.1** Sagittal section of normal breast in relation to chest wall and ribcage.

Incision and Drainage

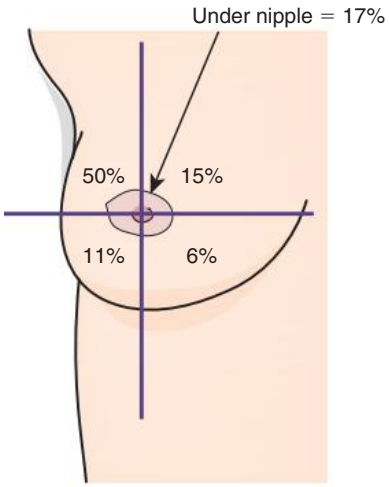
Surgical opening of an inflamed and suppurative area is most often carried out because of infections in the lactating breast. The cavity is usually irrigated, and the wound is packed and allowed to heal by granulation. The causative organism is often *Staphylococcus.*

Breast Biopsy

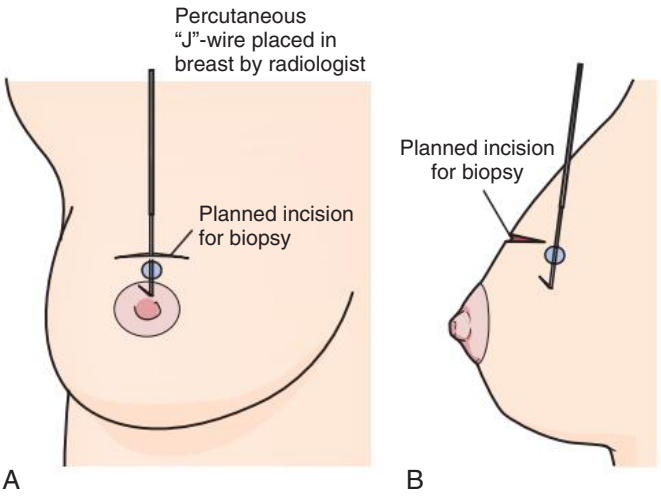
The average size of lumps found by women who do and do not practice breast self-examination (BSE) is illustrated in Chapter 22 (Fig. 22.3). All breast masses are considered malignant until proved benign. To determine the exact nature of a mass in the



• **Fig. 33.2** Normal anatomy of the breast, including vessels and lymph nodes.



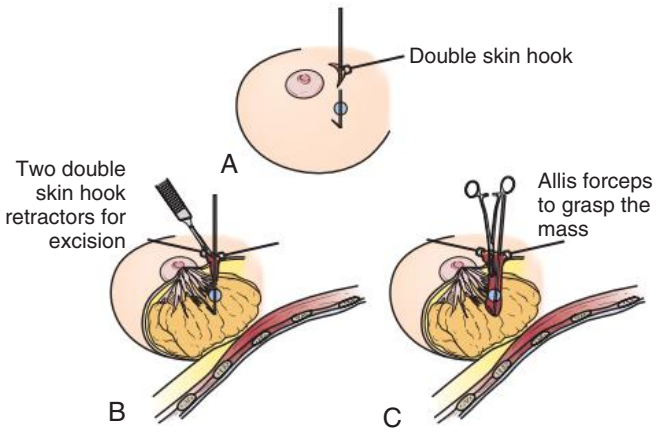
• **Fig. 33.3** Breast cancer location by quadrant.



• **Fig. 33.4** J-wire placement in radiology. **A,** Anterior view. **B,** Lateral view.

breast, tissue is removed for pathologic examination. The size and location (Fig. 33.3) of the lesion influence the type of biopsy:

- *Fine-needle aspiration:* A 22- or 25-gauge needle attached to a syringe is inserted into the tumor mass. A few cells are aspirated and sent to the pathology laboratory for cytologic studies. This may be performed in conjunction with a mammogram (mammographic breast biopsy) or as an office procedure. FNA also may be used to evacuate fluid from benign cysts.
- *Core biopsy:* For this type of incisional biopsy, a large-bore trocar needle, such as a Tru-Cut or Vim-Silverman biopsy needle, is inserted into the mass. A core of suspected tissue is withdrawn for histologic examination. Any retrieved fluid is also sent to the pathology laboratory.
- *Stereotactic breast biopsy:* The patient is placed prone on a special x-ray table, and her breast is placed in an opening in the table. A computer-guided system is used to digitally locate and pinpoint nonpalpable breast lesions. The biopsy is obtained with a vacuum-assisted Mammotome while the patient is under local anesthesia.
- *Incisional biopsy:* The mass is incised, and a portion is removed for histologic examination.
- *Excisional biopsy:* The entire mass is removed for pathologic study.
- *Sentinel node biopsy:* The breast mass is injected with a radioisotope (technetium) in the radiology department several hours before the planned surgical procedure. In the OR, the tumor is injected with a dye containing isosulfan blue that is taken up by the lymph nodes of the breast. The nodes are excised before the primary mass.
  - A sterile Geiger counter probe is used on the field to locate the areas of radioactivity. The specimens are sent to pathology for immunohistochemical staining.
  - Lead containers are used to house the specimens for 24 hours before the pathologist examines them.
- *J-wire or needle localization in radiology department:* The mass is identified on mammography, and the patient undergoes the insertion of a wire into the mass in the radiology department under fluoroscopy (Fig. 33.4). The wire remains taped in place as the patient is taken to the OR. The mass is excised with the wire intact (Fig. 33.5). The specimen is taken back to the radiology department to be x-rayed as a confirmation that the wire is still in the mass. After the confirmatory x-ray, the specimen is taken to pathology.

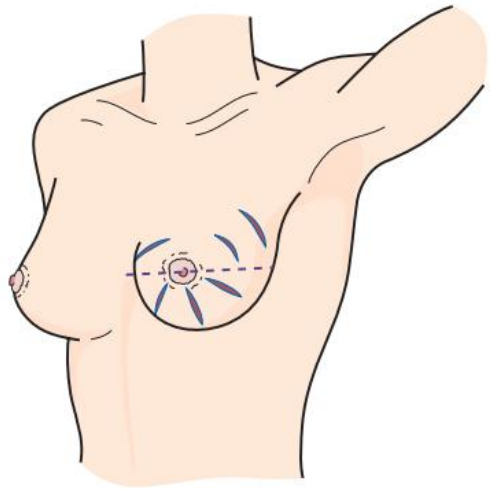


• **Fig. 33.5** Excision of breast mass in OR with J-wire in place. **A,** Visualization of mass. **B,** Increased exposure. **C,** Removal of mass.

- *Fiberoptic ductoscopy:* A flexible 0.9-mm scope with a 0.2-mm working channel is used in the ductal lumens of the breast. Studies have shown that 85% of breast cancer originates in the ductal system in the epithelial lining. The image is enlarged to 200 times by magnification. The scopes are approved for 10 uses each by the Food and Drug Administration (FDA).
  - Anesthetic cream is applied to the nipple. A fine catheter is introduced, and sterile saline is instilled. Specimens can be obtained by this method, and ductal lavage is performed for cell studies.
  - The ducts may need to be dilated with fine lacrimal probes before inserting the catheter. Additional anesthetic can be introduced via the catheter.

Preoperatively, the surgeon discusses with the patient possible findings and treatment options.[3] The patient may agree to an immediate definitive surgical procedure such as mastectomy or lumpectomy if warranted by the biopsy and frozen section results. Two separate prepping, draping, and instrument sets are necessary to avoid mixing cancerous cells of the breast specimen with the freshly prepared reconstructive site. The team should change gown and gloves.

To minimize disfigurement, many women with early operable breast cancer (a mass less than 5 cm) opt for limited resection



• **Fig. 33.6** Common conservative breast incisions followed by radiation therapy.

followed by radiation and chemotherapy (Fig. 33.6). The difference between tumor and deep tumor-free resection margin remains an important consideration in determining the most appropriate type of mastectomy incision (Table 33.1).

Lumpectomy

Lumpectomy, a partial mastectomy, consists of removal of the entire tumor mass along with at least 1 to 2 cm of surrounding nondiseased tissue. This procedure is recommended for peripherally located tumors that measure less than 5 cm. Lumpectomy is contraindicated if breast size precludes postoperative radiation or if negative margins around the tumor cannot be obtained. Compared with mastectomy, the lumpectomy incisions are less disfiguring.

Breast conservation, the surgical treatment of choice for many women with breast cancer, includes a lumpectomy to excise a primary tumor and axillary node dissection followed by radiation therapy. This approach maintains the appearance and function of the breast (Fig. 33.7). The surgeon may prefer to perform the lumpectomy first, followed by axillary dissection (Fig. 33.8).

The patient should be reprepped and redraped between procedures. A separate set of instruments is used for each procedure to avoid possible tumor cell implantation in the axilla. A transverse incision for axillary dissection, approximately 1 cm below the axillary hairline, extends from the pectoralis major muscle anteriorly to the latissimus dorsi muscle posteriorly. Lymphoareolar tissue between these muscles is removed—usually at least 10 lymph nodes.

Segmental Mastectomy

In a segmental mastectomy, a wedge or quadrant (quadrantectomy) of breast tissue is removed; this wedge includes the tumor mass and the lobe in which it is growing. Some surgeons explore the axilla and take a few lymph nodes for histologic studies.

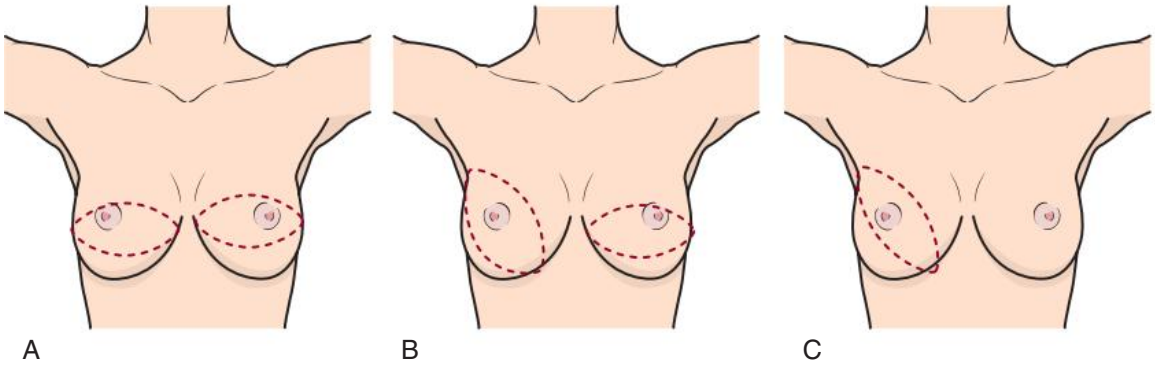
Simple Mastectomy

In a simple mastectomy, the entire breast is removed without lymph node dissection. A simple mastectomy may be performed for a malignancy that is confined to breast tissue with negative nodes, as a palliative measure for an advanced ulcerated malignant tumor, or for the removal of extensive benign disease. Skin grafting may be necessary if the primary closure of skin flaps would create unacceptable tension. Skin flaps are then loosely approximated, and grafts taken from the thigh are applied to the remaining defect. A latissimus dorsi or transverse rectus abdominis myocutaneous (TRAM) flap may be preferred for reconstruction.

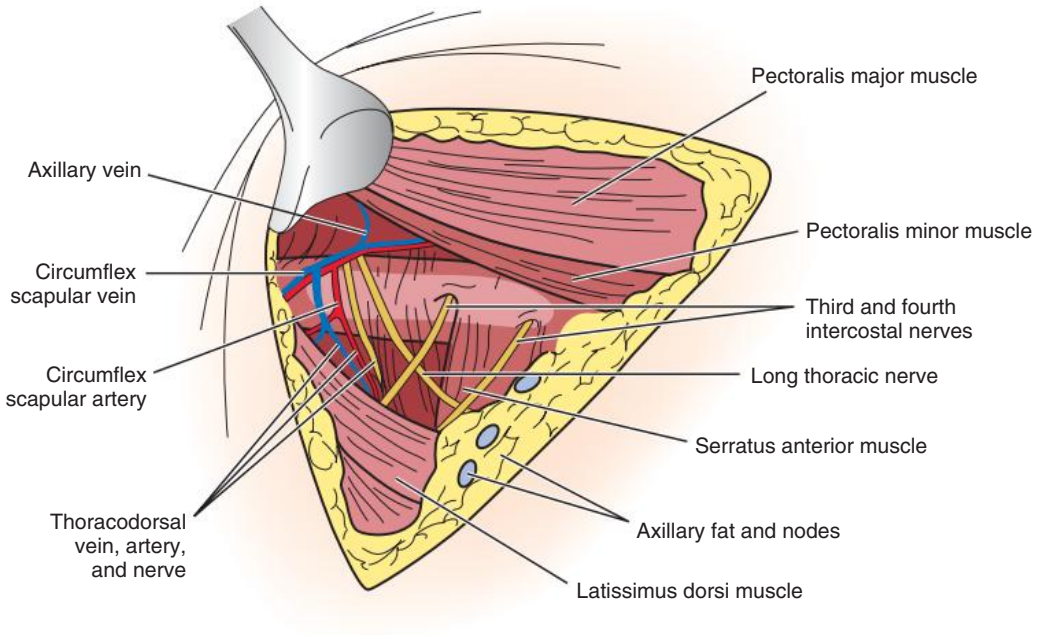
A subcutaneous mastectomy may be performed for patients with chronic cystic mastitis who have had multiple previous

TABLE 33.1 Stages of Breast Cancer

Stage I	Stage II	Stage III	Stage IV
Size			
<1-2 cm	2-5 cm	>5 cm	Large and fully integrated with surrounding tissue
Location			
Confined to breast	Breast mass with or without suspicious axillary lymph nodes	Breast mass with palpable, fixed axillary, and/or subclavicular lymph nodes	Distant metastasis; extension to skin
	May or may not extend to pectoral fascia or muscle	Mass may be adherent to surrounding tissue	Lymphedema above or below the clavicle
	No distant metastasis	No distant metastasis	
Surgical Options			
Segmental mastectomy	Total mastectomy	Modified or radical mastectomy	Radical or extended radical mastectomy
Breast conservation surgery for stages I and II lumpectomy with axillary node dissection and radiation therapy			



• **Fig. 33.7** Common mastectomy incisions. **A,** Bilateral. **B,** Alternative incisions based on tumor location, **C**, Unilateral.



• **Fig. 33.8** Axillary lymph node dissection for breast cancer.

biopsies, for patients with multiple fibroadenomas or hyperplastic duct changes, and for patients with central tumors that are noninvasive in origin. Some patients with a strong family history of breast cancer may have prophylactic mastectomies as a precaution. All breast tissue is removed, but the overlying skin and nipple remain intact. A prosthesis may be inserted at the time of the surgical procedure, depending on the surgeon's decision and the patient's wishes.

Modified Radical Mastectomy

A modified radical mastectomy is usually performed for infiltrating ductal and localized small malignant lesions. The term *modified* encompasses various techniques, but all include removal of the entire breast (total mastectomy). In addition, all axillary lymph nodes are resected. The underlying pectoralis major muscle is left in place; the pectoralis minor muscle may or may not be removed. In patients with small lesions and no metastases, breast reconstruction may be performed immediately or a few days after the procedure.

Radical Mastectomy

A radical mastectomy is performed to control the spread of malignant disease from large infiltrating cancers. After a positive finding on the tissue biopsy, the entire involved breast is removed along with the axillary lymph nodes, the pectoral muscles, and all adjacent tissues. During the surgical procedure, skin flaps and extensive exposed tissue are covered with moist packs for protection. The chest wall and axilla are irrigated with sterile water before closure. Skin grafts are usually required to cover the defect.

Extended Radical Mastectomy

Cancer is a disease that grows both deeply and laterally. An extended radical mastectomy is indicated when malignant disease is present in the medial quadrant or subareolar tissue because it tends to spread to the internal mammary lymph nodes. The involved breast is removed en bloc along with the underlying pectoral muscles, axillary contents, and upper internal mammary (mediastinal) lymph node chain. This procedure is more difficult than a classic radical mastectomy.

Considerations for Female Breast Procedures

For a breast procedure, the patient is placed in the supine position; the involved side is positioned close to the edge of the OR bed, and the arm on the affected side is extended on an armboard. The affected side is elevated with a small pillow, or the OR bed is tilted. The anterior part of the chest is prepped from the chin to the umbilicus and from the axilla on the affected side to the nipple line of the opposite breast. The entire arm on the affected side is included in this preparation. General anesthesia is usually preferred for a mastectomy because local infiltrate may obscure a tumor.

Because of the vascularity of breast tissue, a laser or ESU is commonly used for hemostasis. Larger vessels may require a tie. Patients undergoing a mastectomy should be watched for excessive bleeding. Some surgeons prefer to irrigate the mastectomy wound with sterile water instead of sterile normal saline solution to crenate (shrivel or shrink) cancerous cells. The circulating nurse should check with the surgeon about the care of the specimen for the pathologist. The specimen is placed in sterile normal saline solution if estrogen or progesterone receptor studies are to be performed. Formalin is used for permanent sections.

A bulky compression dressing and Surgi-Bra may be applied in the OR. Depending on the amount of tissue resected, a closed-wound suction system may be inserted to remove blood and serum and to prevent pressure necrosis of skin flaps.

Lymphedema of the arm on the affected side is a possible complication after mastectomy causing the arm to painfully swell and lose function.[4] The patient is highly susceptible to infection. When axillary dissection is performed, the lymphatic structure of the arm is compromised, causing primary lymphedema. Secondary causes include radiation, extreme inflammation, or infection. Although lymphedema can be an immediate problem, it most frequently builds up over time during the postoperative period. The severity is classified by the degree of pitting and loss of arm mobility. Patients experience neck and back pain as the arm becomes heavier with accumulated lymph. Obesity significantly increases the risk for lymphedema development. The enlarged arm causes self-perception issues and is a constant reminder of cancer treatment.

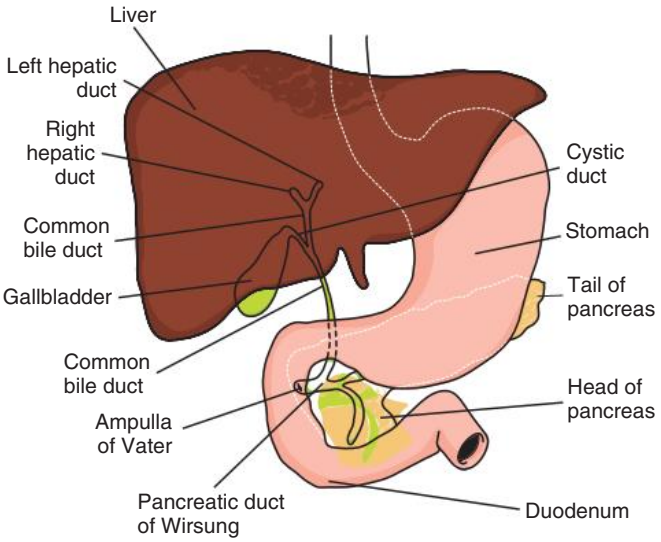
Management of lymphedema involves one or more of the following: (1) manual drainage, (2) compression garment/sleeve, (3) physical exercise, and (4) meticulous skin care. Some patients are candidates for a liposuction procedure to reduce the size of the arm. The patient must wear a compression sleeve at all times after a reduction procedure for life to keep the arm in a reduced state. Lymphatic grafts to the axilla from the medial thigh have been used with some success; however, the risk for lymphedema of the donor leg is possible.

Patients who have undergone a mastectomy are often referred to The American Cancer Society's Reach to Recovery rehabilitative program. In this program, volunteers who have had mastectomies visit patients, share information with them, and give them encouragement.

Abdominal Procedures

Biliary Tract Procedures

The gallbladder is located in the right upper quadrant in a fossa under and immediately adjacent to the right lobe of the liver (Fig. 33.9). The gallbladder is a thin-walled sac and has a normal capacity of 50 to 75 mL of bile. Bile secreted by the hepatic cells enters the intrahepatic bile ducts and progresses to the common bile duct. When not needed for digestion, bile is diverted through the cystic duct into the gallbladder, where it is stored. When bile is needed, the gallbladder contracts and empties bile into the cystic duct; the bile flows into and through the common duct into the duodenum.



• **Fig. 33.9** Normal anatomy of the biliary system and portal system.

Gallstones are concretions of elements of bile, particularly cholesterol (about 50%), and may be found in the gallbladder or in any portion of the extrahepatic biliary duct system. Brown stones are usually fatty acids, and black stones are composed of inorganic salts. The incidence of stones, referred to as cholelithiasis, increases with age and is more prevalent in women and in people who are obese.

Acute or chronic inflammation of the gallbladder, common duct stones (choledocholithiasis), carcinoma, and the congenital absence of bile ducts (biliary atresia) are the most common indications for a surgical procedure. Obstructive jaundice, which is potentially fatal, may be a sign of ductal cholelithiasis or the presence of a neoplasm. The cause of jaundice should be determined and the condition relieved to spare the patient irreversible progressive liver damage. Biliary stones are sent as dry specimens if removed separately.

The greatest hazards of biliary tract surgery are associated with the anatomic relationships of the ducts and the cystic artery and with pathologic changes in the gallbladder. Complications include hemorrhage and injury to the extrahepatic biliary duct system. Spilled bile can cause peritonitis postoperatively.

Ultrasonography, nuclear imaging such as hepatic intraductal assay (HIDA) scan, and CT scanning are used for the diagnosis of gallbladder disease. Oral (PO) and IV cholecystography may be used for visualization of the gallbladder in the initial evaluation of patients with biliary symptoms.

Endoscopic retrograde cholangiopancreatography also may be performed, usually by a gastroenterologist, to identify stones, tumors, inflammatory lesions, or an obstruction. A flexible fiberoptic duodenoscope is introduced with the patient under IV sedation and with the use of a topical anesthetic to control the gag reflex.

Contrast media is injected to opacify the entire biliary tract and pancreatic duct under fluoroscopy. Care is taken when preparing the contrast in the syringe without air bubbles. Air bubbles will appear like stones on x-ray. Some definitive therapy is possible

during this procedure, such as stone retrieval (endoscopic papillotomy), stent insertion, and sphincterotomy. A percutaneous transhepatic puncture is used to resect tumors for biopsy, dilate strictures, place stents in the bile duct, and establish temporary drainage through ducts. A contrast medium can be injected for a cholangiogram.

Cholecystectomy

Gallbladder disease is cured by removal of the gallbladder in a procedure referred to as a *cholecystectomy*—the most common surgical procedure performed on the biliary tract. A cholecystectomy is performed to relieve the gastrointestinal distress common in patients with acute or chronic cholecystitis (with or without gallstones); it also removes a source of recurrent sepsis. Persistent infection in the biliary tract may cause recurrent stones.

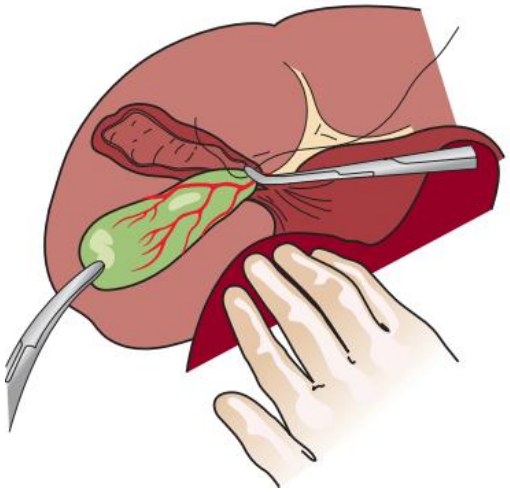
For an open cholecystectomy, the patient is placed in the supine position. As requested by the surgeon, the right upper quadrant may be slightly elevated on a gallbladder rest or pillow after the induction of general anesthesia. The OR bed may be tilted slightly into a reverse Trendelenburg's position so the abdominal viscera gravitate downward, away from the surgical area.

Open Abdominal Cholecystectomy

With an open abdominal cholecystectomy, the gallbladder is usually exposed through a right subcostal incision (Kocher incision) that may be extended over to the midline at the level of the xyphoid. The incision should be adequate for good exposure of the gallbladder and bile ducts. After exploration of the abdominal cavity, laparotomy packs are used to wall off the surrounding organs for exposure.

The bilious contents of the gallbladder may be aspirated to prevent bile from spilling into the peritoneal cavity—a potential source of peritonitis, especially if the gallbladder is inflamed and tightly distended. The cystic duct, cystic artery, hepatic ducts, and common bile duct are accurately identified.

After palpation of the ducts for stones, the cystic duct and artery are ligated with hemostatic clips and divided. Using blunt dissection, the gallbladder is freed and removed from the liver and its fossa (Fig. 33.10). Some surgeons use ESU and/or neodymium:yttrium aluminum garnet (Nd:YAG) or holmium:yttrium aluminum garnet (Ho:YAG) laser for sharp dissection and coagulation. Stones removed as part of the specimen should be sent to pathology for analysis and documentation. If bile leakage or hemorrhage has been excessive, a sump drain or closed-wound suction drain may be placed in the subhepatic space and brought out through a stab wound after copious intraabdominal irrigation.



• **Fig. 33.10** The gallbladder is dissected from the liver bed.

Laparoscopic Cholecystectomy

With a laparoscopic cholecystectomy the patient is supine in a slight to moderate reverse Trendelenburg's position. A rigid fiberoptic laparoscope is inserted through a sheath into the peritoneal cavity. In conventional laparoscopy, multiple trocars are inserted through triangulated puncture wounds in the right upper quadrant: one or two just right of midline, with the uppermost trocar slightly below the xyphoid and costal margin and the other midway to the umbilicus; one laterally in an anterior axillary line above the iliac crest at the costal margin; and another in a midclavicular line slightly above the level of the umbilicus and 2 cm below the rib. The location of puncture sites will vary according to patient size and surgeon preference (Fig. 33.11).

Single-port access technology employs an open laparoscopic method in which a single incision is made at the umbilicus and a flexible multilumen port is inserted through which insufflation and additional instruments are placed. A Veress needle is not used. Single-incision laparoscopy is discussed in Chapter 32.

A camera attached to the laparoscope allows the surgeon to view the manipulation of instruments through the sheaths of these trocars. Viewing monitors are positioned on each side of the head of the OR bed (Fig. 33.12). With this procedure, the fundus of the gallbladder is grasped through one or more lateral ports and held by the assistant. After careful dissection, the surgeon ligates and divides the cystic duct and artery with suture loops or clips. A laser, an ESU, or microscissors may be used to transect these structures.

The gallbladder is freed, most often by using an ESU or by using argon, potassium titanyl phosphate (KTP), or a contact Nd:YAG or Ho:YAG laser. The gallbladder is usually lowered into an Endo Catch pouch and aspirated to remove bile and collapse the sac. It then may be removed in one piece or cut into sections and withdrawn through the periumbilical incision.

The perioperative team must be ready to convert from laparoscopic to an open procedure in the event of bleeding or other difficulty during the procedure. Supplies and instrumentation should be immediately available. It is advantageous to have precounted sets in the room during these procedures.

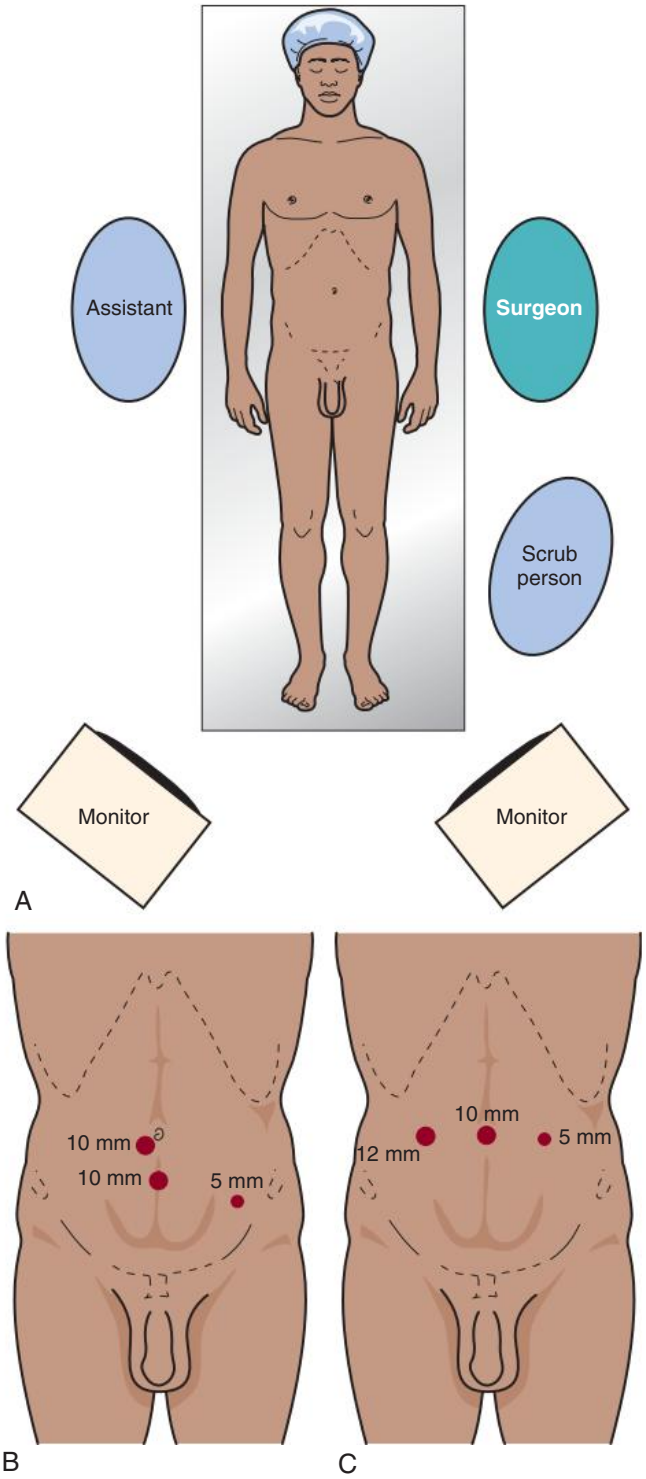
Common Bile Duct Exploration

Concomitant exploration of the common duct is often but not routinely performed during cholecystectomy. Curved stone forceps, small malleable scoops, dilators of various sizes, balloon catheters, stone baskets, and nylon brushes are useful in clearing the hepatic and biliary ducts of stones to prevent them lodging in the duct and causing subsequent obstructive jaundice.

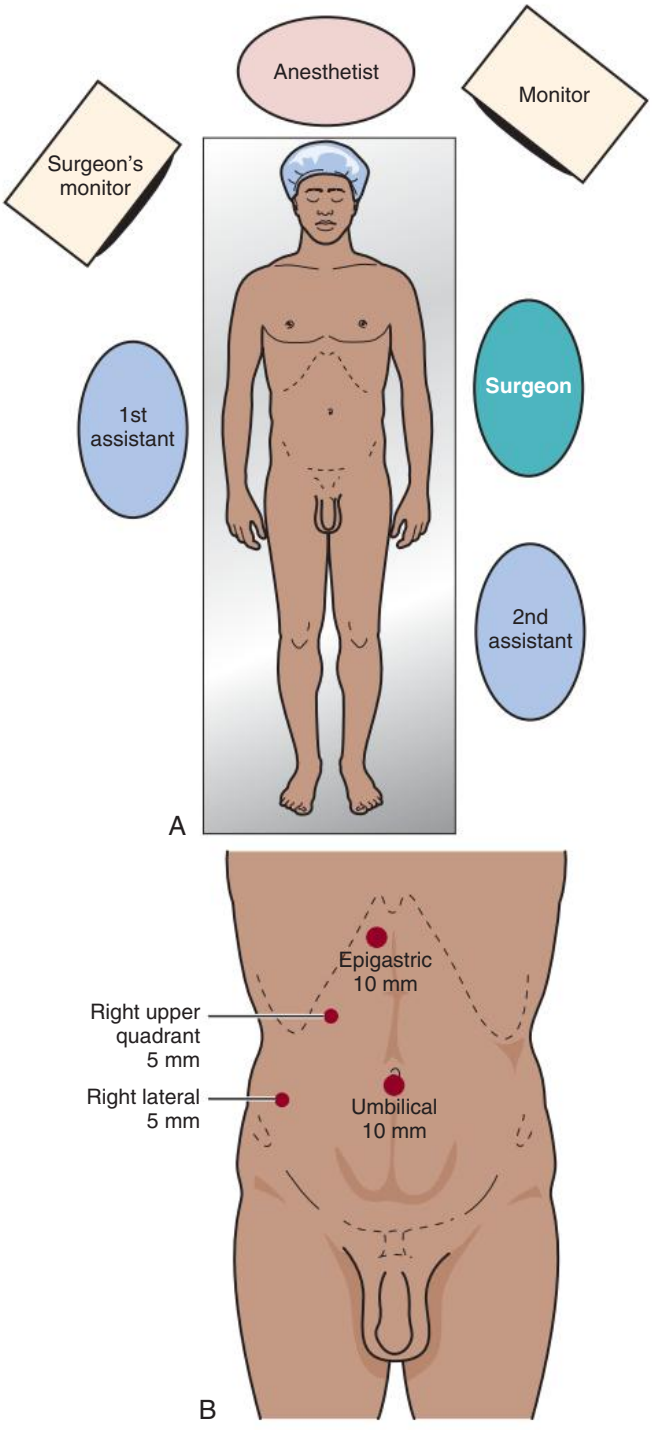
Palpable stones, jaundice with cholangitis, and dilation of the common bile duct are indications for exploration. A T-tube drain may be inserted to stent the duct and provide postoperative drainage. The surgeon may choose other intraoperative techniques to identify unsuspected stones, pathologic conditions, or anatomic variations in the hepatic duct system.

Intraoperative Cholangiograms

X-rays are obtained during either open abdominal or laparoscopic procedures. The radiology department is notified in advance if a cholangiogram is anticipated. To check for patient position, scout



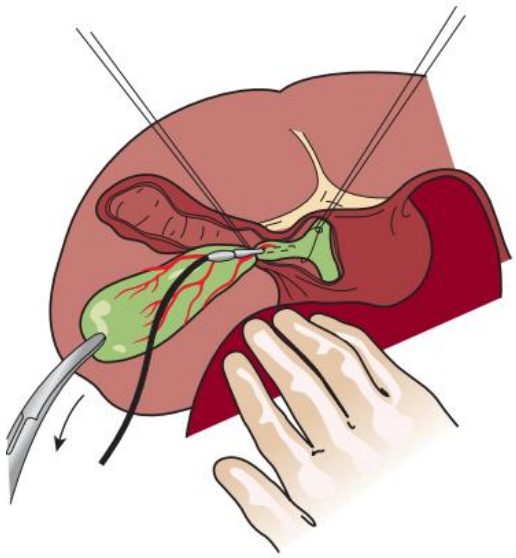
• **Fig. 33.11** Laparoscopic setup. **A,** Position of personnel for a basic laparoscopy. **B,** Trocar placement is determined by the target organ position. **C,** Trocars used vary in size according to position of function for dissection and hemostasis.



• **Fig. 33.12** Laparoscopic cholecystectomy. **A,** Placement of personnel and monitors for gallbladder removal. **B,** Trocar placement for gallbladder removal.

films may be obtained when the patient is initially positioned on the OR bed, before the procedure is started. The circulating nurse should assess the patient for allergies or sensitivities to contrast media and should ensure that the OR bed has an x-ray top or can be equipped for x-ray or fluoroscopy. Most facilities use digital x-rays.

The radiology technician returns to the OR when the surgeon is ready for films. Cholangiograms may be obtained after the gallbladder is removed or before the cystic duct and artery are ligated. A radiopaque contrast medium, usually diatrizoate sodium (Hypaque or Renografin), is injected into the cystic duct or common bile duct with a 30 to 60-mL syringe.



• **Fig. 33.13** Cholangiograms are taken with x-ray. The cystic duct is ligated.

Unless fluoroscopy is used, a series of three or four x-rays are obtained and displayed in digital format. Before each exposure, the surgeon injects contrast media through a Cholangiocath (a plastic catheter inserted into cystic or common duct), cannula, or direct needle puncture in the common duct (Fig. 33.13). Instruments are removed from the field to the extent possible to minimize the obstruction of structures on the x-rays. The field is covered with a sterile barrier before the x-ray machine or C-arm is positioned over the patient. Sterile x-ray tube and C-arm covers are commercially available. All other radiologic precautions for patient and personnel safety and shielding should be observed.

Ultrasonography

Ultrasonography, a noninvasive technique, takes less time and does not have the radiation hazards of intraoperative cholangiograms. A sterile ultrasound probe is manipulated along the common bile duct from the liver to the duodenum. The probe transmits high-frequency sound waves back to the ultrasound unit in the form of echoes, which are displayed on a screen as black-and-white real-time images. To enhance the transmission of ultrasound waves, the abdominal cavity is irrigated with warm normal saline solution. Density in tissue causes sound waves to echo in altered patterns and directions. Gallstones appear as bright echoes, often with an acoustic shadow. Photographs or video can be obtained to document the findings of ultrasonography.

Choledochoscopy

Intraoperative biliary endoscopy provides image transmission and illumination, thus allowing the surgeon visual guidance in exploring the biliary system. Intrahepatic and extrahepatic bile ducts can be visualized with a flexible fiberoptic choledochoscope introduced into the common duct. To provide distention of the biliary tract, normal saline solution must continuously flow through the irrigation channel.

Stones are easily seen and are usually free-floating under the pressure of the irrigating solution. A flexible stone forceps, a basket, or a balloon-tipped biliary catheter may be inserted through the instrument channel of either a rigid or flexible scope to allow manipulation of a stone under direct vision. A biopsy forceps may be inserted to obtain a tissue sample. An Nd:YAG laser fiber may be used through the choledochoscope to crush bilirubin stones in the distal common hepatic duct; this allows easy removal of the stones.

Cholelithotripsy

Cholelithotripsy is a noninvasive procedure in which high-energy shock waves are used to fragment cholesterol gallstones. The procedure is performed under IV sedation or general anesthesia. The patient is usually placed in the prone position, but may also be in the supine or lateral position, on a lithotripter table, or submerged in a water bath. Spark-gap shock waves generated from an electrode pass through a fluid medium into the body until they reach the stone, which is focused with an ultrasound probe and computer.

The shock waves are synchronized with the R waves of the patient's cardiac rhythm, which is monitored by ECG to avoid dysrhythmias. Each shock pulverizes the stones into small fragments, which then pass through the bile duct. This passage may be aided by oral administration of deoxycholic acid (ursodiol) taken daily after lithotripsy to dissolve the fragments.

Choledochostomy and Choledochotomy

With choledochostomy, a T-tube is used to drain the common bile duct through the abdominal wall. A choledochotomy is the incision of the common bile duct for the exploration and removal of stones. Intraoperative cholangiography may be performed before and after exploration and/or stone removal. The duct is irrigated after calculi are removed. Patency of the duct and of the ampulla of Vater is investigated, often through a choledochoscope. If a neoplasm is found during exploration, resectability is determined; many tumors of the liver or pancreas are inoperable.

Cholecystoduodenostomy and Cholecystojejunostomy

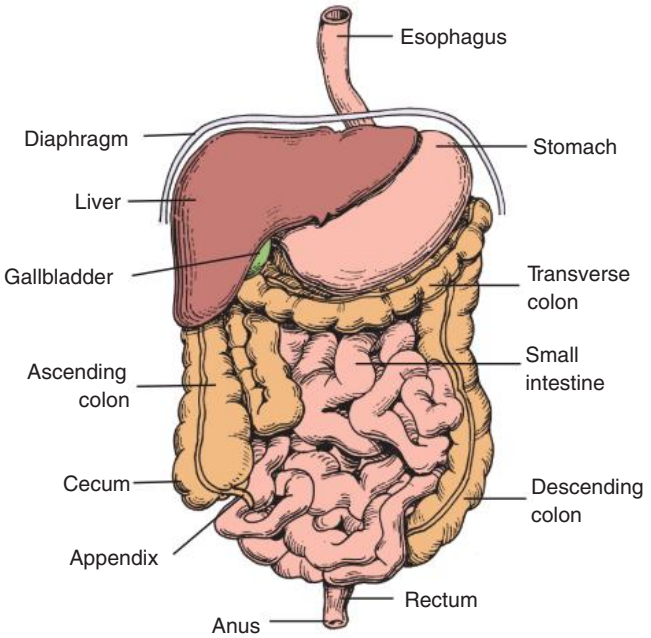
Either a cholecystoduodenostomy or cholecystojejunostomy is performed to relieve an obstruction in the distal end of the common duct. Through **anastomosis**, these procedures establish continuity between the gallbladder and either the duodenum or jejunum. Careful evaluation precedes the surgical procedure.

Cholecystoduodenostomy and cholecystojejunostomy are bypass procedures to avoid further obstructive jaundice, but they do not solve the problem. Common causes of the obstruction are calculi, stricture of the duct, or neoplasms of the duct, ampulla of Vater, or pancreas.

Choledochoduodenostomy and choledochojejunostomy are side-to-side anastomoses between the duodenum or jejunum and the common duct. These procedures are carried out for difficult or recurrent biliary or pancreatic obstruction as a result of benign or malignant disease.

Liver Procedures

The liver, the largest gland in the body, is divided into left and right segments (or lobes) and is located in the upper right abdominal cavity beneath the diaphragm (Fig. 33.14). Part of the stomach and duodenum and the hepatic flexure of the colon lie directly beneath the liver. A tough fibrous sheath, the Glisson capsule, completely covers the organ; the tissue within this capsule is very friable and vascular. The hepatic artery, a branch of the celiac axis, maintains the arterial supply. Blood from the stomach, intestine, spleen, and pancreas is carried to the liver by the portal vein and its branches.



• **Fig. 33.14** Abdominal organs within peritoneal cavity.

The many functions of the liver include forming and secreting bile, which aids digestion; transforming glucose into glycogen, which it stores; and helping to regulate blood volume. The liver is vital for the metabolic functioning of the body. It metabolizes fats, proteins, and carbohydrates; synthesizes cholesterol; excretes bilirubin; and secretes hormones. The liver has remarkable regenerative capacity, and up to 80% of it may be resected with little or no alteration in hepatic function.

Liver function tests are used to assess the degree of functional impairment and to evaluate liver activity and reserve. Most of these tests involve taking a series of blood samples from the patient for specific studies. Ascites may result from impaired liver function.

Liver Needle Biopsy

A percutaneous needle biopsy may help establish a diagnosis of liver disease. Because the procedure is performed with the patient under local anesthesia, moderate sedation, or monitored anesthesia care (MAC), the patient should be instructed to take several deep breaths and then hold the breath and remain absolutely still while the needle is inserted. Failure of the patient to cooperate can cause needle penetration of the diaphragm or hepatic injury and result in hemorrhage, a serious complication. Leakage of bile into the abdominal cavity may produce chemical peritonitis, an additional hazard.[5]

After skin preparation and the induction of local anesthesia (with the patient in the supine position), a Franklin-Silverman, Tru-Cut, or EchoTip ProCore biopsy needle is introduced into the liver via a transthoracic intercostal or transabdominal subcostal route. The needle is rotated to separate a small core of tissue, and it is then withdrawn to remove the specimen. As soon as the needle is removed, the patient is told to resume normal breathing and is assisted to turn onto his or her right side to compress the chest wall at the penetration site and prevent the seepage of bile or blood.

Slight bleeding may follow a liver biopsy; the patient's prothrombin time is checked. This method of biopsy is not used if the patient has a coagulopathy.

In select patients under local anesthesia, a laparoscopic-assisted approach may be used to enhance visualization of the biopsy site. The anterior abdominal wall is elevated with a low volume of carbon dioxide insufflation or a planar lift device without insufflation. The biopsy needle is inserted through the abdominal wall as described previously. A topical hemostatic gelatin sponge or other topical chemical hemostatic agent is laparoscopically applied to the biopsy site on the liver. The patient remains supine after this procedure.

Drainage of Subphrenic and Subhepatic Abscesses

Abscesses in and around the liver may be caused by a variety of microorganisms or as a result of secondary infections from abdominal organs. In general, these abscesses are treated by incision and drainage. A catheter may be introduced into the abscess cavity, which has been localized on a CT scan. The location of the abscess determines the percutaneous approach (i.e., transpleural, subpleural, transperitoneal, or retroperitoneal). Care must be taken to avoid contamination of the pleural or peritoneal cavity.

Intraoperative Hepatic Ultrasound

Intraoperative ultrasound can be used to identify anatomic structures or liver densities associated with a primary tumor or metastasis. Before rotating the liver forward and excising diseased or injured lobes or segments, it is necessary to divide the appropriate ligamentous attachments and to ligate the veins and arteries. Lesions not accessible for resection may be treated with cryosurgery or a Cavitron ultrasonic aspirator. These techniques may be used in conjunction with resection. An ultrasonic aspirator permits the precise removal of tissue and controls bleeding during resection.

Hepatic Resection

The standard anatomic resections of the liver are right or left lobectomy, right or left trisegmentectomy, and left lateral segmentectomy. Because it is a vital organ, the entire liver cannot be removed without liver transplantation. Lobectomy or segmental resection is indicated for cysts, benign or malignant tumors, or severe penetrating or blunt trauma. Depending on the location of the lesion to be resected, a right or bilateral subcostal incision or an upper midline incision is made and can be extended as needed for exposure and exploration. The liver is the most commonly injured abdominal organ. Hepatic parenchymal injuries usually cause intraperitoneal hemorrhage and shock.

Liver tissue is very friable. The prevention or arrest of hemorrhage is a prime concern. Omental flaps, falciform ligament, or a Gerota fascia flap may be used for coverage and tamponade of bleeding surfaces in conjunction with local hemostatic substances. Microfibrillar collagen, oxidized cellulose, or spray hemostatic agents are often used to control bleeding. Large, blunt, noncutting needles are used to suture the liver. Drains are usually placed in the wound and brought out through stab wounds. Equipment for blood replacement, portal pressure measurement, and chest drainage should be available.

Portosystemic Shunts

Portal hypertension, bleeding esophageal varices, or massive gastrointestinal hemorrhage may necessitate an emergency surgical procedure for decompression of the portal venous system. Often the patient is alcoholic, with cirrhosis, poor nutrition, and unstable blood volume, or generally is a poor surgical risk. A portosystemic shunt is a vascular anastomosis between the portal and systemic venous systems. The surgeon may select one of several techniques for a portacaval or mesocaval shunt. In patients with portal hypertension and hypersplenism, a splenorenal shunt may be performed in conjunction with a splenectomy for portal decompression.

Splenic Procedures

The highly vascular spleen is located in the upper left abdominal cavity and lies beneath the dome of the diaphragm; it is protected by the lower portion of the ribcage. The capsule of the spleen is covered with peritoneum and is held in place by numerous suspensory ligaments. The splenic artery furnishes the arterial blood supply, and the splenic vein drains into the portal system.

As the largest lymphatic organ of the body, the spleen has an intimate role in the immunologic defenses of the body and acts as a blood reservoir. The main functions of the spleen involve the formation of blood elements. Radionuclide scanning and other radiographic studies provide information for analysis.

Splenectomy

The most common reason for removal of the spleen is hypersplenism—overactivity that causes a reduction in the circulating quantity of red cells, white cells, platelets, or a combination of them. Splenectomies are often scheduled at specific times because patients often require the administration of whole blood immediately before a surgical procedure. Often these patients are also receiving steroid treatment, and provisions are made to maintain therapy during the surgical procedure and postoperatively.

Hematologic disorders, tumors, or accessory spleens may also necessitate surgical intervention. A splenic rupture requires an immediate surgical procedure to prevent fatal hemorrhage and may require a splenectomy. In certain patients with benign disease, a laparoscopic approach has been successfully used for splenectomy.

In performing a splenectomy, a left rectus paramedian, midline, or subcostal incision is used to enter the peritoneal cavity, and the spleen is displaced medially by careful manual manipulation. The splenorenal, splenocolic, and gastrosplenic ligaments are ligated and divided. Great care should be exercised in ligating the splenic artery and vein because these vessels are often friable. Hemorrhage is the principal intraoperative hazard. After removal of the spleen and before closure, careful inspection for bleeding from the splenic pedicle and retroperitoneal space is essential.

Splenorrhaphy

After a splenectomy, patients—especially children—are immunologically impaired (i.e., more susceptible to infection), which sometimes can produce catastrophic results. To protect the patient's immune competence, surgeons attempt to salvage splenic tissue after splenic trauma. Splenorrhaphy, or splenic repair, can be accomplished in several ways. Once the spleen is mobilized, actively bleeding vessels are ligated and devitalized tissues are debrided. The spleen then can be sutured or stapled along the edge of a partial splenectomy. Microfibrillar collagen or absorbable gelatin sponges can be placed over a small laceration or capsular tear to effect hemostasis. The splenic artery may be ligated.

The spleen may be wrapped in omentum or synthetic mesh. Segments can be reimplanted into an omental pouch in the intraperitoneal space to preserve splenic function. In patients with extensive trauma, a drain that is exteriorized through a stab wound may be inserted into the left subdiaphragmatic space.

Pancreatic Procedures

The pancreas is both an endocrine gland and an exocrine gland. The islets of Langerhans form the endocrine division and secrete the hormones insulin and glucagon, both of which are essential to the metabolism of carbohydrates and the storage of calories. Acini and the ducts leading from them constitute the exocrine portion, which secretes pancreatic juice into the duodenum. Pancreatic juice neutralizes stomach acid; the loss of pancreatic juice results in severe impairment in the digestion and absorption of food.

The pancreas lies transversely across the posterior wall of the upper abdomen behind the stomach. The head, or right extremity of the pancreas, is attached to the duodenum; the tail, or left extremity of the pancreas, is in proximity to the spleen.

Disorders of the pancreas generally include acute and chronic inflammation, cysts, and tumors. The head of the pancreas is the most common site of a malignant pancreatic tumor. Cancer in the body or tail of the pancreas is often asymptomatic until advanced and beyond surgical resection. Malignancies are more common in males than females. It is rare before the age of 45 years and is most common after the age of 60. Accuracy in the diagnosis of pancreatic problems is difficult, but evaluation by ultrasonography, endoscopic retrograde cholangiopancreatography (ERCP), and scanning has led to significant improvements in planning surgical treatment.[6]

An exploratory **laparotomy** is the most reliable means of diagnosing and evaluating pancreatic trauma. Pancreatitis is associated most often with pancreatic duct stones, gallstones, or alcoholism. Corrective biliary tract procedures usually alleviate gallstone pancreatitis.

Pancreaticojejunostomy

Pancreaticojejunostomy may be performed for relief of pain associated with chronic alcoholic pancreatitis and pseudocysts of the pancreas. There are several types of procedures for the drainage of obstructed ducts or pseudocysts. These methods involve anastomosing a loop of the jejunum (Roux-en-Y loop) to the pancreatic duct. Hemorrhage and leakage of bile are complications to be avoided.

Pancreaticoduodenectomy (Whipple Procedure)

Pancreaticoduodenectomy is an extensive procedure performed on patients with carcinoma of the head of the pancreas or the ampulla of Vater. A gastrointestinal setup is used for this procedure. The abdominal cavity is exposed through one of several possible anterior incisions, but a long right paramedian incision is usually made. The abdominal and pelvic cavities are explored for distant metastases. Because many vital structures and organs are involved in resecting the diseased proximal portion of the pancreas, careful

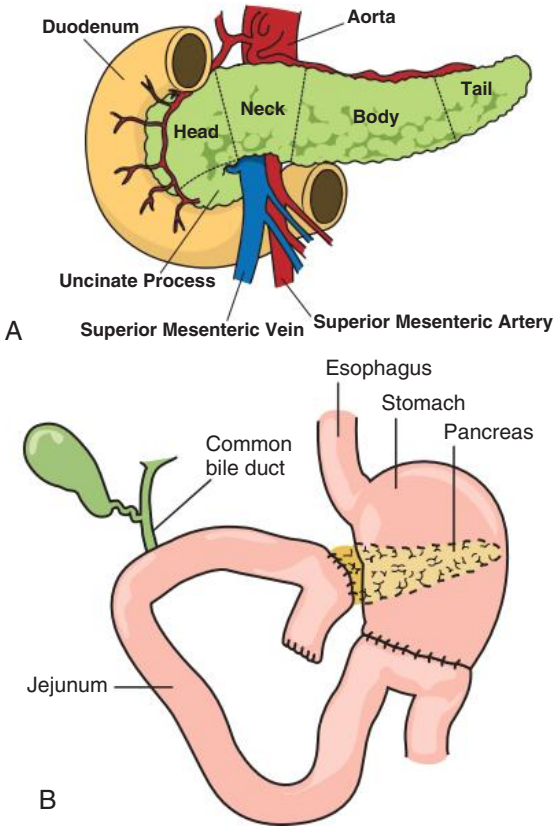
dissection of vessels is necessary to prevent hemorrhage, which complicates the procedure. Resection includes the distal stomach, the duodenum distal to the pylorus, the distal end of the common bile duct, and all but the tail of the pancreas.

Several methods of reconstructing the digestive tract are possible, but all include anastomosis of the pancreatic duct, common bile duct, stomach, and jejunum. Most surgeons reestablish biliary-intestinal continuity by end-to-side choledochojejunostomy (Fig. 33.15). The stomach and pylorus may be preserved in patients with benign disease or localized, small tumors. After pancreatic and biliary reconstruction, the divided end of the duodenum is anastomosed to the side of the jejunal limb used for the reconstruction. A watertight seal of all anastomoses is essential to prevent peritonitis or pancreatitis. Drains are inserted.

Improvements in preoperative and postoperative care and the refinement of technical details have increased the survival rate of patients who undergo this potentially hazardous radical surgical procedure. The most common postoperative complications of pancreaticoduodenectomy are shock, hemorrhage, renal failure, and pancreatic or biliary fistula. If a fistula should occur, wound suction is continued until the fistula closes. In general, the fistula will close spontaneously if adequate nutrition and electrolyte balance are maintained.

Pancreatectomy

Subtotal distal pancreatectomy is usually performed to resect a benign tumor or for chronic pancreatitis. The distal tail is resected to the head of the pancreas. A splenectomy is usually performed with this procedure because the blood supply to the tail of the pancreas comes from splenic vessels that are sacrificed. A total pancreatectomy allows a wide resection of a primary malignant tumor and its multifocal sites in the pancreas. A patient who has undergone a total pancreatectomy will have endocrine and pancreatic insufficiency.



• **Fig. 33.15** **A,** Surgical anatomy of the pancreas. **B,** Whipple procedure.

Pancreaticoduodenal Trauma

Combined injuries of the pancreas and duodenum from penetrating wounds or blunt trauma are among the most complicated to treat. A midline incision is used to explore the abdomen. Suturing to control bleeding, debridement of devitalized tissue, and draining are the initial therapies. Pancreatic fistulas and abscesses are potential complications. Extensive injury of the head of the pancreas and duodenum may require pancreaticoduodenal resection with gastrojejunostomy.

Esophageal Procedures

The esophagus is the 25 to 30-cm-long musculomembranous tube between the pharynx in the throat and the stomach in the abdomen. It is composed distally of striated skeletal muscle and proximally of smooth muscle. It passes through the thoracic cavity and enters the abdominal cavity through the esophageal hiatus (opening) in the right crus of the diaphragm; it joins the right medial surface of the stomach. The esophagus propels food by peristalsis. Within the abdominal cavity, the esophagus is bordered by the liver anteriorly and the aorta posteriorly and slightly to the left (with the spleen on the left) and between the right and left branches of the vagus nerve. The blood supply is derived from the inferior thyroid arteries and the bronchial, gastric, and phrenic branches directly off the aorta.

Patients with long-standing (more than 5 years) gastroesophageal reflux with erosive esophagitis can develop Barrett's esophagus.[7] This can happen when the cellular structure at the gastroesophageal junction has changed from squamous cells to columnar cells. It is more common in males than females and starts between the ages of 40 and 60 years.

Although there is no cure, further damage can be prevented with appropriate medical treatment. If strictures form, frequent dilation with bougie (pronounced boogee) instrumentation may be necessary. The bougies range in size from 16 to 60 French. The risk for developing cancer is between 5% and 10%, and patients with Barrett's esophagus are frequently assessed and screened by esophagoscopy and biopsy.

Surgical options include antireflux surgery (hiatal hernia repair), endoscopic ablation (with laser, radiofrequency, or cryosurgery), endoscopic mucosal resection, or esophagectomy.

Diverticula (pouches or pockets) can be present at the distal end of the esophagus near the dorsal aspect of the throat at the level of C5-C6. These pockets can herniate and collect food and can progressively become larger. These pockets are referred to as Zenker's diverticula, which account for 65% of all diverticula in the esophagus. They can become infected and necrotic or engorged to the point of rupture, which then becomes a surgical emergency. Some texts refer to a herniated diverticula as Killian's dehiscence.

Esophageal Hiatal Herniorrhaphy

When intraabdominal pressure exceeds pressure in the chest, the abdominal esophagus and a portion of the stomach may slide

through the esophageal hiatus and into the thoracic cavity. Although this condition (referred to as hiatal or diaphragmatic hernia) is quite common, a surgical procedure is indicated when the resultant esophagitis causes ulceration, bleeding, stenosis, or chest and back symptoms. Reflux esophagitis and sphincter incompetence also may have other causes that necessitate a surgical procedure.

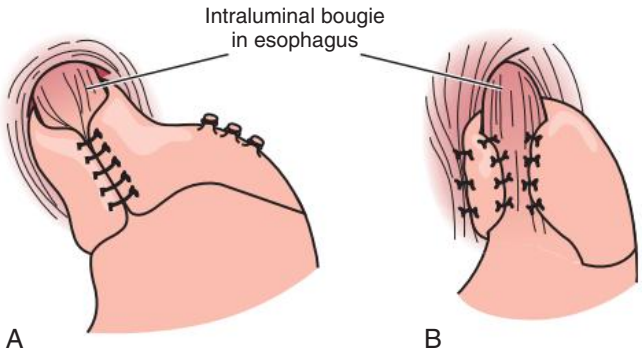
The abdominal approach to correct the problem involves a midline or left subcostal incision. Because visualization of the hiatal area may be difficult, the incision may be extended over the lower ribcage. The patient may be placed in a slight reverse Trendelenburg's position. Organs and vital structures should be protected with moist sponges and gently retracted to expose the hiatus. Long-handled clamps are needed. After mobilization, the hiatus is narrowed with heavy sutures, and the fundus of the stomach is anchored against the diaphragm to prevent recurrent herniation and gastroesophageal reflux.

Prevention of reflux is one of the prime objectives of fundoplication because it was the cause of the patient's previous esophagitis. Lengthening the intraabdominal esophagus and increasing pressure on the lower esophageal sphincter also help control reflux. The esophagus is secured by wrapping the proximal stomach (fundus) around the gastroesophageal junction in one of two ways: either by a total 360-degree wrap (Nissen fundoplication) or by a 180 to 200-degree wrap (Toupet partial fundoplication) (Fig. 33.16). The fundus of the stomach acts as a flap valve to create pressure around the distal esophagus, thus decreasing reflux. As an alternative to fundoplication, some surgeons insert an antireflux collar-like prosthesis around the esophagus just above the gastroesophageal junction.

A laparoscopic fundoplication, which may be performed in select patients, has similar advantages to laparoscopic cholecystectomy. The procedure involves mobilizing the esophagogastric junction and repairing the hiatal defect with a continuous suture technique. This is followed by a total fundoplication to fix the anterior margin of the diaphragmatic hiatus proximally and the esophagogastric junction distally. The laparoscopic approach has been successful in treating gastroesophageal reflux as a minimally invasive procedure.

Esophagogastrectomy

Removal of the lower portion of the esophagus and proximal stomach may be indicated to resect malignant tumors, benign strictures, or perforations at or near the esophagogastric junction. A left thoracoabdominal or upper midline incision is made. After the esophagus and stomach are mobilized and divided, an end-to-end esophagogastric anastomosis may be completed with staples and/or sutures. An end-to-side anastomosis with plication of the stomach around the distal part of the esophagus may be preferred. Depending on the extent of esophageal resection, other options for restoring continuity of the alimentary tract may be necessary.



• **Fig. 33.16** Hiatal hernia repair. **A,** Nissen. **B,** Toupet.

Surgical Procedures for Esophageal Varices

Esophageal varices are tortuous, dilated veins in the submucosa of the lower esophagus that may extend up into the esophagus or down into the stomach. This condition is caused by portal hypertension and is usually associated with obstruction within a cirrhotic liver. The rupture of esophageal varices can cause massive hemorrhage. The patient may come to the OR with a Sengstaken-Blakemore tube in place to control bleeding by the use of pressure from the inflated balloon in the tube. A nasogastric (NG) tube may be inserted through the central lumen to drain stomach contents and blood.

During the surgical procedure, varices may be sclerosed through an esophagoscope. A sclerosant is injected via a needle puncture into each varix. Several injections may be necessary to achieve complete hemostasis.

Sclerotherapy is usually attempted before more radical procedures are performed. The lower esophagus may be transected and the distal segment anastomosed with a circular stapler just proximal to the stomach. A portosystemic shunt procedure may be performed for portal decompression.

Gastrointestinal Surgery

Advances in the surgical management of patients with gastrointestinal problems have lessened the mortality rate. Interference with the gastrointestinal tract affects its functioning; specific deficiencies may result from gastrointestinal surgery depending on the site and extent of the surgical procedure.

Massive resection of the small intestine can produce long-term nutritional problems such as weight loss and malabsorption of most nutrients. Metabolic bone disease may follow gastric surgery because of poor absorption of calcium and vitamin D. Patients who have undergone extensive gastrointestinal procedures should have a periodic nutritional evaluation. Biochemical tests monitor nutritional status and include serum proteins, albumin-globulin ratio, and blood urea nitrogen (BUN). Body weight is also significant. If caloric intake is inadequate, protein is converted to carbohydrates for energy and as a result protein synthesis suffers.

Considerations for Gastrointestinal Surgery

The separation of instruments used for resection and anastomosis and for abdominal closure is a matter of preference of the surgeon and institution. Two distinct setups may be used, but the single setup is most commonly used. The single setup consists of identifying and using only selected instruments and supplies for resection, anastomosis, and abdominal closure and discarding contaminated instruments and equipment from the field after use. Acid secretions from the gastric resection site are very irritating and may cause peritonitis. In addition, the intestinal tract harbors many microorganisms. Leakage into the peritoneal cavity can be a source of generalized peritoneal sepsis. Gloves should be changed after anastomosis is completed; gowns also may be changed.

An NG tube is often inserted for the aspiration of gastric contents or for decompression of the intestinal tract. A variety of gastrointestinal tubes should be available for aspiration and irrigation.

Normal saline solution is used in abdominal procedures to moisten laparotomy sponges. Normal saline is an isotonic solution and has the same osmotic quality as blood serum and interstitial fluid. It will not alter sodium, chloride, or fluid balance because it does not cross cell membranes. (Hypotonic solutions cause cells to swell; hypertonic solutions cause them to shrink.) Normal saline is used for intraperitoneal irrigation unless the surgeon prefers to use a solution such as lactated Ringer's solution. Antibiotic solutions also may be needed for irrigation.

ESUs are used routinely by many surgeons for electrocoagulation of bleeding vessels in the abdominal wall, omentum, and mesentery. Ligating clips or suture ligatures are used for large vessels. To reduce tissue trauma, the jaws of intestinal forceps should be protected with soft covers made of rubber or fabric.

Stapling devices are preferred by most surgeons for mechanical organ anastomosis. An intraluminal circular stapler can be used for end-to-end, end-to-side, or side-to-side anastomoses from the esophagus to the rectum. A straight linear stapler may be preferred for some gastrointestinal anastomoses and resections. Because the size of the lumen varies in different organs of the gastrointestinal tract, the circulating nurse should not open a sterile disposable stapler until the surgeon determines the appropriate head size or cartridge length for the instrument to be used.

The technical principles that guide the surgeon for all gastrointestinal anastomoses include the following:

- Good blood supply
- No tension
- Adequate lumen
- Watertight and leak proof
- No distal obstruction

A hand-sutured anastomosis produces an inverted suture line with serosa-to-serosa approximation. Many surgeons prefer anastomosing the inner seromuscular layer with absorbable interrupted or continuous sutures and the outer layers with either absorbable or nonabsorbable interrupted stitches.

A stapled anastomosis results in anastomosed mucosa-to-mucosa apposition.

Gastric Procedures

The stomach, a hollow muscular organ, is situated in the upper left abdomen between the esophagus and duodenum (see Fig. 33.20). Anatomically, it is divided into the fundus, body, and pyloric antrum. The two borders of the stomach, the lesser and greater curvatures, are important surgically because of their relation to the major vascular and lymphatic systems that supply the stomach.

The blood supply is derived from the celiac axis. The gastroduodenal artery and the right and left gastric arteries are the main tributaries. The splenic artery gives rise to the gastroepiploic arteries that are located at the greater curvature. The venous drainage follows the arterial supply but empties into the portal circulation of the liver.

The lymphatics empty into the pancreaticosplenic nodes and into the cisterna chyli via the celiac group. Omentum, a double fold of peritoneum attached to the lesser and greater curvatures, loosely covers the stomach and small intestine.

The innervation is both sympathetic and parasympathetic. The vagus nerve controls the reflex activities of movement and the secretions of the alimentary canal and is significant in rhythmic relaxation of the pyloric sphincter.

Food entering the stomach is reduced to chyme, a semiliquid, and then passes through the duodenum and small intestine. The chyme is absorbed through the lacteals of the intestine into the lymphatics, where it is converted to a milky white chyle. The chyle flows into the cisterna chyli and into the thoracic duct.

The main functions of the stomach are motor, secretory, and endocrine. The motor aspect moves the food along. The secretory actions cause the food to break down. The endocrine component is responsible for the release of gastrin and somatostatin. Gastrin causes the release of acid, and somatostatin inhibits the release of gastrin.

The interference of gastric motor activity or muscular contractions results in gastrointestinal complaints of abdominal pain, nausea, vomiting, hemorrhage, and dyspepsia. Some diseases, such as cancer, may not produce symptoms until the condition is far advanced. A surgical procedure is indicated when the presence of disease is established after laboratory tests such as gastric analysis, gastroscopy, and/or x-ray studies.

After gastric surgery, dumping syndrome may be experienced by patients shortly after eating. This complication occurs when food and fluids empty rapidly into the jejunum. It is characterized by nausea, vomiting, weakness, dizziness, pallor, sweating, palpitations, and diarrhea. Dumping syndrome after eating may persist for 6 months to 1 year postoperatively.

Gastroscopy

Gastroscopy involves the passage of a flexible fiberoptic gastroscope. This procedure is usually performed while the patient is sedated, with a topical anesthetic applied in the oropharynx to control the gag reflex. The operator visually inspects the mucosal walls of the stomach, and tissue specimens are sometimes obtained. Bleeding points may be coagulated with a laser, ESU, or sclerosing agent.

Gastrostomy

Establishment of a temporary or permanent opening in the stomach may be indicated for gastrointestinal decompression or to provide alimentation for a prolonged period when nutrition cannot be maintained by other means. A gastrostomy tube eliminates the incidence of aspiration that may occur around an NG tube. Often the patient is too debilitated to tolerate a major surgical procedure or may have an inoperable esophageal tumor or oropharyngeal trauma. A Foley, Malecot, Pezzer, or mushroom catheter may be inserted percutaneously into the stomach.

Simple Gastrostomy

With the patient under general anesthesia, the stomach is exposed through a small upper left abdominal or midline incision. The catheter is inserted into the anterior gastric wall and is held in place with purse string sutures; it is brought out through a separate stab wound in the left upper quadrant. The stomach is sutured to the abdominal wall at the exit site of the catheter. After an abdominal procedure on a critically ill patient, the surgeon may prefer to place a small-bore catheter into the jejunum rather than the stomach for enteral hyperalimentation.

Percutaneous Endoscopic Gastrostomy

With percutaneous endoscopic gastrostomy, the patient is placed under IV sedation and an endoscopist introduces a fiberoptic gastroscope and insufflates the stomach with air to create a working space and a turgid surface to the stomach.[8] Light from the

scope is directed anteriorly for transillumination through the abdominal wall. The surgeon infiltrates the skin with a local anesthetic at a selected gastrostomy site, usually approximately one third of the distance along the left costal margin at the midclavicular line. The gastrostomy tube is introduced through a percutaneous puncture and secured with sutures.

Gastric Resections

The stomach may be totally or partially resected for removal of a malignant tumor or for benign chronic ulcer disease. Although surgical resection is the only cure, gastric carcinomas are often inoperable because of metastases to the liver or extension into surrounding tissues. In such cases, palliative procedures may be performed. The appropriate procedure is determined after thorough exploration of the abdominal cavity by the surgeon. Circular staplers are commonly used for anastomosis after resection. Leakage at the site of anastomosis leads to peritonitis. Some surgeons oversew the staple line.

Total Gastrectomy

With a total gastrectomy, the entire stomach is excised for malignant lesions through a bilateral subcostal, long transrectus, or thoracoabdominal incision. A total gastrectomy necessitates reconstruction of esophagointestinal continuity by establishing an anastomosis between a loop of jejunum and the esophagus. This anastomosis may be end-to-side with a lateral jejunojejunostomy or end-to-end with a Roux-en-Y jejunojejunostomy. The purpose of the jejunojejunostomy is to prevent the reflux of bile and pancreatic fluids into the esophagus. Some surgeons create a jejunal pouch for this purpose.

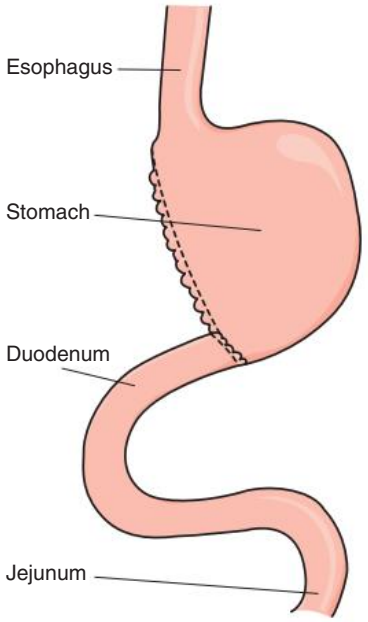
Subtotal Gastrectomy

Partial resections of the stomach, originally described by Theodor Billroth (1829–1894), are often referred to as Billroth procedures. A benign lesion (usually an ulcer) or a malignant lesion located in the pyloric half of the stomach requires removal of the lower half to two thirds of the stomach. In a patient with a gastric or duodenal ulcer, a partial resection limits gastric acidity and relieves pain, bleeding, vomiting, and weight loss.

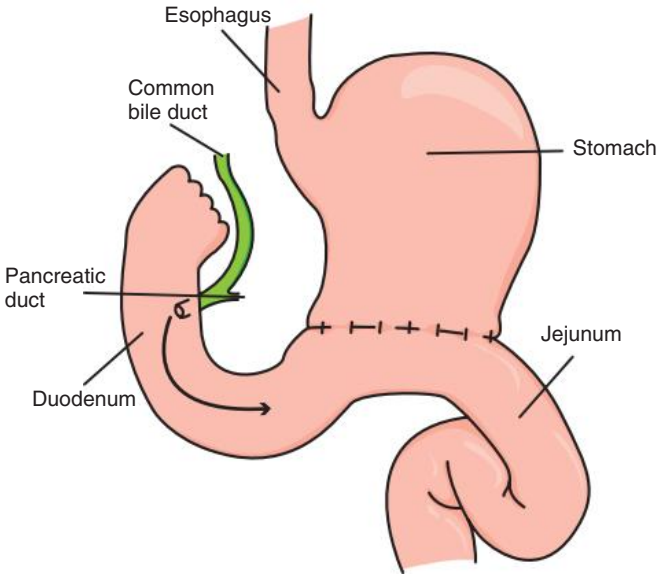
In this procedure, the peritoneal cavity is entered through a right paramedian or upper midline abdominal incision. A variety of surgical procedures may be used to reestablish gastrointestinal continuity. Anastomosis of the remaining portion of the stomach to the duodenum (gastroduodenostomy, antrectomy, or Billroth I, Fig. 33.17) or to a loop of the jejunum (gastrojejunostomy, or Billroth II, Fig. 33.18) is often performed. A truncal vagotomy, which is discussed in the following section, is performed to eliminate the possibility of postoperative peptic ulceration.

Common modifications of the Billroth I procedure are the Schoemaker and von Haberer-Finney techniques. The Schoemaker procedure involves end-to-end anastomosis of the stomach and duodenum after the lesser curvature of the stomach is sutured to make the anastomosis site the same size as the duodenum. With the von Haberer-Finney method, the lateral wall of the duodenum is brought up to the stomach so that the entire end of the stomach is open for direct anastomosis.

Popular modifications of the Billroth II procedure include the Polya and Hofmeister techniques, both of which involve variations of end-to-side gastrojejunostomy.



• **Fig. 33.17** Billroth I gastrectomy with anastomosis to duodenum.



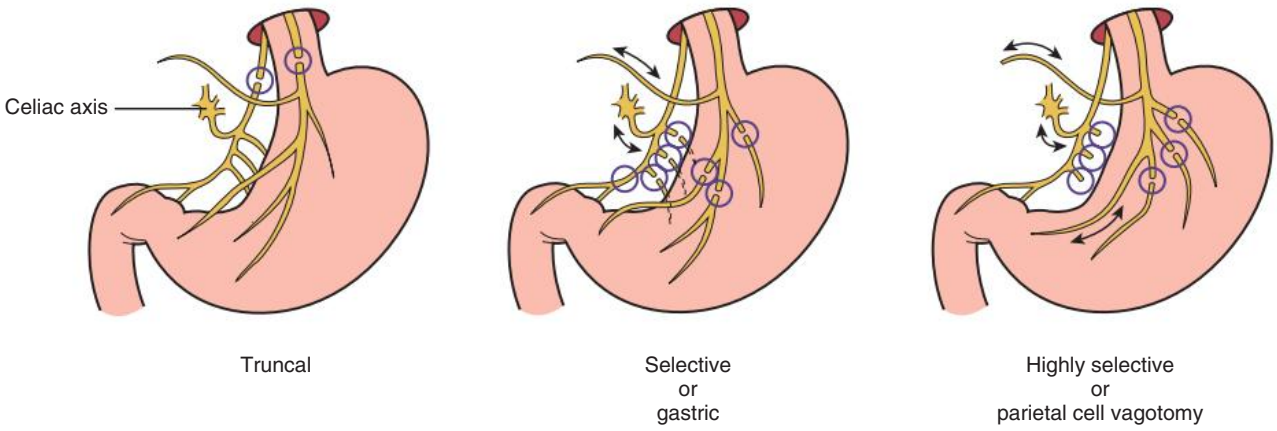
• **Fig. 33.18** Billroth II subtotal gastrectomy with anastomosis to jejunum.

Vagotomy

Chronic gastric, pyloric, and duodenal ulcers that do not respond to medical treatment cause patients severe pain and difficulty in eating and sleeping. Vagotomy, the division of the vagus nerves, may be recommended to interrupt vagal nerve impulses, thus lowering the production of gastric hydrochloric acid and hastening gastric emptying. Vagotomy can be performed at several different locations along the course of the vagus nerve (Fig. 33.19).

Proximal gastric vagotomy, also known as parietal cell vagotomy, divides the vagal nerve fibers to the proximal stomach but maintains the entire stomach and vagal nerves to the antrum. These sections of the vagal nerve inhibit the release of gastrin, a stimulant of gastric secretion.

Truncal vagotomy and selective vagotomy require a concomitant drainage procedure because these procedures denervate the stomach. A gastroenterostomy is performed with a truncal vagotomy, which divides the vagal trunks at the distal esophagus. An antrectomy is performed with a selective vagotomy, which transects the



• **Fig. 33.19** Vagotomy.

gastric branches. Vagotomy with drainage is a compromise procedure and is restricted to high-risk patients or those with severe duodenal deformity.

Pyloroplasty, enlarging the pyloric opening between the stomach and duodenum, may be performed in patients with an obstructing pyloric ulcer or in conjunction with vagotomy to treat bleeding duodenal ulcers. Duodenal dilation or duodenoplasty may be indicated.

Vagotomy procedures, which are conservative surgical therapies compared with gastrectomy, decrease the surgical risk for select patients with chronic ulcers. It is now known that ulcers caused by the *Helicobacter pylori* organism can be cured with antibiotics.

Gastrojejunostomy (Roux-en-Y Gastroenterostomy)

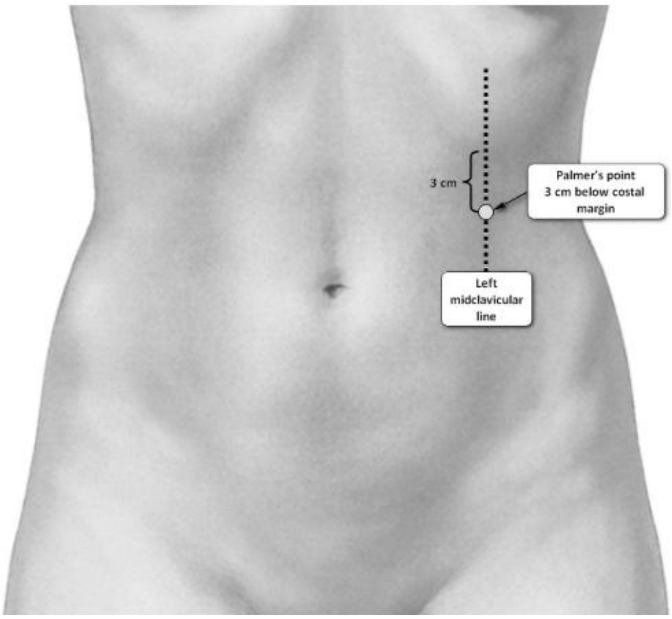
A procedure may be necessary to reestablish continuity between the stomach and intestinal tract, such as after a partial gastrectomy or when the lower end of the stomach is obstructed by an ulcer or a nonresectable tumor. A gastrojejunostomy may be performed to treat alkaline reflux gastritis, postgastrectomy syndromes such as postvagotomy diarrhea, and dumping syndrome. Except in geriatric patients, a concomitant vagotomy is necessary to prevent a postoperative gastrojejunal ulcer when the acid-forming portion of the stomach is not resected.

In this procedure, a loop of jejunum may be anastomosed to either the anterior or the posterior wall of the stomach; both approaches have advantages and disadvantages. In a Roux-en-Y gastrojejunostomy, the jejunum is divided. The distal end is anastomosed to the side of the stomach, and the proximal end is anastomosed to the side of the jejunum at a lower level. The result is a Y-shaped double anastomosis that diverts the flow of bile and pancreatic enzymes directly into the jejunum, bypassing the created gastric stoma.

An adaptation of a Roux-en-Y anastomosis is also used to drain the biliary tract or other organs, such as the pancreas or esophagus, directly into the jejunum to bypass the stomach and prevent the reflux of intestinal contents.

Bariatric Surgery

The study of morbid obesity, or bariatrics, has led to the development of a subspecialization in general surgery: bariatric surgery. AORN (The Association of periOperative Registered Nurses) has published guidelines for the safe care of patients undergoing bariatric procedures.



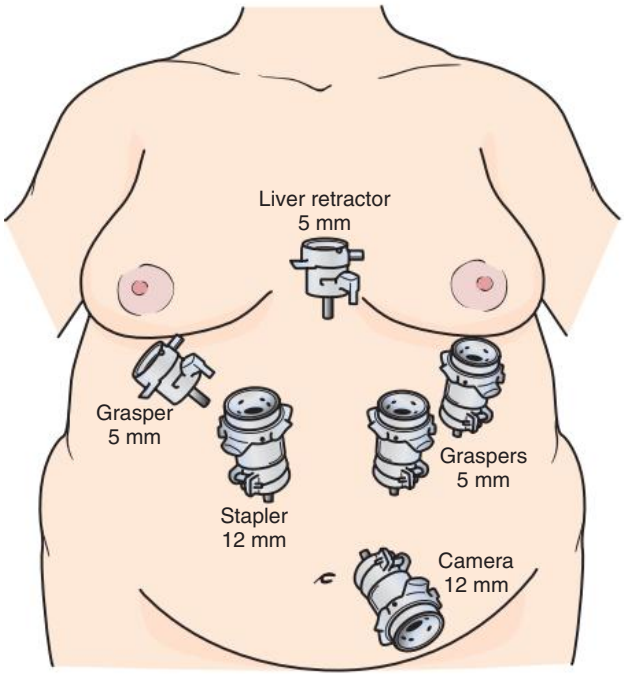
• **Fig. 33.20** Palmer's point for alternative insufflation when the umbilical area is not safe. (From Granata M: Are we underutilizing Palmer's point entry in gynecologic laparoscopy? *Fertil Steril* 94(7):2716–2719, 2010.)

Bariatric surgery can be performed as an open abdominal surgery or as a laparoscopic procedure. The surgical landmarks are altered in obese patients because the body habitus is large and extends beyond the borders of the average-sized patient. Insufflation via Veress needle may not be performed at the umbilicus. An alternative site is Palmer's point, because the risk for injury is less (Fig. 33.20). The umbilicus, for example, lies several inches lower on a pendulous abdomen. Using the infraumbilical or supraumbilical area of the patient as an inflation or primary trocar site could cause injury to nontarget organs (Fig. 33.21).

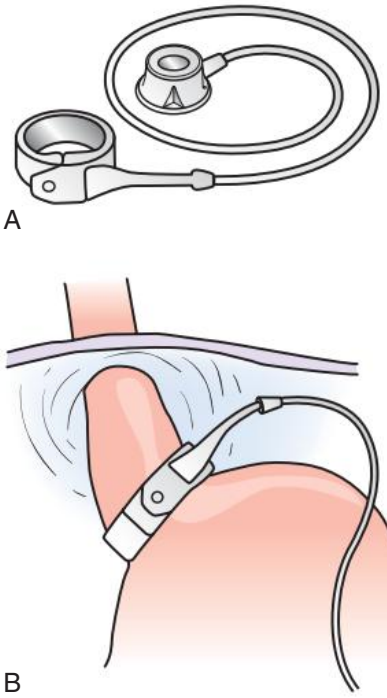
Bariatric procedures produce three types of results:

1. Restricted intake caused by an inflatable Silastic band (Fig. 33.22)
2. Bypass the food and decrease absorption (Fig. 33.23)
3. Bypass absorption and restrict intake

People who have a body mass index (BMI) of 40 or more, weigh 100 lbs (45.4 kg) more than their ideal weight, and have failed to lose weight despite years of medical treatment are potential

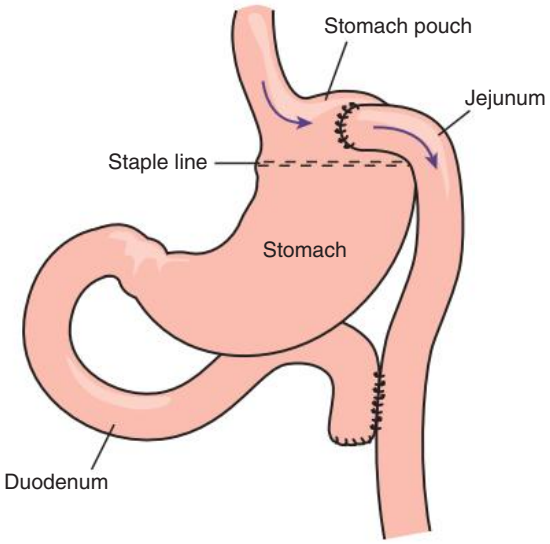


• **Fig. 33.21** Laparoscopic ports for a bariatric procedure. Note the displacement of the umbilical landmark.



• **Fig. 33.22** Gastric banding. **A,** Gastric band with port. **B,** Gastric band in place.

candidates for bariatric surgery. Patients with a BMI of 35 to 40 and have serious comorbid disease, such as obstructive sleep apnea, cardiomyopathy, and type 2 diabetes, may be candidates after careful screening. The plan of care requires the patient to have psychologic and physiologic support during the process, or the procedure could be a failure. Some facilities have extended the procedure to obese adolescents aged 11 years and older, with varying degrees



• **Fig. 33.23** Gastric bypass for a bariatric procedure.

of success. The average age for adolescent bariatric surgery is 15 to 19 years old.[9]

The physical size of a patient who is obese presents special needs with respect to transporting and positioning, selecting instrumentation, and providing psychologic and physiologic support. The OR bed must support the patient's weight and fit the length and width of the patient's body habitus. The standard OR bed cannot do these things safely, so a special OR bed must be used.

Many morbidly obese patients have medical complications such as hypertension, peripheral vascular disease, cardiac disease, degenerative arthritis, gallbladder disease, or diabetes mellitus.[10] Consideration is given to pressure-reducing surfaces, such as gel pads and positioning devices designed to hold large limbs.

The plan of care for obese patients usually includes the application of antiembolic stockings and the insertion of an NG tube, a Foley catheter, IV and arterial lines, and central venous pressure (CVP). Because respiratory distress is a potential complication during the induction of anesthesia, intubation while the patient is awake may be the technique of choice. Many obese patients have short, wide necks, so positioning head support in a "sniffing posture" may be necessary to establish a secure airway.

The types of surgical procedures performed for bariatric surgery can be done via open or endoscopic methods. Natural orifice transluminal endoscopic surgery (NOTES) is feasible, but not widely developed for the gastric alterations necessary to restrict absorption or reduce volume in weight loss surgery. The procedures and instrumentation for any approach are modified to suit the patient's size. Single-incision laparoscopy has been adapted to accommodate longer instrumentation and a deeper port matched to the thickness of an obese patient's abdominal wall. The average surgical landmarks are not reliable because of adipose layers and redundant skin. This in combination with adhesions from previous abdominal surgery can disqualify the patient from a single-incision approach.

Bariatric procedures for gastric restriction are not without risks. Nutritional deficiencies, anemia, wound infection, and a failure of staple lines have occurred postoperatively. The capacity of the stomach is reduced to approximately 30 mL to restrict food absorption or intake. Patients lose at least 25% to 60% of their excess body fat.

Gastroplasty

In gastroplasty, which is usually referred to as a vertical banded gastroplasty, four linear staple lines are placed vertically on the lesser curvature side of the stomach just left of the gastroesophageal junction in addition to a gastric band to cause restriction of intake. This creates a small channel for the passage of gastric contents from the proximal to the distal segments. The total intake at any given time is about 1 ounce. The stomach is divided between staple lines and oversewn with sutures.

To prevent dilation, the outlet at the end of the staple line is usually reinforced with a Silastic band. This method does not have the same restricted absorption as gastric bypass. Some patients do not lose satisfactory amounts of weight because they take in excess high-calorie liquids and sugary foods.

Gastric Bypass

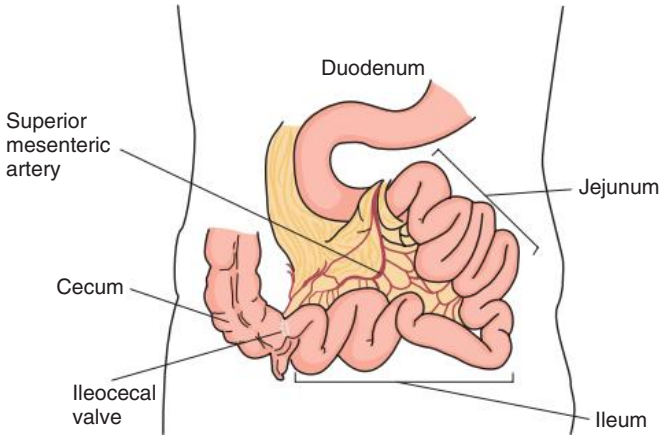
In a gastric bypass procedure, the capacity of the stomach is restricted by creating a small pouch in the fundus (the proximal segment of the stomach) and bypassing portions of the small intestines to decrease the absorptive qualities of the gastrointestinal tract (see Fig. 33.23). The stomach is transected horizontally with a linear stapler, and the proximal jejunum is divided. A Roux-en-Y gastrojejunostomy is constructed between the 1 ounce size pouch, vertically oriented stomach pouch, and the jejunum, bypassing the remainder of stomach to establish intestinal continuity for the passage of gastric contents. The proximal jejunal segment is anastomosed end-to-side to the distal segment for drainage of gastric, biliary, and pancreatic fluids.

Patients are advised not to eat concentrated sugars because it stimulates dumping syndrome. Nutrient supplements, such as vitamins, iron, and calcium, are necessary to prevent anemia and osteoporosis.

Intestinal Procedures

Anatomically, the intestines are divided into the small (upper) and large (lower) intestines, and there are subdivisions of each.

The small intestine extends from the pylorus to the ileocecal valve. The three sections include the duodenum (proximal portion), the jejunum (middle section), and the ileum (distal portion that joins the large intestine). The ileocecal valve, a sphincter muscle, lessens the backflow of material that has been discharged to the large intestine. The blood supply to the small bowel is divided into arcades with several subdivisions (Fig. 33.24).



• **Fig. 33.24** Small bowel arterial blood supply.

The large intestine, or colon, extends from the ileum to the rectum and is generally divided into the ascending, transverse, descending, and sigmoid colon. The cecum is the pouch formed where the large intestine joins the small intestine. The blood supply to the large bowel is united on the mesenteric border by the marginal artery of Drummond with widely dispersed arcades of vessels (Fig. 33.25).

The mesentery, a peritoneal fold, attaches the small and large intestines to the posterior abdominal wall and contains the arteries, veins, and lymph nodes that supply the intestines.

Inflammation, intestinal obstruction, and disruption in absorption and motility are disorders that may lead to surgical intervention. Etiologic factors determine the surgical procedure. Segments of bowel can be removed, and the continuity can be reestablished by anastomosis (Fig. 33.26).

Resection of the Small Intestine

Tumors, as well as strangulation from adhesions, volvulus, obstruction, and regional ileitis, usually are treated by resection of the involved segment. An abdominal incision is made over the suspected or known site of disease. After exposure, clamps are placed above and below the diseased segment of the bowel and mesentery to avoid spillage. The involved area is resected, and an end-to-end, end-to-side, or side-to-side anastomosis is performed to restore continuity.

Variations of this technique are used for other related problems of the small intestine, such as extensive perforation. Bowel strangulation and obstruction necessitate an immediate surgical procedure to prevent necrosis, peritonitis, and death.

Hemicolectomy, Transverse Colectomy, Anterior Resection, and Total Colectomy

Colitis, diverticulitis (or diverticulosis), obstruction, and neoplasms are the most common reasons for surgical intervention to remove a diseased segment of the colon. Most surgical procedures involve opening the abdomen, walling off the peritoneal cavity, incising and clamping at the points where resection is to be carried out, and, finally, reestablishing continuity by anastomosis.[11] In select patients, a laparoscopic approach may be used to mobilize the segment of the large or small bowel to be resected. The resected bowel is removed through a small minimal-access incision in the abdominal wall. Stomas also can be created with the laparoscopic technique.

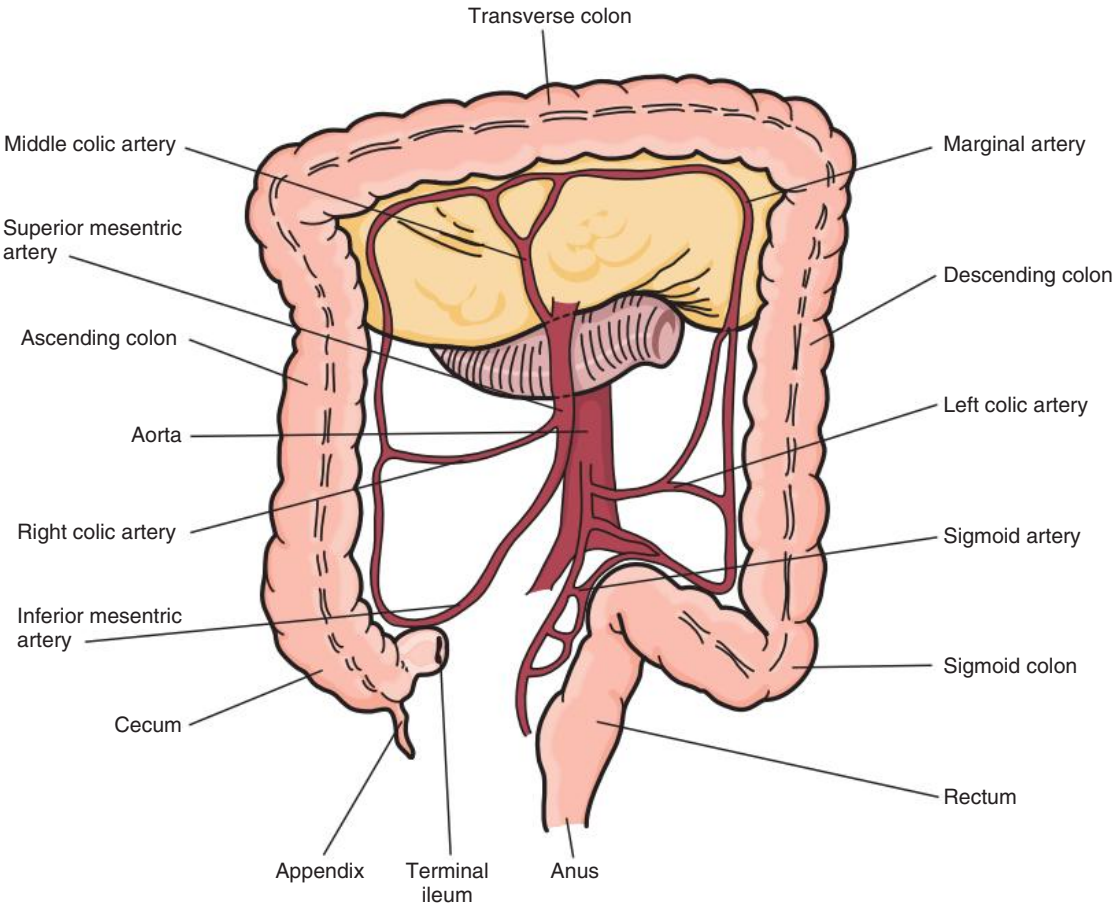
The perioperative plan of care includes preoperative administration of intestinal antibiotics, bowel-cleansing methods, and diet restrictions (e.g., a clear liquid diet). Bowel cleansing can cause depletion of electrolytes and is performed only as necessary.

Intraoperatively, contaminated instrument technique should be used during the procedure. Instruments used on the interior aspect of the bowel should not be used on other tissues and should be isolated after use.

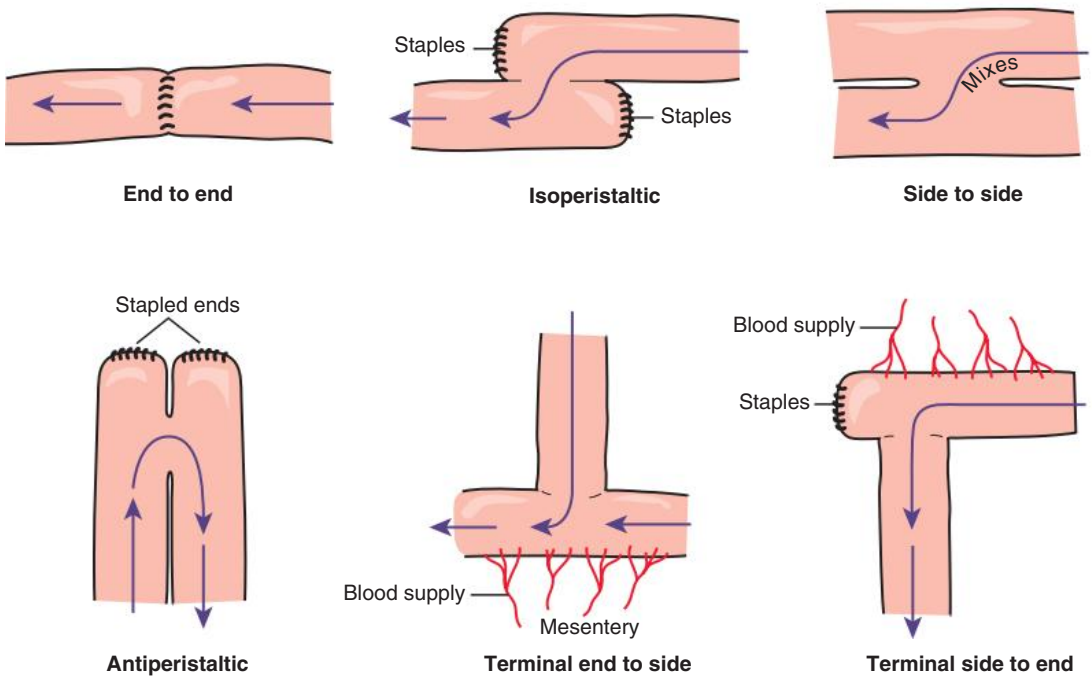
An NG tube may be inserted before the surgical procedure begins and may remain in place until partial healing of the anastomosis occurs and effective peristalsis returns. Fluid and electrolyte balance is maintained.

Intestinal Stomas

An intestinal ostomy is a surgically created opening, or **stoma**, that extends from a portion of the bowel to the exterior via the



• **Fig. 33.25** Large bowel arterial blood supply.



• **Fig. 33.26** Intestinal anastomoses. Intestinal anastomoses can be performed with sutured anastomoses or with circular or linear staplers, as shown here. Same principles apply to other anastomoses, such as vascular structures.

abdominal wall. This procedure may be performed to divert intestinal contents so inflamed bowel can heal, to decompress pressure caused by an obstructive lesion, or to bypass an obstruction such as a benign or malignant tumor. A stoma can be created from the large or small bowel. Some intestinal stomas are temporary; others are permanent.

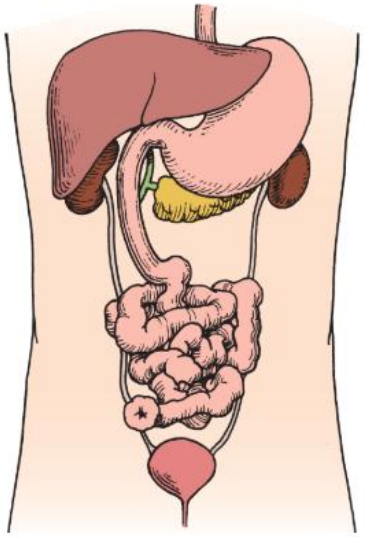
The type and level of the lesion determine whether an ileostomy, cecostomy, or colostomy is indicated. Preoperatively, the patient's abdomen will be assessed for stoma placement based on the type of stoma, body size, and belt line. The stoma site is marked so the patient's clothing will not interfere with the collection appliance. Most facilities have stoma nurses available to assist with stoma planning and teaching. An ileostomy will be positioned on the right side of the lower abdomen. The output will be more frequent and liquid. A colostomy is usually positioned on the left side of the abdomen. The output will be more formed.

In patients with a temporary stoma, intestinal continuity is reestablished after healing, through closure of the opening in the bowel and anastomosis of the previously separated ends. If the stoma will be permanent, the patient will wear a collection appliance at all times.

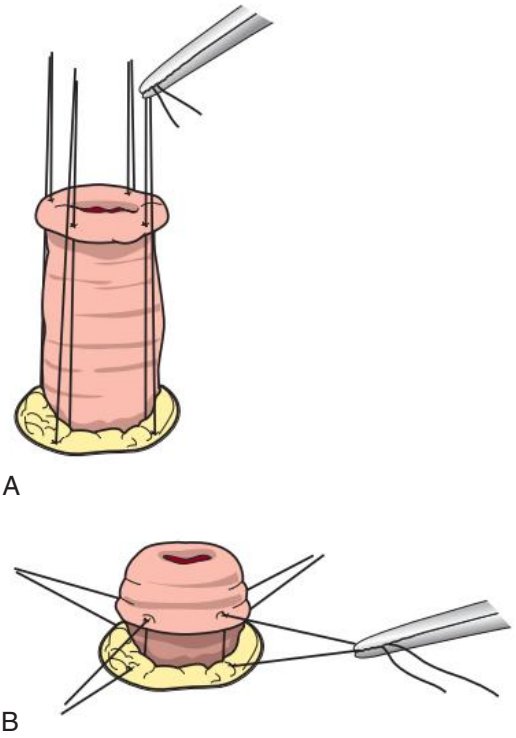
The patient's acceptance of these procedures is as varied as an individual's emotional reactions. Each patient requires a rehabilitation plan based on personal needs. These plans should include care of the collection appliance, maintenance of skin integrity, proper diet, odor control, and comfortable clothing. Patient participation is an integral part of the preparation for self-care and enhances self-confidence.

Ileostomy

An ileostomy is performed for conditions such as chronic ulcerative colitis or after removal of the colon (colectomy). In this procedure the proximal end of the transected ileum is exteriorized through the abdominal wall (Fig. 33.27). The usual stoma site is the midportion of the right rectus sheath, approximately 3 cm below the level of the umbilicus. First, a disk of epithelium the size of the planned stoma is excised. The anterior and posterior sheaths are then incised, and the rectus sheath is divided with a muscle-splitting incision. The proximal end of the ileum is brought out through the peritoneum and muscle to the skin; here the edges are everted and sutured to the skin (Fig. 33.28). Liquid or semisolid discharge is collected in an ileostomy bag placed over the stoma. The surrounding skin requires special care to prevent excoriation and irritation.



• **Fig. 33.27** Ileostomy. Proximal end of transected ileum is brought out through peritoneum and muscle. The end is everted and sutured to skin. Stoma site is in midportion of right rectus sheath below level of umbilicus.



• **Fig. 33.28** Ileostomy stoma is brought through an opening in the skin and sutured into place. **A,** The edges of the intestinal mucosa are aligned with subcuticular tissues by sutures. **B,** The stoma is formed by everting the mucosa and tying the sutures.

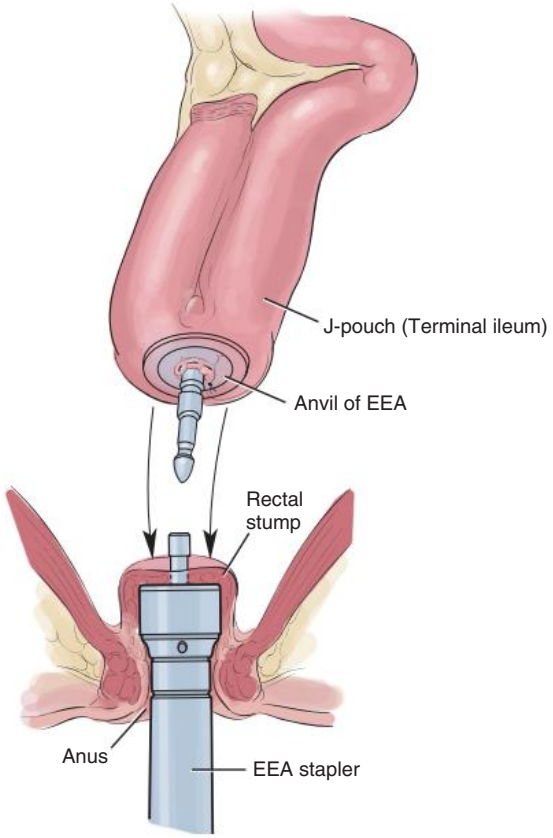
The entire cecum and colon, as well as the rectal mucosa (mucosal proctectomy), are resected in an endorectal-ileoanal pull-through procedure. The ileum is anastomosed to the anus with a circular stapler. The rectal and anal muscles are preserved for anal continence.

In a multistage procedure, a pouch can be constructed for use as a fecal reservoir using loops of the terminal ileum. This procedure can be performed as an open surgery or laparoscopically. Pouch configurations can resemble a J, W, or S. Studies have shown that the J pouch is the preferred method overall. A 20-cm J pouch is fashioned of the ileum with a linear stapler. The lower curve of the J is anastomosed to the rectal stump with a circular stapler side to end (Fig. 33.29). During the healing period, a temporary ileostomy may be in place. Fecal material will pass through the ileostomy, pouch, and the rectum. The anal anastomosis is closely monitored during this time for integrity. Once it is confirmed that the pouch is healed and the anastomosis is secure, the ileostomy will be closed as a final step in the process.

Although not without complications, these procedures offer acceptable alternatives to a permanent ileostomy stoma, especially in children and young adults.

Cecostomy

With a cecostomy, an opening is created in the cecum, and a tube is inserted for decompression of the massive distention caused by colonic obstruction. The tube is placed into the cecum through the lower right side of the abdomen. Less severe distention may



• **Fig. 33.29** Ileorectal anastomosis of a J pouch created from a loop of ileum. Anastomosis is 1.5 cm superior to dentate line performed with a circular stapler (end-to-end anastomosis [EEA]). (From Khatri VP: *Atlas of advanced operative surgery,* Philadelphia, 2013, Saunders.)

be relieved by suction and irrigation through a colonoscope and the insertion of an intestinal tube through the anus to the cecum. Cecostomy or colonoscopic decompression may precede subsequent colon resection.

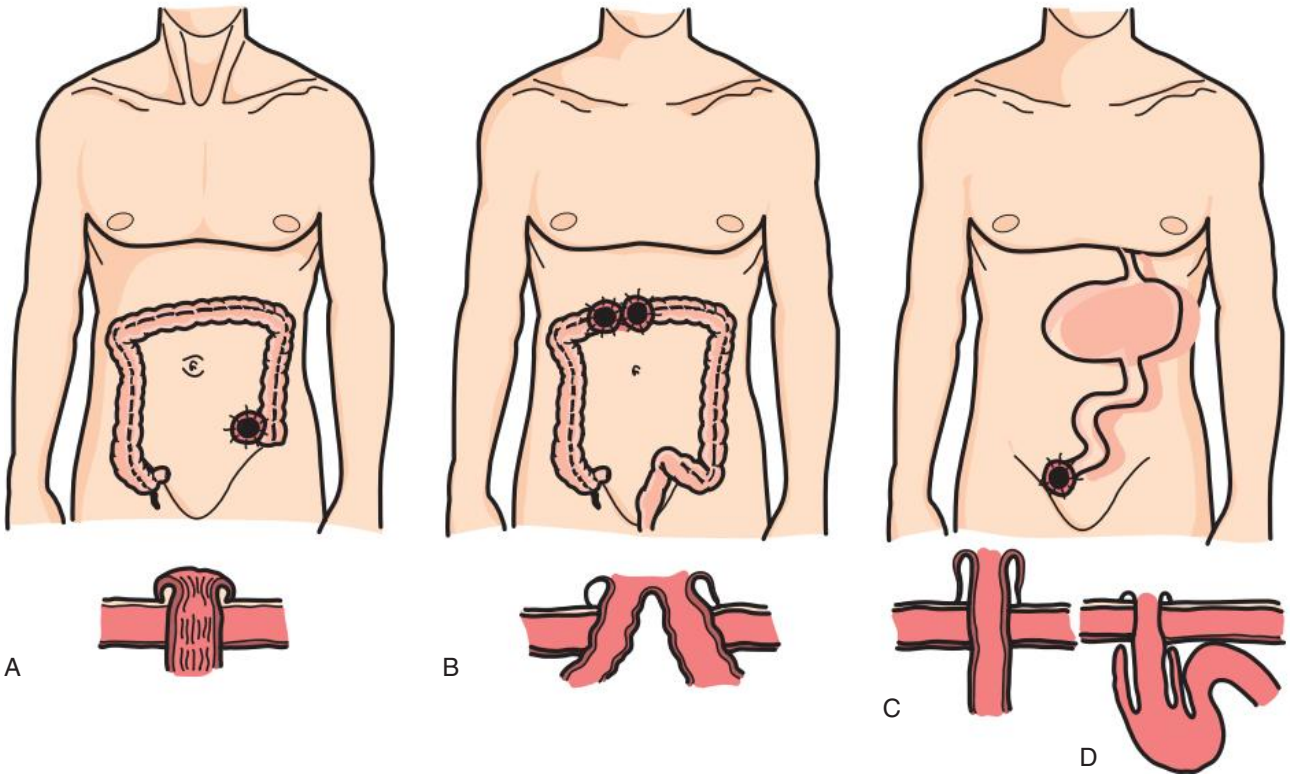
Colostomy

An opening anywhere along the length of the colon to the exterior skin surface creates an artificial anus (Fig. 33.30). The section of colon to be exteriorized depends on the location of the lesion to be resected or treated. For example, a low anterior bowel resection necessitates a sigmoid colostomy. A permanent colostomy in the sigmoid colon forms an artificial anus after a combined abdominoperineal resection for rectal carcinoma (see Fig. 33.30, *A*). The rectum is removed. A collection device for fecal material is not needed after a patient's bowel evacuation becomes regulated. Most patients wear a stoma cap even when they are in the process of regulation.

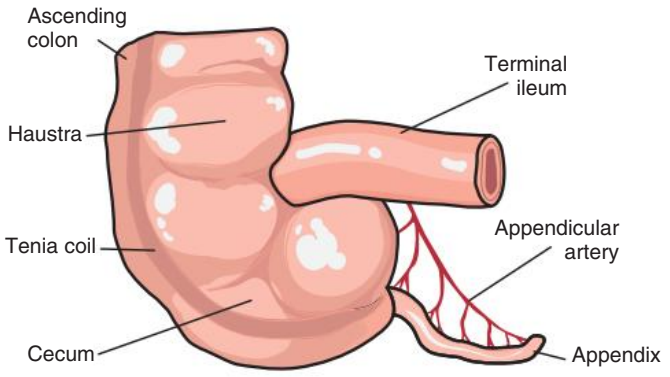
Either a double-barreled or a loop colostomy may be performed as a temporary measure. In a double-barreled colostomy (see Fig. 33.30, *B*), the transverse colon is divided and both ends are brought out to the margins of the skin incision. The proximal stoma serves as an outlet for feces, and the distal opening leads to the nonfunctioning bowel. In a loop colostomy (see Fig. 33.30, *C*), a loop of colon is brought out onto the abdominal wall. A plastic rod or ostomy bridge is placed under the loop to hold it out on the exterior abdominal wall. The peritoneum is closed, and the wound around the colostomy is sutured.

Appendectomy

Appendicitis can occur at any age but is seen most often in adolescents and young adults. It may imitate other conditions such as a ruptured ovarian cyst or ureteral calculus. Some appendices are retrocecal, which makes diagnosis and excision more difficult



• **Fig. 33.30** Comparison of intestinal stomas. **A,** Colostomy. **B,** Transverse double-barrel colostomy. **C,** Ileostomy. **D,** Continent ileostomy.



• **Fig. 33.31** Cecum and appendix.

(Fig. 33.31). Classic symptoms of early appendicitis include pain in the right lower quadrant at McBurney's point, rebound tenderness, nausea, and moderate elevations in temperature and white blood cell count.

An emergency appendectomy is necessary to prevent a progression to gangrene and the perforation of friable tissue, with subsequent peritonitis. Most appendectomies can be performed via laparoscopy. The open abdominal approach involves a muscle-splitting incision in the right lower quadrant, over McBurney's point. The blood supply to the appendix is ligated and severed. A crushing clamp is applied to the appendiceal base, which is then ligated and severed from the cecum. After amputation, the surgeon may elect to cauterize the stump with phenol and alcohol or wipe it with a sponge soaked with an iodophor (povidone-iodine [Betadine]) to reduce contamination. The stump is then inverted into the cecum as a purse string suture is tightened around the stump (Fig. 33.32). Instruments used in the appendectomy are isolated as contaminated and not used on other tissues.

Drainage is indicated in the presence of an abscess, appendix rupture, or any gross contamination of the wound. An appendectomy is usually an uncomplicated procedure with rapid convalescence unless life-threatening peritonitis results.

Laparoscopic Appendectomy

After creation of a peritoneal working space with carbon dioxide, trocars are placed, the laparoscope is inserted through the infraumbilical incision, and the patient is placed in Trendelenburg's position. If a single-lumen approach is not used, secondary trocars are inserted in the suprapubic area and left lower quadrant for placement of graspers and dissectors. The appendix is located and hemostatically dissected from the mesoappendix with endoscopic clips or staples. Endoloop ligatures are placed at the base of the appendix, and endoscopic scissors are used to transect it. Grasping forceps are used to place the appendix into an Endopouch collection reservoir to prevent the extrusion of contents during evacuation through the infraumbilical trocar.

Colorectal Procedures

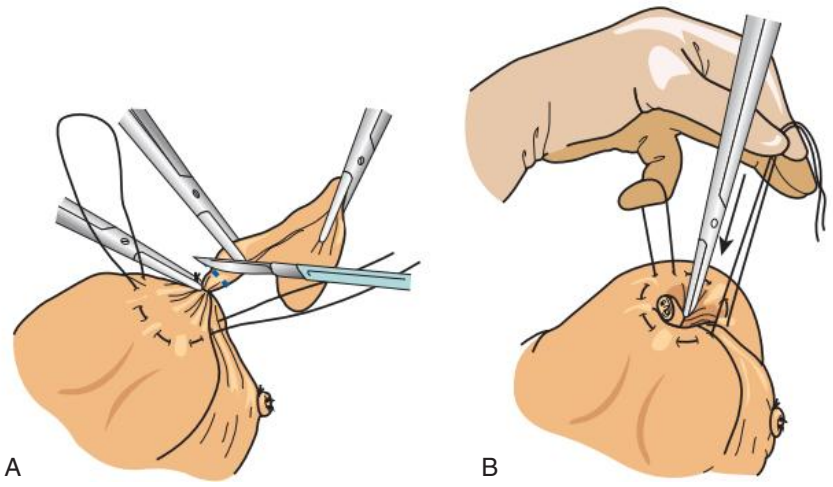
Colorectal carcinoma is one of the most common abdominal malignancies, with the highest incidence in people older than 60 years. Resection of the carcinoma is the surgical procedure of choice; radiation and chemotherapy are adjuvant therapies or palliative therapies for advanced disease. Early diagnosis and prompt treatment of asymptomatic carcinoma improve the survival rates.

Diagnostic procedures are routinely performed in patients with bowel or rectal bleeding, chronic diarrhea, or a history of intestinal polyps and/or carcinoma of the colon. Serial guaiac stool tests may detect the presence of occult blood. A barium enema provides a complete radiographic study of the colon. Colonoscopy is commonly done in place of a barium enema. An endoscopic examination is routine. Some therapeutic procedures may be accomplished with laser or ESU through an endoscope.

Sigmoidoscopy

Sigmoidoscopy is direct visual inspection of the sigmoid and rectal lumens by means of a flexible fiberoptic or rigid lighted sigmoidoscope. The flexible scope is more comfortable for the patient and gives the surgeon better visualization of the mucosal surface to evaluate the left colon and rectosigmoid. It may be used intraoperatively to check an anastomosis or for preoperative diagnosis. Water-soluble lubricant is used to help ease insertion of the scope.

The patient is prepared preoperatively with enemas and colon cleansing. Placing the patient in the left lateral position allows for anatomic positioning of the sigmoid colon. The knee-chest or Kraske position allows the sigmoid colon to fall forward into the



• **Fig. 33.32** Ligation of the appendiceal stump. **A,** A purse string suture is placed around the base of the appendix. It is double-clamped and dissected with a scalpel. **B,** The appendiceal stump is inverted into the circumference of the purse string suture. The suture is tightened as the stump is buried within.

abdomen. The Sims or lithotomy position may be used for an extremely obese or extremely ill patient.

The surgeon may inflate room air into the colon with a hand-pumped bulb to create a working space during insertion of the well-lubricated scope to better visualize the mucosal walls and folds. This insufflation stimulates the stretch receptors of the bowel, causing a feeling of desire to defecate, which necessitates reassurance of the patient. Have the suction handy for evacuation of air from the colon at the conclusion of the procedure.

Colonoscopy

Colonoscopy provides visual inspection of the lining of the entire colon. This is facilitated by placing the patient in left lateral position so that the folds of the large intestine will be in anatomic alignment (Fig. 33.33). The colonoscope is flexible and consists of two channels: one for suctioning and irrigating and one for operating. Its greatest uses are to examine the lumen of the colon, to perform a biopsy of tissues, and to search for and excise or ablate polyps. Other indications are for the study of inflammatory bowel or diverticular disease, the passage of blood in the feces (hematochezia), or a change in bowel habits; as a preoperative screen before colostomy closure; for confirmation of radiographic findings; and as a follow-up for patients who have undergone intestinal procedures. Argon and Nd:YAG lasers or ESU are used through a colonoscope to ablate some tumors and to treat polyps, arteriovenous malformations, and bleeding disorders.

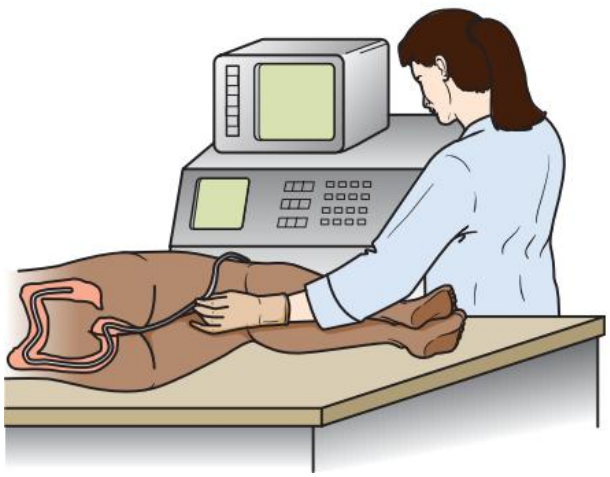
Because the presence of stool in the rectum prevents adequate examination with the scope, the patient should have a preoperative bowel evacuation prep. Colonoscopy without moderate sedation is contraindicated if the patient is uncooperative. Relative contraindications may include acute, severe, or radiation-caused inflammatory disease or complete obstruction. Perforation can occur. Vital signs should be monitored during the procedure.

Complications of colonoscopy include electrical burn during polypectomy, tearing or perforation of the colon by tip pressure, tearing of the liver or spleen by air pressure, and tearing of diverticula resulting from the introduction of air into them.

Polypectomy

Most surgeons and pathologists agree that adenomatous mucosal polyps in the colon are potentially malignant and should be removed. A polypectomy is usually performed through a fiberoptic colonoscope. Polyps, which are often familial, may be single or multiple and are easily excised at the base. The colonoscope may be used intraoperatively to locate polyps.

If the polyps are pedunculated, they are cauterized at the stalk and retrieved by a snare for microscopic examination. Electrocoagulation or lasing of the base provides hemostasis. Some polyps or the involved segment of colon is removed by laparotomy or laparoscopy. After a polypectomy, patients should have annual colonoscopic examinations.



• **Fig. 33.33** Correct anatomic left lateral position for colonoscopy.

Abdominoperineal Resection

Abdominoperineal resection (also known as the Miles procedure) is a radical type of colectomy and excision of the rectum and anus performed for colon cancer or extreme inflammatory disease. This procedure may include not only the lower sigmoidal segment, but any portion up to the entire colon. The distal resection is too deep to permit anastomosis of the colon or ileum to the anal region. The patient will have a permanent colostomy or if the entire colon is removed, a permanent ileostomy.

Preoperative preparations include presurgical bowel prep to evacuate the bowel contents. The patient will be positioned supine in low lithotomy using boot-style stirrups after the administration of general anesthesia. Sequential compression devices should be used on the legs. The anesthesia provider will insert an NG tube to decompress the gastrointestinal tract. The circulating nurse will open two prep sets; one for the perineum and a separate one for the abdomen.

Some surgeons prefer to use ureteral stents to make ureteral identification and preservation easier. This requires a cystoscopy setup and two ureteral catheters prepared for the urologist. The perineum is prepped, and the urologist inserts the ureteral catheters that will be connected to ureteral drainage collection. A Foley catheter is inserted at this time because the ureteral catheters will be removed postoperatively and the indwelling catheter will remain in place. The cystoscopy table should be kept sterile at the side of the room in case the urologist needs the instrumentation to remove the stents at the conclusion of the procedure.

If ureteral stents are not used, two prep sets are necessary. The perineum is prepped first, and a Foley catheter is inserted. Using the second prep set, the abdominal skin is prepped from the xyphoid to the pubis.

The instrumentation is set up on two separate tables and requires two separate teams (abdominal and perineal) to work simultaneously. The perineal team will drape the patient using a lithotomy drape pack with leggings. The abdominal team will then drape the abdomen. Great care is taken to keep the instrumentation and counted items separated. Usually one circulating nurse can manage the separation of the materials. Both teams work at the same time.

The abdominal team will open the abdomen with a full midline incision from subxyphoid to the pubis. Some surgeons use a left paramedian incision. The surgeon will "take down" the colon from its mesenteric attachments. When the colon is mobilized, the distal rectum is divided with a linear stapler (GIA). The remaining proximal end of the resected colon will be clamped and transected from the segment being removed. Some surgeons tie off the remaining bowel segment with saline-moistened cotton umbilical tapes. The bowel specimen is removed and handed off in a basin to the circulating nurse. The abdominal surgeon mobilizes the remaining rectal stump remnant in preparation for its removal by the perineal team. The pelvic floor is reperitonealized,

and the anorectal stump is removed by the perineal team. The abdomen is irrigated with sterile normal saline and suctioned using a Poole tip to protect the organs. The terminal portion of bowel will be exteriorized to form a stoma.

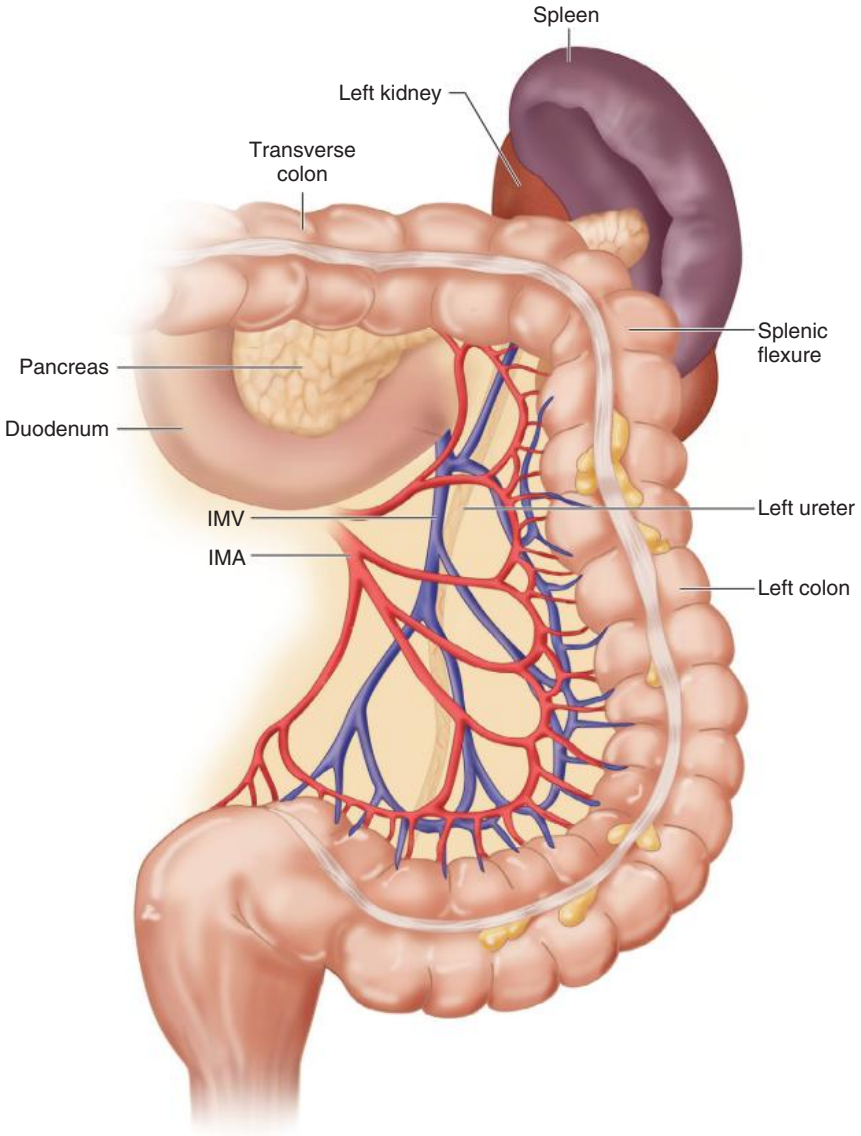
The abdominal tissue layers are closed with suture, and the skin is usually closed with staples. One or more drains may be used. Dry sterile dressings are applied. A stoma appliance will be positioned to collect intestinal contents.

The perineal team will close the anus with a heavy silk purse string suture and simultaneously direct the elliptical dissection from distal to proximal, separating the perianal tissues from the tip of the coccyx to midperineal floor and circumferentially from the anus toward the rectal margins. The lower blood supply arises laterally from the middle hemorrhoidal artery at the point where the abdominal resection and the perineal dissection meet. The anorectal stump is removed from the perineum. The levator ani muscles are approximated if possible, and the skin layers closed with suture. Some surgeons use a Penrose drain in the perineal incision for 24 to 48 hours. Fluff gauze and mesh pants are commonly used as dressings.

Postoperatively, the NG tube may remain in place for 24 hours and the Foley catheter may stay in for several days. If ureteral stents were used, they will be removed before the patient leaves the OR. The patient will be taken to the PACU and remain there until stable enough to be discharged to the patient care division. Sequential compression devices should be used on the legs until the patient is ambulatory to minimize the risk for deep vein thrombosis.

Low Anterior Colon Resection

The sigmoid colon and rectum lie within the bony pelvis, which makes the resection of tumors in the lower sigmoid colon, rectosigmoid, and rectum technically difficult. The objective is to achieve wide local excision with en bloc resection of the lymphatics and perirectal mesentery (Fig. 33.34). Intraluminal and linear



• **Fig. 33.34** Left colon resection. *IMA,* Inferior mesenteric artery; *IMV,* inferior mesenteric vein. (From Fleshman JW, Birnbaum E, Hunt S, et al: *Atlas of surgical techniques for colon, rectum, and anus,* Philadelphia, 2013, Saunders.)

staplers facilitate colorectal anastomosis in a low anterior colon resection. The distal colon is transected after closure with a linear stapler. The intraluminal stapler, with the anvil removed, is introduced through the anus and rectal stump either through or adjacent to the linear staple line. After the anvil is replaced, an intraluminal end-to-end or end-to-side anastomosis with the proximal segment of colon is completed.

Total excision of the mesorectum is necessary to prevent recurrence of the tumor in the pelvis or at the staple line; a distal tumor clearance of at least 2 cm is necessary. With this technique for low anterior colorectal anastomosis, colorectal continuity is restored and anal sphincter control is maintained without necessitating a permanent colostomy; with an abdominoperineal resection, a permanent colostomy is necessary.

The surgeon may check the colorectal anastomosis with a sigmoidoscope at the completion of the surgery before closing the abdomen. The sigmoidoscope will be placed in the rectum, and room air will be used to insufflate and expand the anastomosed segment. The abdomen will be simultaneously filled with warm saline irrigation. The anastomotic line will be observed for air leak. If a leak is present, air bubbles will rise to the surface of the irrigation solution. If no leak is present, the irrigation is suctioned out of the abdomen using a Poole tip with a guard. The sigmoidoscope is withdrawn, and the air is permitted to escape.

Abdominal Trauma

Trauma is the major cause of death in people younger than 40 years. Bleeding from the disruption of solid organs or major vessels in the abdomen (including the pelvis) and infection from perforation of a hollow viscus are life-threatening injuries.

Abdominal trauma is usually caused by one of the following:

- Blunt trauma caused by direct impact, rapid deceleration, shearing forces, and/or increased intraluminal pressure can rupture or sever multiple structures, including those that are retroperitoneal.
- Penetrating injuries involve structures within the path of the weapon; gunshot wounds may also injure adjacent structures through the blast effect or cavitation. A stab or gunshot wound of the abdomen can penetrate across the diaphragm into the chest or vice versa.

Planning Perioperative Care for Abdominal Trauma Patients

Many patients have multiple injuries that affect more than one body system. These patients require a comprehensive approach to diagnosis and treatment by a multidisciplinary team. The philosophy of trauma management has changed from that of an individual surgeon treating an injured patient in the emergency department and OR to a system that begins at the site of the accident with stabilization by trained personnel and continues with definitive care, including rapid surgical intervention and rehabilitation. This section will concentrate on abdominal trauma and its surgical evaluation and treatment.

Systematic Approach to Evaluation

When dealing with abdominal trauma patients, the first thought is hemorrhage or fecal spill. Other injuries such as biliary or pancreatic spillage are less common. Severe penetrating trauma can be complicated by evisceration.

Ultrasonography, x-ray, and CT scan are useful presurgical diagnostic tests to assess the extent of abdominal injuries and determine indications for surgical intervention. Free air in the abdomen generally indicates a ruptured organ, such as the bowel. This necessitates immediate laparotomy to locate the torn organ and control seepage of bowel contents. CT scan and ultrasonography provide additional assessment data.

Peritoneal Lavage

The patient who is hypotensive with left upper quadrant pain requires a peritoneal lavage to determine active intraabdominal bleeding. Before the procedure, the patient is positioned supine and an NG tube placed to decompress the stomach and observe contents (if not contraindicated by upper body or facial injury). A Foley catheter should be inserted to decompress the bladder and observe the urine.

The peritoneal lavage procedure is done under local anesthesia by creating a 2-cm midline incision in one of two planes: infraumbilical or supraumbilical (if the patient is pregnant or has a fractured pelvis). The incision extends to the peritoneal membrane, which is anesthetized and grasped with hemostats. The peritoneum is incised only under direct vision. If blood is seen immediately rushing from the peritoneal incision, a rapid-sequence induction is performed by the anesthesia provider, and an immediate exploratory laparotomy is performed.

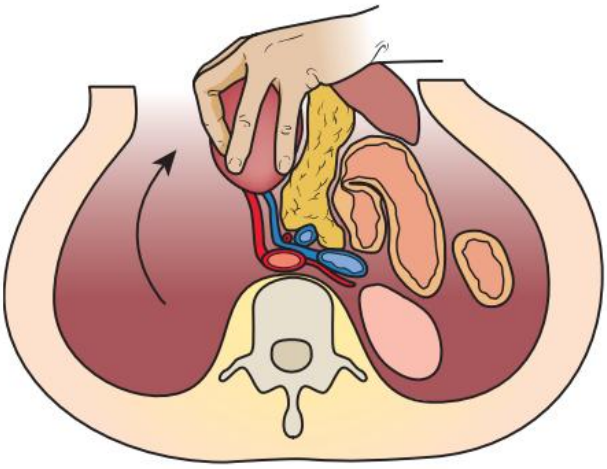
If no immediate hemorrhage is seen, proceed by instilling body-temperature lactated Ringer's solution or sterile normal saline, 10 mL/kg. The circulating nurse and anesthesia provider document all fluids into or out of the patient's abdomen. Allow the solution to sit in the abdomen for a few moments. The organs can be slightly agitated by hand and the solution drained into a basin or container with a lid. The circulating nurse labels the irrigant and sends it to the laboratory for a rush cell count. The laboratory personnel look for blood cells, stool, vegetable matter, or any other indicator of intraabdominal injury. Negative findings mean that the patient needs no further intraabdominal surgery at that time but will be monitored closely for any change in condition.

Keep in mind that retroperitoneal bleeding may not be diagnosed with peritoneal lavage. Many major structures such as the great vessels and kidneys are retroperitoneal. Injuries to the great vessels require an immediate surgical procedure to control bleeding and restore vascular continuity. Major organ injuries mandate an open laparotomy for repair or reconstruction or to resect severely damaged tissues.

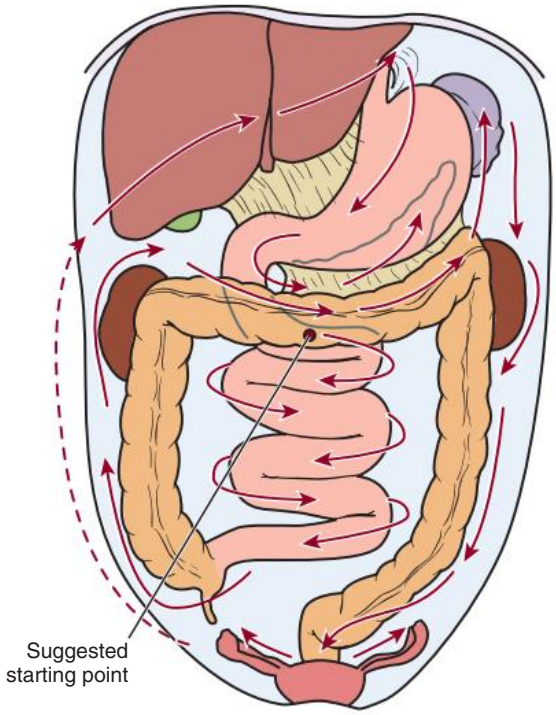
Emergency Exploratory Laparotomy

The patient is positioned supine and prepped from chin to groin. An NG tube is placed and a Foley catheter inserted. The surgeon makes a midline incision from xyphoid to pubis in some cases. The surgeon carefully displaces the abdominal contents laterally to examine each angle of the individual organs (Fig. 33.35). After careful inspection of the viscera, the surgeon manually palpates the entire length of the bowel, starting at the duodenum and ending at the sigmoid flexure. This process is referred to as "running the bowel" (Fig. 33.36).

After the exploration, any injuries to the organs caused by the trauma are repaired, and the abdomen is closed. If the exploratory procedure was extensive, the patient's tissue may be extremely edematous and might not approximate without undue tension. The patient's abdomen may have to remain open for several days



• **Fig. 33.35** Displacing organs during exploratory laparotomy.



• **Fig. 33.36** Direction for running the bowel. Examination of the bowel for injury after trauma.

and the patient brought back to the OR for a delayed primary closure.

Each surgeon has a routine for protecting the patient's open incision until the edges can be approximated. Some surgeons use sterile Silastic sheeting circumferentially stapled to the wound edges to form a temporary cover. If Silastic sheeting is not available, some surgeons have cut sterile 3000-mL IV bags to fit like a patch (referred to as a Bogota or silo bag). A bulky dressing is placed over the area, and the patient is transferred to intensive care for stabilization and monitoring.

Great care is taken to count and be accountable for instruments, sharps, and items used in the emergency procedure. The organized team works in concert to perform counts as possible based on the patient's condition. Some surgeons order a routine x-ray of the patient's abdomen before transfer to the unit. If laparotomy sponges or towels must be left inside the patient as visceral retainers, the circulating nurse documents the exact number placed inside the patient and communicates the same information to the surgeon and the intensive care nurse in the hand-over report. This information could be valuable if the patient crashes in the unit and some of the sponges must be removed outside the OR.

Non-OR personnel may accidentally discard the sponges by not realizing that they are counted items. When the patient is brought back to the OR for closure, the sponges are to be accounted for in their entirety and documented as being retrieved. Care again is taken not to mix the removed sponges with the sponges used for the closure procedure.

Complications of Abdominal Surgery

Patients are particularly prone to pulmonary complications after abdominal surgery. They are also subject to a variety of fluid and electrolyte imbalances because they generally have nothing-by-mouth (NPO) status postoperatively. They may also lose sodium, potassium, chloride, and water through NG suction. If great quantities of alkalotic pancreatic secretions are lost through decompression of the small bowel, metabolic acidosis may result. The loss of acidic stomach secretions may lead to metabolic alkalosis.

Peritonitis and wound infection may result after gastrointestinal surgery because of spillage of contaminants from the lumen of the gastrointestinal tract. *Escherichia coli* and *Bacteroides fragilis* are the most common organisms; *Clostridium perfringens* (endospore-forming bacteria), the chief cause of gas gangrene, can be found in the intestinal tract. Blood supply can be compromised, causing ischemic bowel. Wound infection can cause wound disruption and/or the formation of scar tissue; the latter is enhanced by peritonitis or postoperative radiation therapy. Even years after an abdominal procedure, increased intraabdominal pressure may induce an incisional hernia through an old scar that has weakened.

Adhesions are the most common cause of postoperative intestinal obstruction. They are caused by an outpouring of fibrin from traumatized tissues, which causes intestinal surfaces to stick together and thus limits mobility.

Foreign bodies in the peritoneal cavity can produce granulomas that stimulate fibrin. Glove powder, lint from sponges, and some powerful antibiotics also can produce granulomas. Some patients must return to the OR for lysis of adhesions. Adhesions may present a contraindication for future laparoscopic surgery.

Anorectal Procedures

Hemorrhoids, abscesses, fissures, and fistulas are often indications for surgical intervention. The anal region is well supplied with nerves, and these procedures often cause much discomfort. Patients are also sensitive and embarrassed because of the surgical site. After rectal surgery, patients may have an initial difficulty voiding and usually experience considerable pain, which requires medication and sitz baths.

Anoscopy, Proctoscopy, and Sigmoidoscopy

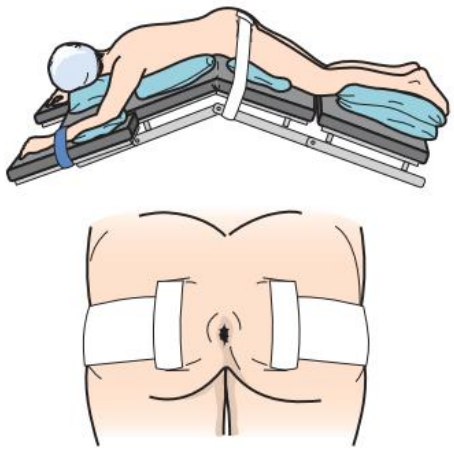
Endoscopic diagnostic procedures such as anoscopy, proctoscopy, and sigmoidoscopy are used for visual examination of the mucosa of the anus, rectum, and sigmoid. Sigmoidoscopy is routinely performed before rectal surgery. Some surgeons prefer a sigmoidoscope setup to be available for all colorectal procedures for periodic anastomosis

checks. Fiberoptic equipment has aided in the early detection and treatment of tumors, polyps, and ulcerations.

Hemorrhoidectomy

Hemorrhoidectomy is the surgical removal of varicosities of veins or prolapsed mucosa of the anus and rectum that do not respond to conservative treatment. Hemorrhoids are classified as internal (occurring above the internal sphincter and covered with columnar mucosa) or external (appearing outside the external sphincter and covered with skin). Often both types are present in the patient. External hemorrhoids cause pruritus and pain, whereas the internal type often bleed and may become thrombosed and edematous. Rectal bleeding cannot be assumed to be a result of hemorrhoids; a thorough investigation is required to rule out gastrointestinal disease.

The usual procedure for a hemorrhoidectomy consists of dilating the sphincter, ligating the hemorrhoidal pedicle with suture ligatures, staples (circular stapler), or Silastic bands, and excising each hemorrhoidal mass with a sharp dissection, laser, ESU, or cryosurgical unit. Sclerotherapy can be done by injecting a hypertonic solution to shrink the hemorrhoidal veins, this is usually done on smaller hemorrhoids. The Kraske position generally is used, with the patient's buttocks retracted by wide adhesive strips that are fastened to the edges of the OR bed (Fig. 33.37).



• **Fig. 33.37** Patient positioning for hemorrhoidectomy.

Some surgeons prefer to position female patients in the lithotomy position to avoid contamination of the vagina with bloody anal fluid. When lithotomy is used for males, the scrotum gets in the way and may need to be retracted with temporary stay sutures or superficial skin staples. Petrolatum gauze packing may be inserted in the anal canal, or a fluff gauze dressing and mesh pants are applied at completion of the surgical procedure. Some surgeons insert a belladonna suppository to suppress peristalsis during the healing period.

As an alternative to a surgical procedure, McGivney rubber band ligation of internal hemorrhoids is a common office procedure. After infiltration of a local anesthetic, the hemorrhoid is visualized with an anoscope and grasped with the McGivney ligating instruments (Fig. 33.38). Two bands are placed around the base of each hemorrhoid. Sloughing of the avascular hemorrhoid occurs in 7 to 10 days.

Incision and Drainage of an Anal Abscess

Localized infection in tissues around the anus results in abscess formation. Early incision and drainage are essential to prevent spreading of the infection.

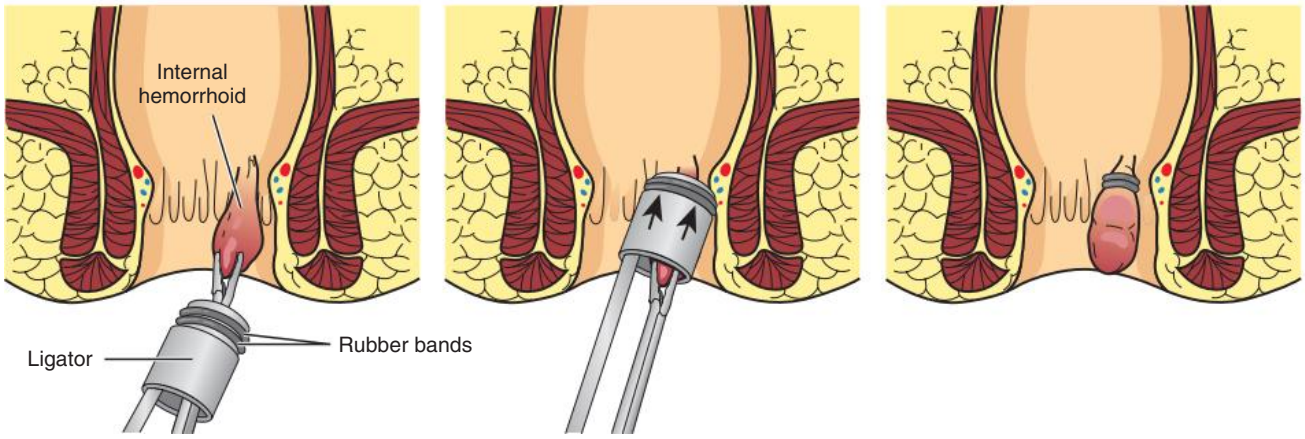
Fistulotomy and Fistulectomy

An anal fistula often develops after incision and drainage or the spontaneous drainage of an anorectal abscess. A fistulous tract may be opened (fistulotomy) to allow drainage and healing by granulation, or the tract may be excised (fistulectomy). Injection of a dye or the use of a probe and grooved director aids in identifying the tract.

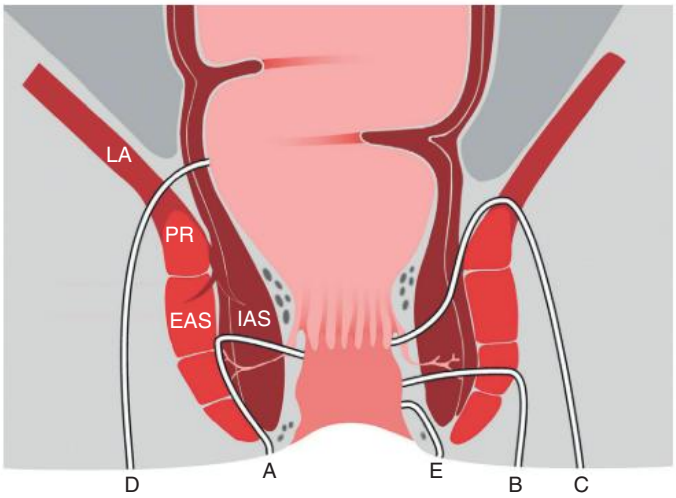
Fistulas tend to follow a predictable path along the ischiorectal or supralevator planes. The prediction of the path (origin and exit) is referred to as Goodsall's rule of anal fistulas (Fig. 33.39). A Seton drain can be placed to assist drainage and healing of abscess collections. Surgical excision is staged to prevent injury to the anal sphincter.

Fissurectomy

When a benign ulcerative lesion occurs in the lining of the anal canal, the anus is dilated, and the infected tissue is excised. Some fissures can be vaporized with a laser. Fecal incontinence caused



• **Fig. 33.38** Hemorrhoid banding instrument.



• **Fig. 33.39** Pathways of perianal fistulae. Park's Classification: **A,** intersphincteric, **B,** transsphincteric, **C,** suprasphincteric, **D,** extrasphincteric, **E,** superficial. *EAS,* External anal sphincter; *IAS,* internal anal sphincter; *LA,* levator ani; *PR,* puborectalis. (From Yassin NA, Day N, Phillips R: Imaging of anal fistulas, *Semin Colon Rectal Surg* 25(4):176–182, 2014.)

by damage to the anal sphincter is a potential complication that the surgeon tries to avoid.

Treatment of Rectal Tumors

Surgeons prefer to resect a small rectal cancer instead of performing a radical surgical procedure. Many cancers within 20 cm of the anal verge are amenable to local treatment with endoscopic, laser, or cryosurgical techniques. Electrosurgical cutting and coagulating can be combined to remove superficial anorectal and pararectal lesions. For electrosection, the lesion should be small, mobile, and polypoid, with no palpable lymph nodes. The procedure may be performed for palliation to relieve bleeding, painful sphincter spasms (tenesmus), or severe constipation. Interstitial radiation therapy is sometimes used for small anorectal squamous cell carcinomas. The protocol may include external radiation, but bleeding lesions do not respond well to radiation.

In a procedure called transanal endoscopic microsurgery (TEM), tumors in the upper half of the rectum may be excised through an operating rectoscope. This long, tubular instrument improves the surgeon's visual image by incorporating a binocular stereoscope. With TEM, carbon dioxide (CO_2) is insufflated to hold open the walls of the rectum. Tissue graspers, a high-frequency knife, suction, needle holders, and other instruments can be inserted through ports in the airtight eyepiece on the rectoscope. TEM may be used to remove benign lesions and some malignant tumors.

Excision of Pilonidal Cysts and Sinuses

A painful draining cyst with fistulous tracts may occur in the soft tissues of the sacrococcygeal region. When the cyst becomes infected, drainage is necessary to relieve pain, swelling, and suppuration. The cyst and sinus tracts are excised or marsupialized to prevent recurrence. Marsupialization is the suturing of cyst walls to the edges of the wound after evacuation; this permits the packed cavity to close by granulation. A Z-plasty may be preferred for primary closure to produce a strong transverse scar, or the wound may be closed with a rotational pedicle flap. Surgical judgment determines whether primary closure or healing by granulation is chosen.

Hernia Procedures

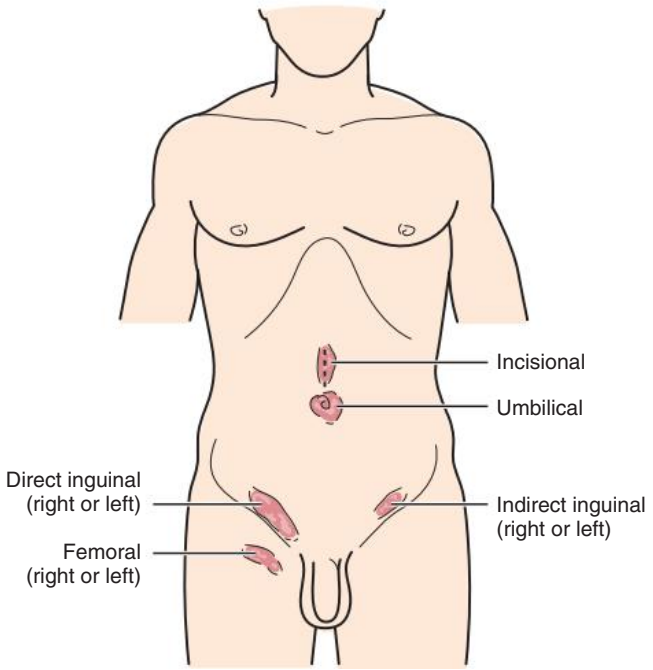
A hernia is the protrusion of an organ or part of an organ through a defect in the supporting structures that normally contain it. A hernia may be congenital, acquired, or traumatic. Most occur in the inguinal or femoral region, but umbilical, ventral, and hiatal hernias also occur (Fig. 33.40). A hernia is usually composed of a sac (covering), hernial contents, and an aperture (opening), but in some locations the sac is absent. Some surgeons send the excised hernia sac to pathology, but minimal pathology is ever found and the processing is an unnecessary cost to the patient.

A hernia is called *reducible* when the hernial contents can be returned to the normal cavity by manipulation. If this cannot be done, the hernia is called *irreducible* or *incarcerated.* Bowel present in an incarcerated hernia not only may lack adequate blood supply but also may become obstructed. This is referred to as a *strangulated hernia,* and an immediate surgical procedure is necessary to prevent necrosis and gangrene of the strangulated bowel.

Inguinal Herniorrhaphy

An inguinal hernia is often repaired with the patient under local anesthesia. An oblique inguinal incision on the affected side is extended through external oblique aponeurosis. The hernia sac is emptied of its contents, ligated, and excised, and the floor of the inguinal canal is reconstructed. Prosthetic mesh is sometimes needed to reinforce a large or recurrent defect.

Repair depends on whether the inguinal hernia is direct or indirect. In both types of inguinal herniorrhaphies in male patients, the spermatic cord and blood supply to the testes are protected from injury. The spermatic cord is retracted with a Penrose drain moistened with saline. Infarction of a testis can occur if the



• **Fig. 33.40** Hernia locations.

blood supply is compromised. The female round ligament, the homolog of the spermatic cord, passes through the inguinal ring.

Direct Hernia

A direct hernia protrudes through a weakness in the abdominal wall in the region between the rectus abdominis muscle and inguinal ligament and medial to the inferior epigastric artery. This area is a surgical landmark referred to as the Hesselbach's triangle. This hernia is the most difficult type to repair and is more common in men.

An acquired weakness of the lower abdominal wall, a direct inguinal hernia often results from straining, such as heavy lifting, chronic coughing, or straining to urinate or defecate. Prompt surgical repair prevents possible discomfort and the threat of later complications.

Indirect Hernia

With an indirect hernia, the peritoneal sac containing intestine protrudes through the internal inguinal ring and passes down the inguinal canal outside Hesselbach's triangle. It directs laterally to the inferior epigastric vessels. It may descend all the way into the scrotum. An indirect inguinal hernia is more common in male patients but can be present in females and originates from a congenital defect in the fascial floor of the inguinal canal. Most inguinal hernias are indirect.

Laparoscopic Repair

A laparoscopic procedure may be used to repair either an indirect or a direct reducible inguinal hernia using mesh behind the hernial defect. This procedure is particularly advantageous for repairing bilateral or recurrent hernias. A transabdominal preperitoneal (TAPP) or intraperitoneal approach may be used, or a transextraperitoneal procedure (TEPP) can be performed. Polypropylene mesh is inserted to reinforce the wall of the inguinal canal; this is sutured, stapled, or tacked in place.

Femoral Herniorrhaphy

Femoral herniorrhaphy involves repairing the defect in the transversalis fascia below the inguinal ligament and removing the peritoneal sac protruding through the femoral ring. The transversalis fascia is normally attached to Cooper's ligament, which prevents the peritoneum from reaching the femoral ring. To repair this defect, it is necessary to reconstruct the posterior wall and close the femoral ring. These hernias are more common in women.

Umbilical Herniorrhaphy

Repair of an umbilical hernia consists of closing the peritoneal opening and uniting the fasciae above and below the defect to reconstruct the abdominal wall surrounding the umbilicus. This type of hernia is seen most often in children and represents a congenital defect of protrusion of the peritoneum through the umbilical ring. It also may be acquired by women after childbirth.

Ventral (Incisional) Herniorrhaphy

Impaired healing of a previous surgical incision, usually a vertical abdominal incision, may cause an incisional hernia. Often the result of a weakening of abdominal fasciae, projections of peritoneum carrying segments of bowel protrude through fascial perforations. It is necessary to reunite the tissue layers to close the defect. After excising the old scar, the peritoneal sac is opened, the hernia is reduced, and the layers are firmly closed. If existing tissue is not sufficient for repair, synthetic mesh may be used to reinforce the repair. Incisional hernias are sometimes the aftermath of postoperative hematoma, infection, or undue strain.

Ventral hernias have a high recurrence rate when mesh is placed on the outside of a large repair. Through an intraabdominal laparoscopic approach, omentum can be placed over the mesh or the peritoneum can be put back over the mesh.

Hiatal (Diaphragmatic) Herniorrhaphy

A hiatal hernia results when a portion of the stomach protrudes through the hiatus of the diaphragm. Ten percent of the population has this condition, but not all cases are symptomatic. The hiatus is the opening for the esophagus through the diaphragm, the chief muscle of respiration. A weakening in the hiatus permits violation of the muscular partition between the abdomen and the chest.

Symptoms are caused mainly by inflammation and ulceration of the adjacent esophagus, which result from the reflux of gastric juices from the herniated stomach. Symptoms include pain, blood loss, and difficulty in swallowing (dysphagia). Diagnosis is made by radiologic and endoscopic studies. This is not the cause of gastroesophageal reflux.

Surgical treatment is appropriate when medical therapy fails to alleviate the problem. The surgical approach may be thoracoabdominal or via the abdomen or chest; each approach offers certain advantages. The abdominal approach is generally preferred, but opening the chest may provide a better view of the hiatal region and thus may be preferred.

Amputation of Extremities

Amputation is the total or partial removal of any extremity. The need for amputation is associated most often with massive trauma, a malignant tumor, extensive infection, and vascular insufficiency. Orthopedic or vascular surgeons may perform these procedures.

In preparing the patient for a lower extremity amputation, the patient's chart is checked, and both legs are exposed for comparison before skin preparation. It must be made absolutely certain that the correct leg is prepared. The surgeon must initial the correct surgical site. During the "time out" phase of incision, the limb is confirmed again for correctness.

Many lower extremity amputations are performed with the patient under spinal anesthesia. It must be ensured that the specimen is never within the patient's sight. Policy is followed in regard to the patient's permission for disposal of an extremity.

In general, two types of amputations are performed: open (guillotine) and closed. The guillotine procedure is regarded as an emergency procedure and is rarely performed. Patients who are severely ill or toxic or who experience severe trauma (e.g., an extremity caught under an immovable object) are candidates for this procedure. In the guillotine procedure, tissues are cut circularly with the bone transected higher to allow soft tissues to cover the bone end. Blood vessels and nerve endings are ligated, but the wound is left open. The surgical procedure is often followed by prolonged drainage and healing, muscle and skin retraction, and excessive granulation tissue. A second procedure is often required for final repair.

The conventional flap or closed type of amputation is more desirable. Fashioning curved skin and fascial flaps before amputation of the bone allows deep and superficial fasciae to be approximated over the bone end before closure of the loose skin. Drainage by catheter or suction apparatus may be required. The wound usually heals in approximately 2 weeks.

Amputations of the Lower Extremity

Amputations of the lower extremity are classified as above-knee (AK), below-knee (BK), toe, transphalangeal, transmetatarsal, or the Syme amputation. The level of amputation is determined by the patient's general health, vascular status, and potential for rehabilitation.

Above-Knee Amputation

Amputation at the lower third of the thigh is selected when gangrene or arterial insufficiency extends above the level of the malleoli. A midthigh amputation involves making a circular incision over the distal femur, creating large anterior and posterior skin flaps, and transecting fasciae and muscles. Vessels and nerves such as the femoral and sciatic nerves, respectively, are ligated and severed. Sharp bone edges of the stump are smoothed and debulked with a rasp. The wound is irrigated with sterile normal saline solution before closure of tissue layers.

Hemostasis is important to prevent massive hemorrhage or painful hematoma. Drains may be used depending on the surgeon's preference. A noncompressive dressing is applied. AK amputation is a more extensive procedure than BK amputation, and thus a longer time is required for rehabilitation. In general, a prosthesis is fitted 4 to 6 weeks after amputation.

Below-Knee Amputation

Amputation at the middle third of the leg provides for more functional prosthesis fitting and the reduction of phantom limb pain; it also permits a more natural gait (Fig. 33.41). An immediate postoperative prosthesis (IPOP) can be applied in the OR. The IPOP dressing requires a stump sock, padding, and a rigid plaster dressing. The dressing not only protects the stump but also aids in controlling the weight placed on it. The prosthesis is metal and provides a pull on the stump. The pylon (foot) may be attached before the patient returns to the unit. If the patient is obese or debilitated, weight bearing may be delayed for several days.

Toe and Transmetatarsal Amputations

Toe and partial foot amputations are generally performed for gangrene and osteomyelitis.

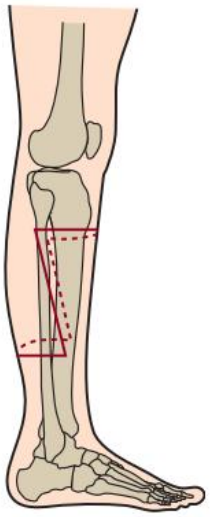
Syme Amputation

A Syme amputation is usually performed for trauma and involves the distal part of the foot. The amputation is above the ankle joint. The skin of the heel is used for the flap (Fig. 33.42).

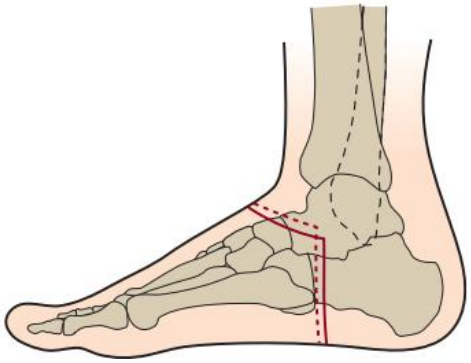
Hip Disarticulation and Hemipelvectomy

Hip disarticulation and hemipelvectomy involve total removal of the right or left pelvis, including the innominate hipbone, along the ipsilateral lower extremity. A multidisciplinary team of orthopedists and general surgeons perform the procedure because it involves massive soft tissue resection and bony excision.

The division of bone may be carried through the sacroiliac joint, or a portion of iliac bone and crest may be preserved. An internal hemipelvectomy includes the removal of innominate bone with adjacent muscles. The large defect created may be covered by a myocutaneous flap of the quadriceps femoris muscle and the overlying skin and subcutaneous tissue. The neck of the femur rests against the soft tissues. These radical procedures are indicated for malignant bone or soft tissue tumors and extensive traumatic injuries. Specialized prosthetic devices are available to permit ambulation.



• **Fig. 33.41** Below-knee (BK) amputation.



• **Fig. 33.42** Syme amputation of the foot.

Amputations of the Upper Extremity

Amputations of the Hand

Hand amputations usually result from trauma and include part or all of the distal phalanges of the digits. Attention is directed to keeping the hand as a working unit when one or more fingers are removed. Every effort should be made to save the thumb; the smallest stump is better than a prosthesis.

Forearm and Forequarter Amputation

Wrist, elbow, and humerus disarticulations are radical procedures performed for malignant tumors or extensive trauma.

Rehabilitation

Postoperative considerations for any amputation include control of bleeding and phantom limb sensations, stump care, immediate

fitting of a functional terminal prosthesis, exercises to prevent flexion contractures, and ambulation or use of a hand or arm.

The loss of an extremity involves major psychologic and physical adjustments. The rehabilitative process is very important and is often affected by the emotional reactions of the patient. Patients with an early postoperative prosthesis have a more positive outlook about their loss. Morale is boosted by being able to walk the first postoperative day or soon thereafter (which, in the case of a leg amputation, depends on the surgeon's orders for the weight-bearing program). This in turn aids in ambulation.

Phantom limb pain is particularly distressing to many patients. The nerves have been severed, but the patient has the sensation that the amputated part is still present. This sensation is often associated with painful paresthesia (i.e., tingling, prickling, tickling, burning). The pain is real. It usually responds to aspirin, acetaminophen (Tylenol), or a similar agent, but narcotics may be necessary to control pain. The combined efforts of the patient, family, and interdisciplinary professional personnel are needed for successful rehabilitation.

Gynecologic and Obstetric Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Identify the anatomy of the female genitourinary system.
- Describe the physiology of the female reproductive system.
- Differentiate between adolescent and adult gynecologic health.
- Describe the pertinent considerations when caring for a pregnant patient.

KEY TERMS AND DEFINITIONS

Abortion Termination of pregnancy. Several descriptions include elective voluntary surgical ending of pregnancy, incomplete natural termination of pregnancy before the age of viability, missed abortion, spontaneous abortion, and threatened abortion.

Amenorrhea Absence of menstrual periods.

Cesarean birth Surgical delivery of a fetus through an abdominal incision. Also known as cesarean section or C-section.

Chromopertubation Instillation of dye through the fallopian tubes as a test of patency.

Dilation and curettage (D&C) Progressive enlargement of the opening of the uterine cervix is to permit instrumentation for debulking the endometrium and other surgical procedures.

Elective voluntary surgical ending of pregnancy First trimester: pregnancy is terminated during first 3 months of gestation. Second trimester: pregnancy is terminated during second 3 months of gestation. Late: pregnancy is terminated after the second trimester has ended.

Endometrium Lining of the uterus that is normally shed during menstruation.

Fundus The round top or dome of uterus.

Leiomyofibroma Term for fibroid tumors. Also known as myoma (e.g., uterine muscle tumor).

Graafian follicle Mature ovum.

Gravid Pregnant.

Incomplete natural termination of pregnancy before the age of viability Products of conception are partially retained and may need surgical removal to prevent sepsis in the mother.

Menarche Beginning of menstruation.

Menometrorrhagia Bleeding between menstrual periods in a premenopausal woman that is surgically treated by dilation and curettage, endometrial ablation, or hysterectomy.

Menorrhagia Excessive bleeding at menstruation that is surgically treated by dilation and curettage, endometrial ablation, or hysterectomy.

Menstruation The shedding of the endometrium during periodic hormonal cycles.

Missed abortion Natural termination of gestation before the age of viability. Products of conception must be surgically removed to prevent sepsis in the mother.

Neoplasia New tissue overgrowth. Potentially cancerous.

Retained secundus Products of conception retained either at delivery of a viable fetus or at the time of incomplete abortion. Placental remnants.

Spontaneous abortion Natural termination of pregnancy before age of viability. Products of conception are expelled without surgical intervention.

Tanner's stages Incremental measurement of sexual development from first signs of puberty to maturity in both sexes.

Thelarche The beginning of breast development that is measured in stages.

Threatened abortion Pregnancy is diagnosed at risk for natural termination before the age of viability. Medical and/or surgical management may be attempted to prevent full natural termination.

Anatomy and Physiology of the Female Reproductive System

The female genitourinary system comprises the organs, glands, secretions, and other elements of reproduction referred to as the *pudendum*. Components of the female reproductive system are both external and internal organs.

External Female Genitalia

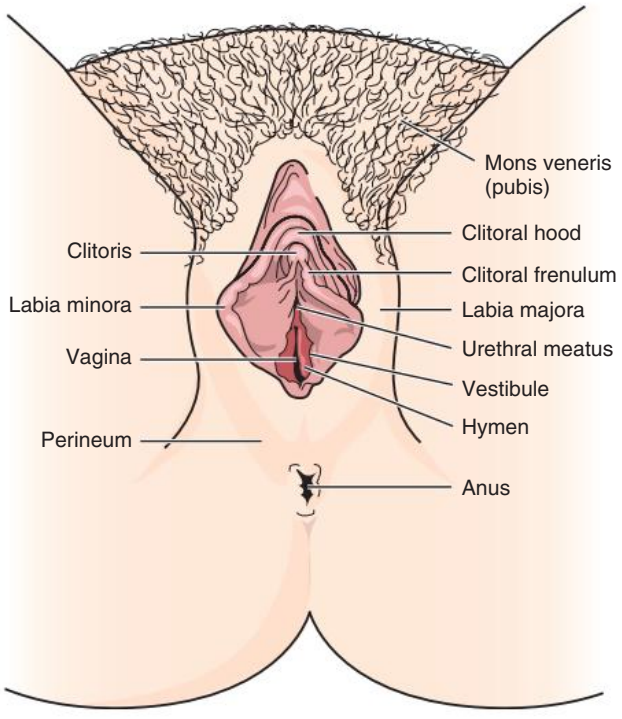
The term *vulva* is used collectively for the female external genitalia (Fig. 34.1). This sensitive, delicate area is highly vascular, with an extensive superficial and deep lymph supply and rich cutaneous sensory innervation. It includes the labia majora, labia minora, clitoris, vestibule, Bartholin glands, hymen, and perineum.

Labia Majora

The labia majora are two large folds, or lips, containing sebaceous and sweat glands embedded in fatty tissue and covered by hair-bearing skin. They join anteriorly in a fatty pad, the mons veneris, which overlies the pubic bone (symphysis pubis). In the adult female this area is covered with a triangular pattern of hair. Sebaceous secretions of the labia lubricate the proximal area. The labia majora atrophy and hair follicles decrease in number after menopause, making the labia minora more prominent.

Labia Minora

The labia minora, or small lips, lying within the labia majora, are flat folds of connective tissue containing sebaceous glands. Anteriorly these labia split into two parts. One part passes anteriorly over the clitoris to form a protective prepuce, or foreskin. The other passes behind the clitoris to shape a frenulum, a fold of mucous membrane. Posteriorly they join across the midline behind the vagina to form the fourchette, or fold of skin, just inside the posterior vulvar commissure.



• **Fig. 34.1** Female perineum.

Clitoris

The clitoris is the female erectile organ, the homolog of the penis. It is composed of bilateral cavernosa and a glans. The clitoris is attached by ischiocavernosus musculature to the pubic rami by a suspensory ligament. It is located at the apex of the labia minora, which join to form a prepuce, or hoodlike covering. The clitoris measures about 4 inches in length, but less than 1 inch is visible at the prepuce.

The mucous membrane covering the glans contains many nerve endings and is a source of sexual stimulation for the female. The blood supply is derived from a terminal branch of the pudendal artery, which is a terminal division of the internal iliac artery. The venous drainage is continuous with the labial plexus. Innervation is from the sacral plexus.

Vestibule

The vestibule is the space, or shallow elliptic depression posterior to the clitoris, enclosed by the labia minora. The urethral opening is located in this region posterior to the clitoris and anterior to the vagina. The fourchette forms the posterior boundary where the labia meet anterior to the perineum.

Bartholin Glands

Small, bilateral Bartholin glands lie deep in the posterior third of the labia majora, within the bulbocavernosus muscle. The mucous secretion is a vaginal lubricant. These glands can become inflamed and infected, causing pain and discomfort.

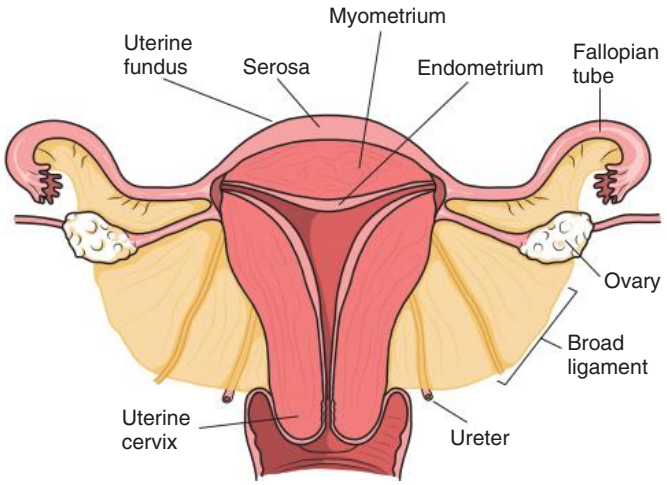
Hymen

The hymen is a thin, vascularized connective tissue membrane that surrounds and may partially or completely occlude the vaginal orifice. It varies in thickness and elasticity among individuals. The central aperture permits passage of menstrual flow and vaginal secretions. This structure will vary according to individual anatomy and physical activity. In some patients the aperture may be imperforate or divided by a septum, requiring surgical intervention. The presence or absence of a hymenal ring is not an indicator of sexual activity.

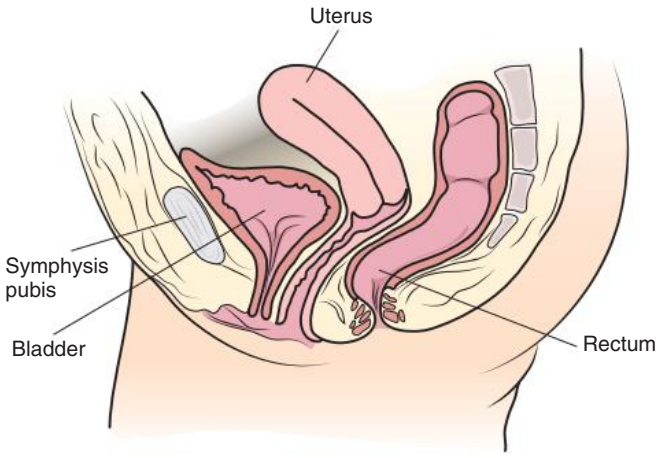
Perineum

The perineum is a diamond-shaped wedge of fibromuscular tissue between the vagina and the anus. It is divided by a transverse septum into an anterior urogenital triangle and a posterior anal triangle. It consists of the perineal body and perineal musculature. With fibers of six muscles converging at its central point, the perineum forms the base of the pelvic floor and helps support the posterior vaginal wall.

These muscles are the bulbocavernosus (vaginal sphincter), the two superficial transverse perineal muscles, the two levator ani muscles, and the external anal sphincter. The levator ani muscles are the largest muscles and, in contrast to the other superficial muscles, are deep. The most important muscles in the pelvis, the levator ani muscles form a hammock-type suspension (pelvic diaphragm) from the anterior to the posterior pelvic wall, beneath the pelvic viscera. These muscles retain the organs within the pelvis by offering resistance to repeated increases in intraabdominal pressure, such as coughing, bearing down in labor, and straining at stool.



• **Fig. 34.2** Female reproductive system.



• **Fig. 34.3** Female reproductive anatomy in sagittal view.

Internal Female Reproductive Organs

The internal female reproductive organs (Fig. 34.2) lie within the pelvic cavity, protected by the bony pelvis. Bones and ligaments form the pelvic outlet. The dilated cervix of the uterus and the vagina constitute the birth canal.

Vagina

The vagina is a thin-walled, 8-cm fibromuscular tube extending from the vestibule obliquely backward and upward to the uterus, where the cervix projects into the top of the anterior wall. The vagina is elastic and capable of distention during intercourse and parturition. The bladder lies anteriorly; the rectum lies posteriorly. It is lined with mucous membrane and contains glands that produce a cleansing acid secretion.

The anterior vaginal wall is shorter than the posterior wall. The upper third of the posterior wall is covered by peritoneum reflected onto the rectum. Normally the anterior and posterior walls relax and are in contact. However, the lateral walls remain rigid because of the pull of the muscles and therefore are in close contact with pelvic tissues.

A rich venous plexus in the muscular walls makes the vagina highly vascular. Uterine and vaginal arteries supplying the area are branches of the internal iliac artery. Branches of the vaginal artery extend to the external genitalia and the adjacent bladder and rectum. Lymphatic drainage is extensive. The upper two thirds of the vagina drain into the external and internal iliac nodes; the lower third drains into the superficial inguinal nodes.

The vault (upper part of the vagina) is divided into four fornices, or arches (Fig. 34.3). During digital pelvic examination, pelvic organs can be palpated through the thin walls of the vault. The anterior fornix, in front of the cervix, is adjacent to the base of the bladder and distal ends of the ureters.

The pouch of Douglas (retrouterine cul-de-sac) directly behind the larger posterior fornix lies behind the cervix. This pouch separates the back of the uterus from the rectum anteriorly by the uterine peritoneal covering, which continues down to cap the posterior vaginal fornix, and posteriorly by the anterior wall of the rectum. Lateral uterosacral ligaments embrace the lower third of the rectum. The floor of the pouch, about 7 cm above the anus, is formed by reflection of the peritoneum from the rectum to the upper vagina and uterus.

The posterior cul-de-sac is the route of entry for a number of diagnostic or surgical procedures because the pouch of Douglas (the lowest part of the peritoneal cavity) is separated from the vagina only by the thin vaginal wall and peritoneum.

The lateral fornices lie on either side of the cervix, in contact with anterior and posterior sheets of the broad ligaments surrounding the uterus. Proximal structures are the uterine artery, ureters, fallopian tubes, ovaries, and sigmoid colon.

Uterus

The uterus is the female organ of gestation. It receives and holds the fertilized ovum during development of the fetus and expels it during childbirth. Resembling an inverted pear in shape, this hollow, muscular retroperitoneal organ is situated in the bony pelvis. It lies between the bladder anteriorly and the sigmoid colon posteriorly. The uterus is divided transversely by a slight constriction into a wider upper part (the body or corpus uteri) and a narrower lower part (the 2- to 3-cm cervix uteri or ectocervix that protrudes into the vagina).

The corpus meets the cervix at the internal os. Peritoneum covers the corpus externally; the **endometrium**, ranging in thickness from 2 to 10 mm, lines it internally. This mucous membrane is uniquely adapted to receive and sustain the fertilized ovum. The **fundus**, or rounded top portion of the uterus, lies above the uterine cavity.

The shape of the uterine cavity (endometrial cavity), flattened from front to back, is roughly triangular in the nonpregnant female. The upper lateral angles extend out toward openings of the fallopian tubes, which enter bilaterally through the uterine walls at the cornua. The apex of the triangle is directed downward to the cervix. The cavity within the cervix, the endocervical canal, narrows to a slit at the distal orifice, where the cervix communicates with the vagina via the external os. The endocervix is the glandular mucous membrane of the cervix. The corpus of the uterus and the cervix are considered individually in relation to disease and therapy because they differ in structure and function.

The uterus is capable of expansion to accommodate a growing fetus. Much of the bulk of the corpus consists of involuntary muscle, the myometrium, which is composed of three layers. The inner layer prevents reflux of menstrual flow into the tubes and peritoneal cavity, which could result in endometriosis. It also contributes to the competency of the internal os to prevent premature expulsion of the fetus. The middle layer encloses large

blood vessels. These muscle fibers act as living ligatures for hemostasis after delivery. The outer layer has expulsive action, ejecting menstrual flow and clots, an aborted embryo, or the fetus at term.

Usually the uterus lies forward at a right angle to the vagina and rests on the bladder. Although the cervix is anchored laterally by ligaments, the fundus may pivot about the cardinal ligaments widely in an anteroposterior plane. Mobility rather than position is the criterion for normality.

Fallopian Tubes (Salpinges)

The fallopian tubes (small, hollow musculomembranous tubes, sometimes called *oviducts* or *uterine tubes*) run bilaterally like arms from each side of the upper part of the uterus to the ovaries. Near each ovary, the open end of each tube expands into the infundibulum, which divides into fimbriae, or fingerlike projections, that sweep up the ovum (the female reproductive cell) as it is expelled from the ovary. Ciliated cells move the ovum toward the uterus.

The lumen of the tube becomes very narrow where it penetrates the uterine wall to reach the uterine cavity. Contractions in the muscular walls change the shape and position of the tubes. At ovulation, they move the fimbriated ends into close apposition with ovarian surfaces. The fallopian tubes serve as a continuous passage from the external environment into the abdominal cavity via the vagina, cervix, and uterine body. Infectious diseases and other substances can enter the peritoneal cavity through this route.

Ovaries

The ovaries are oval glandular gonads located in shallow peritoneal fossae on the lateral pelvic walls, from which they are suspended by the infundibulopelvic ligaments. They are attached to the posterior layer of the broad ligament by the mesovarium (a peritoneal fold) and to the uterus by the ovarian ligament (a fibromuscular cord).

The ovaries, the counterpart of the male testes, contain ova. Each ovary measures 2 × 3 cm and consists of a center of cells and vessels surrounded by the cortex. This main portion contains the stroma or fibrous framework in which the ovarian follicles are embedded. Of the approximately 200,000 primordial follicles present at birth, fewer than 400 are likely to produce a mature ovum (**graafian follicle**) during the reproductive years. A serous covering derived from peritoneum surrounds the ovaries. In addition to protecting maturing ova, the ovaries, which atrophy after menopause, produce female sex hormones.

The ureters course along the retroperitoneum bilaterally and lie close to the ovarian blood supply just anterior to the common iliac arteries. The ovaries, when diseased, may be adherent to the ureters. Some surgeons will have a urologist place ureteral catheters to make the structural identification easier during dissection.

Muscles and Ligaments

Muscles and ligaments support and suspend the uterus and fallopian tubes in the normal position in the center of the pelvic cavity.

Broad Ligaments

Bilateral broad ligaments are composed of a broad double sheet of peritoneum extending from each lateral surface of the uterus outward to the pelvic wall. Between these two layers of peritoneum, the fallopian tubes are enclosed in the free upper borders (mesosalpinx), with the tubal ostia opening directly into the peritoneal cavity.

Round Ligaments

The round ligaments are fibromuscular bands that extend from the anterior surface of the lateral borders of the fundus to the labia majora. They run beneath the peritoneum and anterior sheet of the broad ligament down, outward, and forward through the inguinal canal to the labia.

Cardinal Ligaments

The lower portion of the broad ligaments, the cardinal ligaments, are attached to the lateral vaginal fornices and supravaginal portion of the cervix. They act as a supportive pivot.

Uterosacral Ligaments

The uterosacral ligaments are peritoneal folds containing connective tissue and involuntary muscle. They arise on each side from the posterior wall of the uterus at the level of the internal os, pass backward around the rectum, and insert on the sacrum at the level of the second sacral vertebra. They pull on the cervix to keep the uterus anteverted and, through the cervix, the vagina in position as well.

Physiology

The function of the female reproductive organs is to conceive, nurture, and produce offspring. The development and function of these organs are influenced by the hormonal secretions of the ovaries and adrenal, thyroid, and pituitary glands. These hormonal relationships also affect primary and secondary sex characteristics.

The physiologic hormonal cycle prepares the uterus for the fertilized ovum. Hormone production stimulates the endometrium and breasts, resulting in thickening of tissue and increased blood supply.

Each month during the years from puberty to menopause, one (or both) of the ovaries matures a follicle from within. When the matured graafian follicle ruptures, it discharges the enclosed ovum, which enters the fallopian tube at the fimbriated end. The process of maturation and discharge of the egg is called *ovulation*, resulting in a fertile period that lasts several days. Changes in cervical mucus and vaginal epithelium also accompany ovulation.

Union of the ovum with a viable mature male germ cell (spermatozoon), which has ascended to the fallopian tube from the vagina, results in fertilization within 12 hours of ovulation. The union takes place in the outer third of the tube and travels toward the uterus over a period of 3 days. The fertilized ovum normally proceeds to the cornu of the uterus, where it enters to implant in the endometrium within 14 days of fertilization. By day 17 the blood supply of the fetal and maternal blood vessels is functional. The placental circulation is established. The ensuing pregnancy will last approximately 266 days, or 9 calendar months, if carried to full term.

The ovarian hormone estrogen, together with progesterone, causes a sequence of changes in the endometrial lining of the uterus to prepare for implantation of the fertilized ovum. Estrogen also produces the development of secondary sexual characteristics. Progesterone is responsible for maintaining pregnancy until hormones from the placenta assume this role.

Menstruation is the periodic discharge of blood, mucus, disintegrated ovum, and uterine mucosa formed during the hormonal cycle if pregnancy does not take place. The duration of the menstrual period varies but averages 3 to 5 days. The amount of blood lost varies greatly. The menstrual cycle, the time between the onset of each period, is approximately 28 days.

Regularity of menstruation can be disturbed by disease conditions and emotions, in addition to the onset of pregnancy. This

physiologic cycle continually recurs throughout the reproductive life of the woman. Assessment of the female patient should include documentation of the age of **menarche** (first menses), the date of the last menstrual period (LMP), use of contraception, and sexual history. The possibility of pregnancy should be considered if the female patient is within childbearing age, regardless of age, social status, or vocation. A surgical procedure and/or the administration of anesthetic agents could be hazardous to a developing embryo.

Gynecology: General Considerations

The emotional preparation of gynecologic patients presents a special challenge to the operating room (OR) team. Anticipation of physical exposure, potential loss of sexual function, infertility problems, or termination of pregnancy can create severe anxiety. Some surgical procedures terminate reproductive capability and produce menopause. Patients must be able to express concerns, ask questions, and receive reassurance and support.

Examination with the Patient Under Anesthesia

Bimanual examination of the pelvis with the patient in the lithotomy position and relaxed from anesthesia usually precedes vaginal and abdominal gynecologic surgical procedures. This allows the surgeon to thoroughly assess the size, outline, consistency, position, and mobility of the uterus, fallopian tubes, and ovaries. This examination also helps the surgeon determine or confirm the approach for the procedure and whether a lesion is resectable. This is helpful in evaluating women experiencing pain or nervous tension and those who are obese. The vaginal vault and perineum are prepped, and the examination is performed before prepping the abdomen for a diagnostic laparoscopy or exploratory laparotomy.

Special Features of Gynecologic Surgery

Diagnostic and surgical procedures may be carried out through a vaginal or an abdominal approach, or the two approaches may be combined. Each requires a different position and different preparation, drapes, and setup. Surgical techniques for general abdominal procedures apply to gynecologic surgery. Diagnostic and definitive surgical procedures are often combined and done in one surgical procedure.

The following procedures apply to both vaginal and abdominopelvic procedures:

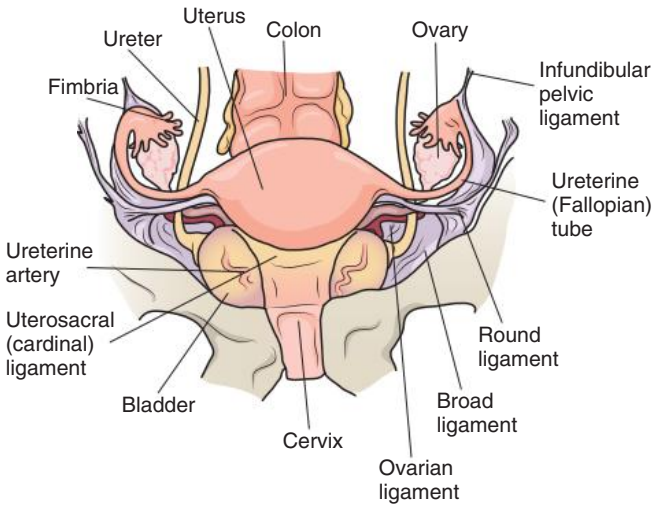
1. Spinal, epidural, or (more commonly) general anesthesia is used. An epidural catheter may be inserted preoperatively for postoperative pain control.
2. A Foley catheter may be inserted after the administration of the anesthetic agent to prevent the bladder becoming distended during the procedure and to record urinary output. The circulating nurse and the anesthesia provider should check the urinary drainage bag frequently and report urine volume or evidence of blood. This could indicate injury to the bladder or ureters. Percutaneous insertion of a cannula directly into the bladder through the abdominal wall (suprapubic cystostomy) provides an alternative indwelling urinary drainage system in select patients.
3. An electrosurgical unit (ESU), with either monopolar or bipolar electrodes, is frequently used.
4. Argon, carbon dioxide (CO_2), and neodymium:yttrium aluminum garnet (Nd:YAG) lasers are used, generally in conjunction with a colposcope or laparoscope and the operating microscope for some procedures.
5. Closed-wound suction drainage, or another type of drain, may be used to prevent hematoma or serum accumulation in the pelvis and/or the wound.
6. Prophylactic preoperative anticoagulation with subcutaneous heparin, antiembolic stockings, sequential compression devices, and early ambulation are especially important in pelvic surgery because of the potential for deep vein thrombosis (DVT) and subsequent pulmonary emboli (PE).

Vaginal Approach

1. The patient is in the lithotomy position. Care is taken not to lean on the patient's legs during the procedure.
2. Instrumentation must be of sufficient length for use within the vaginal canal and uterine cavity. In addition to retracting, cutting, holding, clamping, and suturing instruments, vaginal setups include dilation and curettage (D&C) instruments for intrauterine procedures (Table 34.1).
3. A laser, ESU, or cryosurgical unit may be used to remove hypertrophied tissue or certain benign neoplasms.
4. A suction system, including a Poole suction tip with guard, tubing, and collection canister, is part of the setup.
5. Raytec sponges are rolled and secured on sponge forceps in deep areas (also referred to as *sponge sticks*). Long, narrow, 4 × 18-inch sponges (tapes) with radiopaque markers on the end are used for packing off abdominal viscera in vaginal procedures. All counts are very important in these procedures.
6. Vaginal packing is inserted after certain procedures for hemostasis and/or therapeutic purposes. Antibiotic or hormone cream may be applied to the packing during insertion. Impregnated vaginal packing is commercially available. The packing should be recorded on the patient's chart and removed at the surgeon's order.
7. At the completion of the surgical procedure a sanitary pad is placed against the perineum between the patient's legs. Mesh underwear can be applied to hold the pad in place. Care is taken not to disturb drains or Foley catheter.

TABLE 34.1 Instruments for Dilation and Curettage

Purpose	Instruments
To expose	Vaginal speculum Posterior retractor Weighted posterior retractor Narrow lateral Heaney retractors
To grasp and hold	Single- and double-toothed tenacula
To measure uterine cavity	Uterine sound (graduated probe)
To dilate cervix	Graduated dilators Goodell dilator
To scrape tissue	Sharp and blunt, large and small uterine curettes
To obtain specimen	Endometrial biopsy suction curette
To carry sponges	Sponge forceps
To remove polyps and biopsy tissue	Polyp and biopsy forceps
To insert packing	Uterine dressing forceps



• **Fig. 34.4** Surgical landmarks of the female pelvis.

Abdominal Approach

1. The supine or Trendelenburg's position is used for abdominopelvic procedures to displace pelvic organs cephalad. Preparation and drapes are the same as for abdominal laparotomy. Abdominal incisions commonly used in gynecologic open procedures are shown in Fig. 34.4.
2. When a large abdominal mass is present or the pelvic organs are pushed from their normal relationships, ureteral catheters may be inserted via cystoscopy, before the surgical procedure, to facilitate identification of the ureters to prevent inadvertent dissection. Severing of the ureters during the procedure greatly increases postoperative morbidity and mortality if the injury is not immediately detected and corrected.
3. Instrumentation includes the basic laparotomy setup with the addition of long instruments for deep manipulations within the pelvis and uterine graspers, such as a Somer uterine elevator or a tenaculum.
4. At the completion of the surgical procedure a sanitary pad is placed against the perineum between the patient's legs. Mesh underwear can be applied to hold the pad in place. Care is taken not to disturb drains or Foley catheter.

Abdominal Complications

Injuries to ureters, which can lead to loss of renal function if unrecognized, can occur during the surgical procedure because of their relationship to pelvic structures. The surgeon must identify and isolate the ureter on the affected side to prevent accidental crushing or kinking.

Adhesions after pelvic surgery can cause infertility, intestinal obstruction, and/or chronic abdominal pain. The surgeon may place a biodegradable fabric (Interceed Absorbable Adhesion Barrier) over tissues and pelvic organs before closing the peritoneal cavity. This satin-like knitted fabric acts as a physical barrier to prevent adhesion formation during the healing process. Within 8 hours the fabric becomes a gelatinous protective coating, which is completely absorbed within 28 days.

Combined Vaginal-Abdominal Approach

If vaginal and abdominal surgery is indicated, a combined procedure is planned. For example, the patient may be scheduled for a total abdominal hysterectomy with anterior vaginal colporrhaphy. In such instances the vaginal procedure is performed first. The patient is then removed from the lithotomy position and repositioned in the supine position, and the abdominal preparation and surgical procedure are performed. Care is taken to ensure the dispersive electrode has not been displaced, and a new one should be applied when the patient is repositioned.

The following considerations apply:

1. Because of the possibility of infection, separate sterile setups are used for vaginal and abdominal procedures performed concurrently.
2. Vaginal preparation precedes exploratory pelvic laparotomy in readiness for the unexpected or for a D&C scheduled to precede an abdominal procedure. A separate sterile prep table is used for the external genitalia and vagina. Another sterile setup is used for the abdominal preparation. The vaginal area is prepped first to prevent splashing up to a freshly prepped abdomen.

Diagnostic Techniques

The gynecologist uses both noninvasive and invasive diagnostic techniques. Some are performed as office or ambulatory procedures, especially those using the vaginal approach.

A pelvic examination includes inspection and palpation of the external genitalia; bimanual abdominovaginal and abdominorectal palpation of the uterus, fallopian tubes, and ovaries; and speculum examination of the vagina and cervix. This inspection is augmented by a cytologic study of smears of cervical and endocervical tissue obtained by scrapings.

The Papanicolaou (Pap) smear has significantly facilitated diagnosis of cervical cancer and premalignant lesions. Characteristic cellular changes in cervical epithelial cells are identified. Cytologic aspiration from within the endocervical canal may reveal unsuspected carcinoma of the endometrium, fallopian tubes, or ovaries and occult cervical cancer.

The Schiller test involves staining the vaginal vault and cervical squamous epithelium with Lugol's solution. Glycogen in normal epithelium takes up the iodine. Abnormal tissues, with little or no glycogen, do not stain brown and thereby pinpoint sites for biopsy. Abnormal cytologic findings are an indication for further evaluation by histologic tissue study. Patients susceptible to iodism should not be exposed to Lugol's solution.

Uterine cancer consists of two entities: cervical cancer and endometrial cancer. These differ by age-groups, types, and consequences. Cancer of the cervix appears most often in association with coitus at an early age, multiple partners, nonbarrier contraceptives, poor sexual hygiene, a chronically infected cervix, or a history of sexually transmitted infections (STIs). These include infection with herpes simplex virus (HSV), human papillomavirus (HPV), cytomegalovirus (CMV), *Chlamydia trachomatis*, and *Trichomonas vaginalis*. A higher frequency of abnormal Pap smear findings is associated with these infections.

HPV produces condylomata (venereal or genital warts), which have been identified as a possible cause of cervical carcinoma.[1] HPV screening is part of the routine gynecologic examination. HPV vaccination, a series of three injections given over a 6-month period, may be administered. The Centers for Disease Control and Prevention (CDC) speculate that 50% of sexually active men and women will experience HPV infection (genital warts) during their lifetime.[1]

Cancer of the endometrium occurs primarily in postmenopausal women and is more common than cervical cancer. It is often associated with obesity, low parity, late menopause, hypertension, and diabetes mellitus.

Biopsy of the Cervix

Cervical cancer may not present symptoms in the early stage and may progress to invasion before discovery. Spotting, postmenopausal bleeding, or chronic cervicitis may be the first visible sign. The condition may be suspected by results of cytologic examination or visual inspection, but diagnosis is made by biopsy.

Excisional Biopsy

In excisional biopsy an attempt is made to excise the entire cervical lesion by sharp dissection. Sutures or an ESU is used for hemostasis. Packing may be needed.

Incisional Biopsy

Incisional biopsy involves the use of a scalpel, punch biopsy, or other instrument to obtain tissue for diagnosis but not to remove the lesion. If a malignancy is diagnosed, additional evaluation and further treatment are carried out by additional surgery and/or radiation therapy.

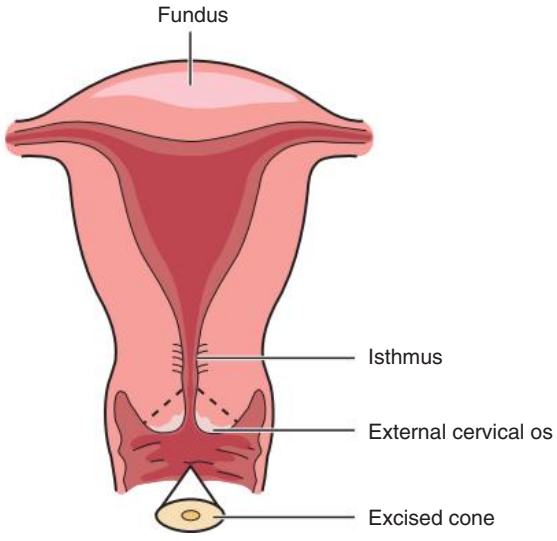
Cone Biopsy

Patients diagnosed by Pap smear as having severe cervical dysplasia or intraepithelial carcinoma of the cervix require conization to remove the lesion and rule out invasive carcinoma. The biopsy, obtained with a laser, scalpel, or cervitome (cold knife conization), includes the squamocolumnar junctions of the ectocervix (transformation zone) and is tapered to include the endocervical canal to the level of the internal os (Fig. 34.5). Most of the lesions categorized as cervical intraepithelial **neoplasia** (CIN), dysplasia, or carcinoma in situ are found in this area. Conization of the cervix provides the most comprehensive specimen to diagnose a premalignant or malignant lesion. Multiple blocks and sections are examined by the pathologist to determine the extent of invasive disease.

Complications include hemorrhage, infection, cervical stenosis, an incompetent cervix, and infertility. The CO_2 laser used for conization minimizes these risks. Hemostasis is secured with sutures as needed.

Cervical dysplasia can occur in sexually active females ages 12 years and older; the peak incidence is between the ages of 25 and 35 years. Used therapeutically for chronic inflammation and for premalignant lesions in women of childbearing age, conization may be performed by scalpel, electrosurgery, or laser. Laser conization is used to treat severe dysplasia and carcinoma in situ.

Loop electrosurgical excision procedures (LEEPs) use a stainless steel or tungsten loop electrode to excise a central core of tissue from the transformation zone of the endocervical canal. Large loop excision of the transformation zone (LLETZ) is performed with minimal bleeding and few complications. These procedures may be performed in the OR or office setting with local anesthesia. Future childbearing is unaffected. Although the specimen is comparable in size to that obtained with cold knife conization, the specimen has superficial desiccation and may be inferior in quality. Wide conization may result in scarring and obstruction of the os.



• **Fig. 34.5** Cone biopsy for cervical cancer.

Fractional Curettage

Tissue is obtained for histologic examination by scraping the uterine cavity. Fractional curettage differentiates specimens between the endocervix and the endometrium in a series of two steps. A biopsy specimen may be taken from the cervix, if indicated by the Schiller test, in association with endocervical curettage. A small curette is introduced into the endocervical canal, which is scraped from the internal to the external os. The specimen is placed on a Telfa pad, and both are put into a container. This scraping precedes cervical dilation to avoid dislodging tissue from above the internal os.

After cervical dilation a different curette is inserted into the uterine cavity for curettage of the endometrium. The endometrial specimen is placed in a container separate from the one used for the specimens obtained by endocervical curettage.

Colposcopy

Illumination and binocular magnification afforded by the colposcope permit identification of abnormal epithelium to target for biopsy. The colposcope has a cool, intense white light that can be fitted with a green filter to improve visualization of the vascular pattern. With the colposcope positioned in front of the vulva, without touching the patient, the colposcopist can focus light through a speculum on the ectocervix, the lower part of the cervical canal, and the vaginal wall.

The cervix is swabbed with 3% acetic acid to eradicate mucus and facilitate viewing the surface and vasculature. Biopsies are performed for histologic confirmation of the diagnosis. Endocervical curettage also may be performed. A video camera or still camera can be attached to a colposcope to photograph lesions.

Vaginal condylomata from HPV and adenoses, preinvasive lesions of the cervix, cervical dysplasia, CIN, and other vaginal and cervical lesions can be treated by laser with the colposcope. Visualization, unobstructed by instruments, is excellent. Condylomata can incubate for 3 weeks to 6 months and will appear as white, raised areas when exposed to 3% acetic acid. Full-strength acetic acid solutions will burn the patient's tissues.

The CO_2 laser permits selective destruction of large areas of vaginal epithelium without vaginal or cervical stenosis. It cuts, coagulates, seals, and sterilizes simultaneously. This results in less blood loss, a shorter period of vaginal discharge after treatment of the cervix, and a lower incidence of infection than in other surgical treatment modalities.

Electrosurgery and cryosurgery are other options to ablate lesions. Care is taken to avoid contact with the plume from viral lesion ablation.

Culdocentesis and Colpotomy

Culdocentesis

In culdocentesis, blood, fluid, or pus in the cul-de-sac is aspirated by needle via the posterior vaginal fornix for suspected intraperitoneal bleeding, ectopic pregnancy, or tuboovarian abscess. Clear, straw-colored peritoneal fluid is a negative finding. Blood can indicate an ectopic pregnancy, trauma, or tumor. Bloody fluid should be sent to the laboratory in a heparinized specimen tube. A flat plate of the kidneys, ureters, and bladder (KUB) (x-ray examination without contrast medium) may reveal air under the diaphragm, which is indicative of a ruptured organ. Air under the diaphragm appears as dark patches on x-ray.

Posterior Colpotomy

In posterior colpotomy a transverse incision is made through the posterior vaginal fornix into the posterior cul-de-sac to facilitate diagnosis by intraperitoneal palpation, inspection of the pelvic organs, or determination of free fluid, blood, or pus in the pouch of Douglas. Pus from a pelvic abscess or blood, possibly a sign of ectopic pregnancy or a ruptured ovarian cyst, is evacuated. Tubes and ovaries are inspected. If they are normal, the incision is closed. A drain may be inserted.

Some surgical procedures, such as aspiration of an ovarian cyst or reproductive sterilization by tubal ligation, can be performed through the incision, although exposure and visualization are limited. A tube or ovary is sometimes removed through the vagina.

Fallopian Tube Diagnostic Procedures

Tubal Perfusion

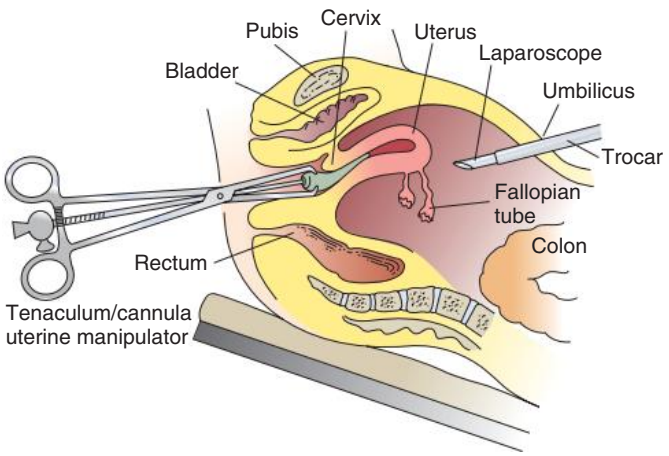
To test tubal patency, **chromopertubation** is performed. Methylene blue or indigo carmine dye in a solution of sterile normal saline is introduced into the uterine cavity via a 50-mL syringe or intravenous (IV) tubing attached to a cervical cannula. The surgeon views the ends of the fallopian tubes through a laparoscope. Dye seen coming from one or both tubes indicates patency.

Tubal Insufflation

Uterotubal insufflation may be used to test the patency of the fallopian tubes. It usually is done as an office procedure to study infertility. The test may be therapeutic in relieving minor obstructions. Contraindications include genital tract infection, possible pregnancy, and uterine bleeding.

A cannula with a seal (i.e., Rumi, Humi, Kahn, Kronner, or Jarcho) is inserted into the cervicouterine canal and connected to an insufflation apparatus. CO_2 is introduced slowly under controlled flow. A relationship exists between tubal patency and the pressure required to force gas through the fallopian tubes into the peritoneal cavity.

Resistance to flow (i.e., backpressure) is measured on a mercury manometer. To prevent gas embolism, the Rubin test is done before—never after—curettage. Open vessels could introduce an air embolus. Intraabdominal irritation before total absorption of CO_2 from the peritoneal cavity causes referred pain in the shoulders. The patient may refer to the feeling as "gas pains."



• **Fig. 34.6** Uterine cannula and tenaculum.

Hysterosalpingography

X-ray study of the uterus and tubes may afford further evaluation of infertility after repeated negative Rubin test findings. The patient is placed in the lithotomy position, and the vagina is prepped. The cervix is grasped with a single-toothed tenaculum. A cannula is inserted into the cervical canal, and 10 mL of a water-soluble radiopaque contrast medium is instilled with a syringe through the cannula (Fig. 34.6). This contrast medium ascends into the corpus uteri and fallopian tubes to yield information about structure and function. Serial x-rays may be taken to assess postprocedure tubal spillage. In some patients, tubal spasms prevent immediate passage of the contrast medium through the tubes.

Pediatric and Adolescent Gynecology

Pelvic examination of an infant or child is rarely performed unless there is disease or trauma. Any indication of physical or sexual abuse must be reported to legal authorities. The facility should have a procedure in place for reporting child abuse.

The preadolescent has no hormonal stimulation and has not developed sexual characteristics such as rounded labia or pubic hair. In infants the uterus regresses in size until the age of 6 years, when it regains the size it was at birth. The cervix is not palpable, and the uterine body is difficult to differentiate from surrounding tissues.

From the age of 7 years, the body begins to respond to estrogen stimulation. The mons thickens, and the vagina begins to elongate. The uterus has a growth spurt at age 9 to 10 years and begins to have the pear shape of the adult uterus. The endometrium develops and proliferates. The vagina extends to its full length of 10 to 12 cm, and the external genitalia resemble those of an adult. **Thelarche** (first breast development) begins as nipple buds at about 10 years of age.

Menarche (first menstruation) is common between the ages of 12 and 14 years and averages 3 years from the onset of breast development and within 6 months of the appearance of axillary hair. The first routine gynecologic examination is recommended at age 16 years or when a girl becomes sexually active.

Routine examinations will be individualized according to the needs and sexual activity of the girl. Sexually transmitted disease (STD) testing is performed. Incidences of STD must be reported to the health department.[2] The presence of an STD may indicate an abusive situation.

Females who have not developed secondary sex characteristics and menstruated by age 16 years should seek a gynecology consult. Sexual maturation is measured on a scale of **Tanner's stages**. Each physical secondary sex characteristic happens between specific ages. Breast development and body hair precede menstruation. Menarche can be delayed by anorexia nervosa or other dietary practices that diminish body fat stores below 17%. Menstruation can be obstructed by an imperforate hymen.

Adolescent Pregnancy

According to the CDC the adolescent pregnancy rate is the lowest it has been in 60 years. The 38% decline is in the 10 to 14-year-old group. Births to young mothers place them at high risk for problems, resulting in preterm birth and cesarean delivery. Many of these young girls have had no prenatal care and are subject to preeclampsia (pregnancy-associated hypertension). Often the babies are of low birthweight and are small for gestational age (SGA).

Gynecologic Pathology in Infants

The female infant should be thoroughly examined from a gynecologic standpoint at birth. Clitoral anomalies may be related to androgenic sexual hormones or a true genetic anomaly. If a vagina cannot be visualized, the hymen may be imperforate, or there may be vaginal agenesis. Digital rectal examination is performed, and a slight central mass representing the rudimentary uterine cervix may be palpated. Ovaries are not large enough to be palpable unless a pathologic condition is present. Ultrasonography may need to be performed to differentiate anatomic structures.

Pelvic Endoscopy

Pelvic endoscopy is an established part of the gynecologist's diagnostic and therapeutic regimen. It permits detailed intraperitoneal inspection of the pelvic organs without laparotomy. These procedures are not without danger, however. Inadvertent perforation of vessels or a hollow viscus and/or infection are major potential hazards. Operator expertise, careful patient selection, adequate anesthesia, and safe equipment are essential. Pelvic endoscopy is a sterile procedure. Vaginal and abdominal approaches are used for direct visualization of pelvic organs and adjacent structures.

Culdoscopy

A culdoscope is introduced into the peritoneal cavity via the posterior vaginal fornix and pouch of Douglas. Some gynecologists prefer culdoscopy to investigate ovaries or posterior surfaces in the lower pelvis. Local or caudal anesthesia is used. The patient is placed in the knee-chest or lithotomy position. With the posterior lip of the cervix held by a tenaculum and retracted anteriorly, the uterus is elevated while counterpressure is applied to the posterior vaginal wall by the speculum.

This maneuver stretches the posterior vaginal fornix while a trocar and cannula or sheath penetrate the thin wall and enter the pelvis between the uterosacral ligaments. When the trocar is removed with the cannula in place, air enters the cul-de-sac because of the negative intraabdominal pressure produced by the knee-chest position. Air displaces the bowel to create a working space, and the scope may be inserted through the cannula.

At the completion of the procedure the culdoscope is removed. Before the cannula is removed, the OR bed is straightened and the patient is laid flat while as much air as possible is evacuated by hand pressure on the abdomen into low suction. Care is taken not to aerosolize body substances. Some surgeons place a suture in the puncture site.

Hysteroscopy

A rigid fiberoptic hysteroscope, introduced vaginally through the uterine cervix, provides direct inspection of the interior of the uterus to diagnose disease or treat conditions such as **menorrhagia** and uterine fibroids. The hysteroscope may also be used to identify and remove polyps, lost intrauterine devices (IUDs), or intrauterine adhesions. Adequate expansion of the uterine cavity is a prerequisite for viewing endometrial surfaces and tubal orifices. Fluid is instilled to expand the uterine cavity to create a working space.

Hysteroscopy systems have been developed that use sterile normal saline as an expansion medium to create the working space. The fluid should be delivered through a pressure-controlled infusion pump that tracks volume instilled. Intrauterine pressures should be maintained at or below the mean arterial pressure. Use of a continuous-flow pump makes it difficult to monitor intrauterine pressures.

The circulating nurse monitors inflow and outflow of the uterine expansion fluid medium and informs the surgeon and the anesthesia provider of any discrepancy in excess of 1500 mL. Visibility is further enhanced with a video camera and monitor screen. The procedure may be videotaped.

Hysteroscopy is used to perform endometrial ablation using a laser (Nd:YAG, argon, or potassium titanyl phosphate [KTP]) or ESU to stop or decrease uterine bleeding.

The Nd:YAG laser is the best choice for deep photocoagulation, causing endometrial destruction and scarring the uterine lining. The entire endometrial lining is treated from the fundus to about 4 cm above the external cervical os. The tip of the laser fiber can be held away from tissue (i.e., blanching technique) or in contact with endometrium (i.e., dragging technique). A specialized electrosurgical rollerball electrode is an alternative method to using a laser. This can provide relief from menorrhagia (i.e., excessively heavy menses). The destruction of the endometrium causes the woman to have **amenorrhea**, thereby causing sterility. Hormonal activity is unchanged.

Air or gas is not used for uterine insufflation or laser fiber cooling during hysteroscopy because of the risk for air or gas embolism. In addition, 32% dextran 70 in dextrose (Hyskon) is not used as an irrigant or uterine expansion medium for endometrial laser ablation because of the systemic effects of fluid absorption through open capillaries. Precise measurements of intake and output are critical to patient safety and prevention of congestive heart failure. Hysteroscopy can be performed as an ambulatory surgery or office procedure.

Laparoscopy

Procedures using a 10 or 12-mm fiberoptic laparoscope with a 0 or 30-degree angle lens inserted into the peritoneal cavity permit direct observation of pelvic and abdominal organs and peritoneal surfaces. Single-port or multiple-port laparoscopic methods can be used. Endoscopic techniques may be used to diagnose and treat ectopic pregnancy; inspect the ovaries for evidence of follicular activity and retrieve ova for in vitro fertilization; visualize and reduce pelvic masses; and determine the cause of infertility, endocrinopathies, or amenorrhea. Many pelvic diseases, such as endometriosis, adhesions, and ovarian cysts, may be identified and treated through the laparoscope and its accessory instrumentation.

The gynecologist can perform myomectomy, salpingectomy, oophorectomy, hysterectomy, and other procedures such as tuboplasty and incidental appendectomy without the need for a large abdominal incision. Surgical procedures such as tubal sterilization by electrocoagulation with or without partial resection, placement of a clip or silicone ring on the tube, or biopsy can be performed.

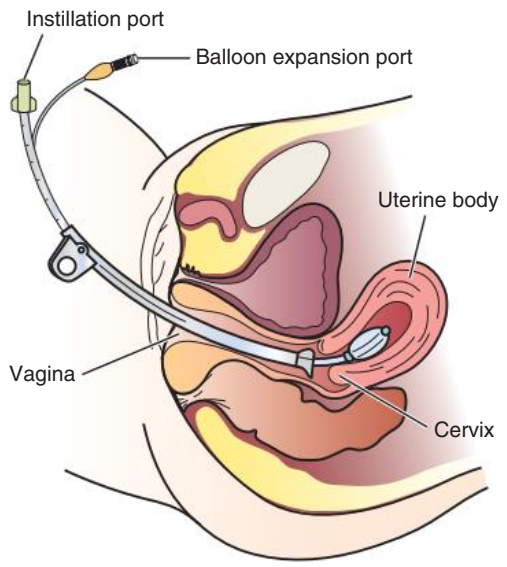
A general anesthetic agent is administered. The patient is placed in a modified lithotomy position with the stirrups adjusted so the legs are at a 45-degree angle to the axis of the OR bed. Improper positioning can result in lower leg neuropathy.

The vaginal area is prepped, followed by the abdominal prep. The patient is straight-catheterized, or an indwelling Foley catheter is inserted to monitor output and keep the bladder decompressed. The patient is draped for a combined abdominovaginal procedure. The sterile drapes must provide two exposures (i.e., an abdominal opening and a perineal opening) and cover the legs.

A tenaculum is placed on the cervix. A cannula is inserted into the uterine cervix for instillation of dye and for manipulation of the uterus during the procedure to provide greater visibility (Fig. 34.7). A D&C may be performed as part of the procedure after the injection of dye or contrast media.

Insertion of the scope is preceded by a pneumoperitoneum of CO_2 to create a working space in the abdomen and pelvis. The infraumbilical midline area is most commonly used if no scars, with possible adherent viscera beneath, are present. This area is preferred because it has no abdominal wall vessels that might be injured. The firm attachment of the fascia to the peritoneum facilitates entry. Great care is taken to avoid injury to the great vessels or intraabdominal organs. Insufflation can be performed with a Veress needle or a blunt trocar, such as a Hasson (open laparoscopy).

The patient is placed in a 10-degree Trendelenburg's position to shift the abdominal organs cephalad. A small, infraumbilical skin incision is made in the anterior abdominal wall. Through it a sharp trocar and sheath are introduced into the peritoneal cavity via blind puncture, if a blunt Hasson is not used. Some sharp trocars and sheaths have spring-loaded end guards that cover the sharp tip and protect the underlying structures after penetration of abdominal tissue layers, although studies have not shown this to be an advantage. The trocar is removed, and a telescope of the same caliber is inserted through the trocar sheath, which remains in the cavity. Some sheaths have threads that are used to anchor it into position.



• **Fig. 34.7** Kronner uterine manipulator for laparoscopy.

Additional secondary trocars and sheaths can be placed in the suprapubic hairline (see Fig. 34.12, later in this chapter). These trocars may be inserted into the peritoneal cavity under direct vision through the endoscope, which offers good transillumination for the puncture when the room lights are dimmed, or visualization on the video monitor. A secondary trocar should have a gas port to which the CO_2 tubing can be attached to prevent the cold gas from causing the scope to fog. The suction-irrigation tubing is attached to a side port on the secondary sheath.

Before use, warming the tip of the telescope in a warm moist towel or normal saline solution can prevent fogging of the distal lens of the endoscope caused by the intraperitoneal temperature and moisture. (Sterile antifog solution is commercially available.) The telescope is connected to the light source by a fiberoptic cable. Because of the potential fire hazard to drapes, the light source is not activated until the cable is attached to the telescope. The video camera is draped and connected to the telescope. The camera may not be sterile and must be draped to prevent contamination.

At completion of the surgical procedure the CO_2, video monitor, and light source are turned off, accessory instruments and sheaths are removed, and the patient is leveled into a flat, supine position. Hemostasis is surveyed before the telescope is removed from the primary trocar site.

The valve of its sheath closes as the telescope is withdrawn to prevent escape of CO_2 gas into the room air. The pneumoperitoneum contains aerosolized blood and body fluids and should be evacuated through the suction tubing into the suction canister. Electrosurgical plume also should be suctioned from the peritoneal cavity because it binds with hemoglobin and causes the arterial oxygenation to decrease. The patient can become hypoxic.

The large fascial incisions are sutured, and the skin can be closed with wound glue. Small dressings or adhesive bandages (Band-Aids or Steri-Strips) are applied.

The patient requires close monitoring by the anesthesia provider because increased intraabdominal pressure may lead to cardiovascular disturbances from vagal reflex. This reflex is caused by stretching of the peritoneum, retention of CO_2, or compression of the inferior vena cava.

Postoperative shoulder pain may follow the use of a pneumoperitoneum. This is referred pain caused by pressure on the diaphragm, which is somewhat displaced by CO_2 during the procedure. Slight elevation of the head after recovery from anesthesia relieves this pain.

Although numerous complications have been reported, the most common are perforation of the intestine or major blood vessel, hemorrhage from a biopsy site, gas embolism from intravascular injection, and burns of the abdominal wall and bowel. Some injuries, such as viscus puncture or thermal damage, may not be immediately apparent. Symptoms may not be present until 48 to 72 hours postoperatively, when tissue necrosis or sloughing occurs.

Vulvar Procedures

Benign growths on the vulva, although rare, consist mainly of fatty and fibrous tumors. These growths are excised if large. Suspicious lesions should be removed for pathologic examination. Cancerous lesions may be multicentric, with the majority found on the labia majora and a lesser percentage on the labia minora, vestibule, clitoris, and posterior commissure. Vaginal smears

should be taken to determine the presence of metastatic growth to the vaginal wall. Treatment depends on the size of the primary lesion, involvement of nodes, and extent of metastasis. Mutilative procedures require emotional adjustment to permanent change.

Diseases of the Vulva

Wide local excision of a single well-localized area with no premalignant changes elsewhere may be performed. Punch biopsies may be obtained. Leukoplakia and preinvasive lesions of the vulva may be treated with a laser or ultrasonic aspirator.

Simple Vulvectomy without Node Dissection

The labia majora and minora, part of the mons veneris, and the hymenal ring, including the clitoris, may be removed for premalignant lesions and early microinvasive cancer of limited penetration. The clitoris and perianal region are spared if the lesion is small. The incision must be wide to avoid local recurrence.

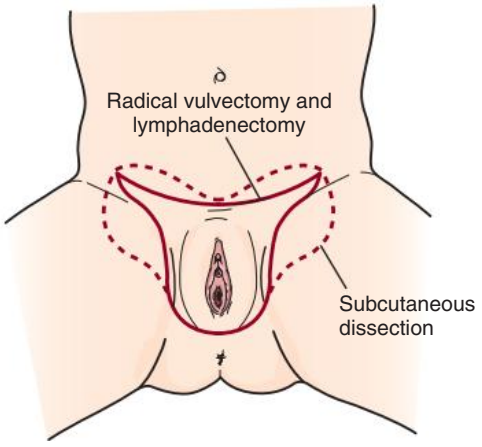
Total Vulvectomy

Basal cell carcinoma usually does not metastasize but is often locally extensive and prone to recur. Treatment consists of wide total vulvectomy, also without node dissection.

Radical Vulvectomy with Bilateral Inguinal-Femoral Lymphadenectomy

Radical vulvectomy is performed for invasive vulvar cancers or melanoma and is usually done in one stage. Resection lines may vary depending on the location and size of the lesion (Fig. 34.8). The procedure involves abdominal and perineal dissection, and both areas, including the thighs to the knees, are prepped. Structures generally removed include all of those from the anterior surface of the pubis to the perianal region posteriorly, with wide lateral excision beyond the vulva, to fascial depth. More specifically, large areas of abdominal and groin skin, the labia majora and minora, the mons, clitoris, Bartholin, and periurethral glands, and bilateral inguinal lymph nodes are removed en bloc. Inguinal skin flaps are retained for closure. Deep pelvic node dissection is carried out if examination of frozen sections determines these nodes are cancerous. If the vagina, urethra, and/or anus are involved, they are removed also. Anal involvement may require a colostomy.

Lymphadenectomy is carried out with the patient in the supine position. Two teams may perform bilateral dissection. The patient is then placed in the lithotomy position for vulvectomy.



• **Fig. 34.8** Incisions for radical vulvectomy.

Reconstruction of the pelvic floor and vaginal walls may be necessary. The legs are abducted for easier approximation of subcutaneous tissue during primary closure with sutures or staples. Closed-wound suction drainage is used postoperatively to avoid fluid collection beneath skin flaps. A pressure dressing is applied.

Bartholin Glands

Obstruction of the secretory duct of the Bartholin gland may be caused by inflammation. A cyst may be prone to secondary infection or abscess formation.

Marsupialization of Bartholin Gland Cyst

A cyst enlarges as mucous secretions accumulate. Marsupialization establishes drainage from within the vagina by creation of a new, enlarged ductal opening. The cyst is incised linearly in the region of the normal opening and evacuated. The edges of the vaginal mucosa and cyst wall are sutured together to produce epithelialization so that the cyst cannot recur. An abscess may be drained.

Vaginal Procedures

The vaginal wall, cervix, and uterus may be approached with the patient in the lithotomy position. Tumors, benign or malignant, may be confined to any one of these structures or may involve adjacent tissues. Herniation or fistula formation may require repair of the vaginal wall and adjacent structures. Excision or repair may require a combined vaginal-abdominal procedure.

Vaginal Wall

Excision of a Vaginal Lesion

A biopsy taken from an epithelial tumor should be studied histologically to rule out adenocarcinoma. Vaginal adenosis and gross cervical abnormalities, as well as clear cell adenocarcinoma of the vagina, have occurred in female offspring of women who received diethylstilbestrol (DES) or similar synthetic estrogen during the first trimester of pregnancy to avoid **spontaneous abortion**. Adenosis may be treated with a laser.

Vaginectomy

Vaginectomy (partial or complete) is performed for carcinoma in situ or carcinoma of the vagina. Vaginoplasty is necessary for reconstruction. External radiation and radium implants, with possible eventual pelvic exenteration, is the treatment for advanced invasive malignancy. The proximity of the bladder and rectum makes therapy difficult.

Radical vaginal or abdominal hysterectomy and vaginectomy with extraperitoneal lymphadenectomy sometimes are combined for carcinoma of the upper and middle thirds of the vagina if the bladder or rectum is not involved.

Vaginoplasty

A vagina may be constructed in patients with congenital absence of the vagina (Rokitansky syndrome) or, more commonly, in those with stenosis after radiation therapy or after surgical removal of the vagina. Care must be taken to avoid damage to the urethra, bladder, and rectum.

The vaginal space is created by blunt and sharp dissection. If a large part of the surface of the space is denuded, a skin or amnion graft is shaped around a vaginal mold. The mold is placed in such a way that the graft will take. With the use of dilators to prevent stenosis and with the use of estrogen cream to assist in epithelialization

of the cavity, an adequate functional vagina can be created in many patients. A pseudovagina is created for transsexual surgery.

Procedures for Repair of the Pelvic Outlet

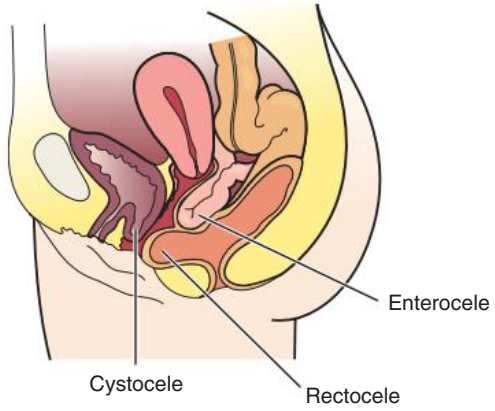
Injury to muscles and fascial layers of the perineum and/or genital tract, usually during childbirth, may result in extensive vaginal relaxation (Fig. 34.9). Manifestation of perineal hernias may be delayed until later years, when generalized loss of elastic tissue develops. Downward pressure is exerted on other structures, such as the bladder. Moderate to severe degrees of herniation of viscera require surgical intervention to restore pelvic floor integrity and sphincter competency.

Vaginal plastic procedures for genital prolapse consist of narrowing and reconstructing the damaged pelvic floor. Vaginal repairs are referred to as vaginal plastic procedures.

Anterior Colporrhaphy

Anterior colporrhaphy, known as the Kelly procedure, is performed for prolapse of the anterior vaginal wall to repair a urethrocystocele (herniation of the bladder into the vaginal canal). The wall is incised, and a strip of redundant vaginal mucosa is excised, the extent of which depends on the severity of the prolapse. The bladder is dissected free from the vaginal septum and returned to normal position by suturing the pubocervical ligaments beneath it. Approximation of the pubococcygeus muscles provides further suburethral support. The vaginal wall is closed with sutures.

By improving support to the bladder neck region, restoring the posterior urethrovesical angle, and narrowing the urethral opening, stress incontinence (urine leakage with coughing, sneezing, or laughter) is relieved. The surgical procedure also prevents voiding difficulty and the recurrent cystitis that accompanies retention of urine caused by a cystocele bulging below the bladder neck.



• **Fig. 34.9** Cystocele, rectocele, and enterocele.

Posterior Colpoperineorrhaphy

Repair of the posterior vaginal wall for rectocele, a herniation of the rectum into the vagina, consists of a triangular excision of redundant vaginal mucosa and separation of the vagina from the rectum. Support is reestablished by suturing together rectovaginal fascia, as well as the levator ani, as high as possible. Perineal muscles are reconstructed to restore continuity of support. A lacerated perineum also may be sutured. The surgical procedure relieves fecal incontinence and/or constipation.

Repair of an Enterocele

An abnormally deep hernial sac may contain a segment of intestine, referred to as an enterocele or cul-de-sac hernia. Repair consists of opening the sac, reducing its contents, excising the sac, closing the aperture or weakness that allowed the sac to descend into the rectovaginal septum, and strengthening the normal anatomic coverings. Approximation of the uterosacral ligaments and levator ani in the midline removes the cul-de-sac defect.

Repair of a Prolapsed Uterus

Various surgical procedures correct and restore support of the prolapsed uterus (procidentia; Fig. 34.10). *Correction* of prolapse anteverts the uterus and shortens an elongated cervix and cardinal ligaments. In a Manchester colpoperineorrhaphy, for example, the cervix is amputated and the cardinal ligaments are united in front of it. The anterior vaginal wall is plicated, and the posterior pelvic floor is reconstructed.

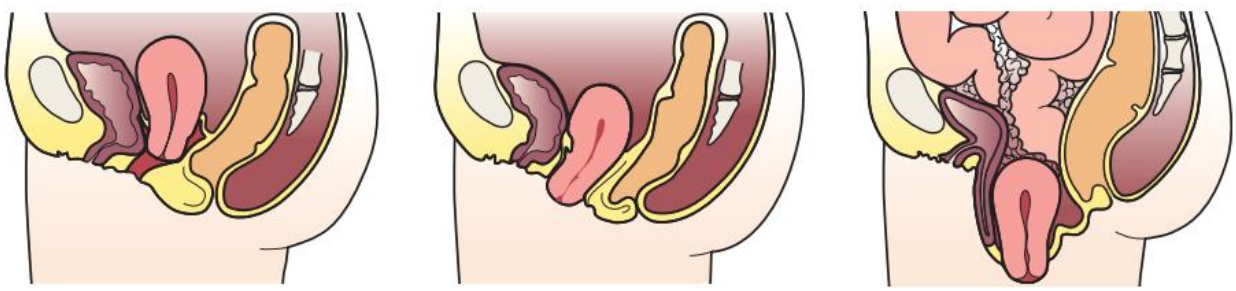
Often, cystocele and rectocele are present and are simultaneously repaired. In complete prolapse both the cervix and the uterine body protrude through the vaginal aperture, and the vaginal canal is inverted. Bleeding ulceration of exposed tissues may ensue. Vaginal hysterectomy is done for severe prolapse or prolapse accompanied by stress incontinence when childbearing is no longer desired. A vaginal pessary to support a retrodisplaced or prolapsing uterus may be inserted in a woman who presents a poor surgical risk.

Repair of Vaginal Eversion

Outward protrusion of the vagina can occur after obstetric or surgical trauma or from inherent weakness in vaginal muscle tone, particularly in a woman's postmenopausal years. The fascia of the vagina is attached to the sacrospinous ligament, located within the coccygeus muscle. The resultant scarring and fibrosis fixate the vagina in a normal anatomic position.

Colpocleisis

Colpocleisis, or the Le Fort procedure, is an obliteration of the vagina by denuding and approximating the anterior and posterior



• **Fig. 34.10** Prolapse of the uterus, in varying degrees.

walls. The procedure is generally reserved for geriatric patients and those who present a poor surgical risk.

Procedures for Repair of Genital Fistulas

A genital fistula is an abnormal communication between a part of the genital canal and either the urinary or the intestinal tract. Various dye tests, cystoscopy, and pyelography help pinpoint a urinary tract fistula. Injury during parturition, surgical trauma (especially radical procedures for cancer), penetrating extension of cervical carcinoma, and radiation necrosis are common etiologic factors.

Repair of a Vesicovaginal Fistula

A vesicovaginal fistula, which develops between the bladder and vagina, is the most common type of genital fistula. A small opening permits seepage of urine, although the patient may void normally. Total incontinence may result from a large fistulous aperture and cause irritation of the vagina, vulva, and thighs. Through a vaginal approach, the anterior vaginal wall is dissected free. The fistula to the bladder is closed, and the attachment of the bladder to the vagina is reestablished. The repair should be made with at least three layers of tissue. The bladder should be decompressed by an indwelling Foley catheter postoperatively. Antibiotics may be administered judiciously to prevent infection in the healing site.

If the vesicovaginal fistula is high in the vagina, a better result will be obtained by entering the bladder via suprapubic incision for direct repair rather than by using a vaginal approach. Care must be taken not to occlude ureteral orifices. This is accomplished by insertion of ureteral catheters, which can be removed after the procedure. Attention is given to excision of any infected tissue, closure with multiple layers, and bladder decompression by the Foley catheter.

Repair of a Rectovaginal Fistula

A fistula between the rectum and vagina may occur after episiotomy or obstetric perineal lacerations, vaginal or rectal surgery, radiation therapy, trauma, or infection. Fecal incontinence and fecal material in the vagina are characteristic, although the anal sphincter is intact. Preoperative bowel preparation, including prophylactic antibiotic therapy, is important because of the contaminated surgical area. A temporary colostomy may be advisable before the surgical procedure to divert the fecal stream from the repair site. With a vaginal approach a plastic repair of the perineum is done. Scar tissue and the fistulous tract are excised, and the edges of the perineal muscles and fascia are approximated.

Cervix

Surgical treatment of an abnormal cervix should be preceded by tests such as a Pap smear to rule out early malignant change.

Cauterization

The cervix may be cauterized by electrocautery to treat chronic inflammation and/or leukorrhea (i.e., vaginal discharge).

Trachelorrhaphy

Lacerations of the cervix may result from childbirth. Repair (i.e., trachelorrhaphy) involves reconstruction of the cervical canal as necessary. A vaginal plastic setup is used.

Trachelectomy

The cervix may be amputated to remove an intraepithelial cancer.[3] Most surgeons prefer total hysterectomy to cervical amputation because the remaining uterine component may become cancerous.

Removal of the uterine cervix in early-stage cancer with lymphadenectomy is a fertility-sparing option for some women. Studies demonstrated that 50% live births resulted from known pregnancies after trachelectomy. **Cesarean birth** was required for most of these deliveries, and most of these infants were born preterm. Complications noted in the studies included preterm labor and spontaneous abortion.

Uterus

Dilation and Curettage

The most frequently performed gynecologic procedure, **dilation and curettage (D&C)** is done for diagnostic and/or therapeutic purposes. The main purpose of a D&C is to establish the cause of abnormal uterine bleeding so the gynecologist can plan definitive treatment.

The procedure is performed for women with postmenopausal bleeding or symptoms suggestive of endometrial cancer, even when cytologic smear findings are negative. It may be performed in infertility studies or to confirm preoperative diagnosis before amputation of the cervix or hysterectomy. D&C is performed therapeutically to relieve dysmenorrhea by cervical dilation only, to remove polyps or benign endometrial pathologic conditions, to remove residual tissue and arrest bleeding after incomplete abortion, or to perform voluntary abortion before the thirteenth week of pregnancy. A regional paracervical block or general anesthesia is required.

With the anterior lip of the cervix held in a tenaculum and the posterior vaginal wall retracted, a uterine sound is introduced into the uterus to determine the depth and direction of the intrauterine cavity. It is important that the surgeon know the shape and position of the uterus to avoid perforation. The cervical os is sequentially dilated with graduated metal probes. A small curette is introduced into the endocervical canal, which is scraped from the internal to the external os. Submucosal fibroids are usually discernible as the curette passes over them. Exploration of the fundus with a polyp or placental forceps usually extracts any polyps present in the endometrium.

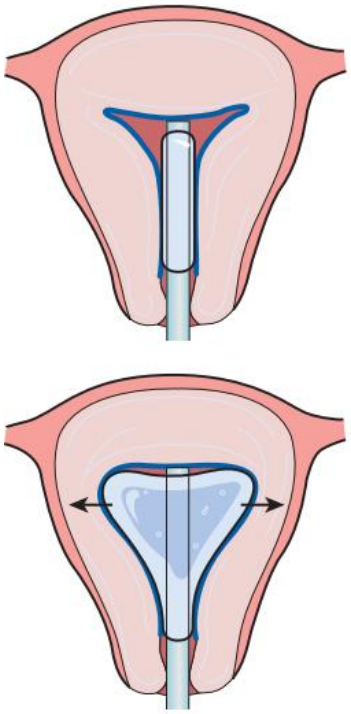
Intrauterine Thermal Balloon Ablation

A specialized electrically heated latex balloon probe can be introduced into the uterine cavity through the cervical os to treat menorrhagia (Fig. 34.11). The intrauterine probe is attached to a cable system controlled by a microprocessing unit that measures temperature, pressure, and time. The thermal balloon is expanded by the computer to fill the capacity of the uterine cavity and heated to 188.6° F (87° C). A depth of approximately 3 to 5 mm of endometrium is ablated within 8 minutes of contact. This procedure is suitable for patients who have regularly shaped uterine cavities with a capacity of less than 30 mL or 10 cm in depth. A larger or irregularly shaped uterine cavity would not evenly accommodate the expansion of the balloon.

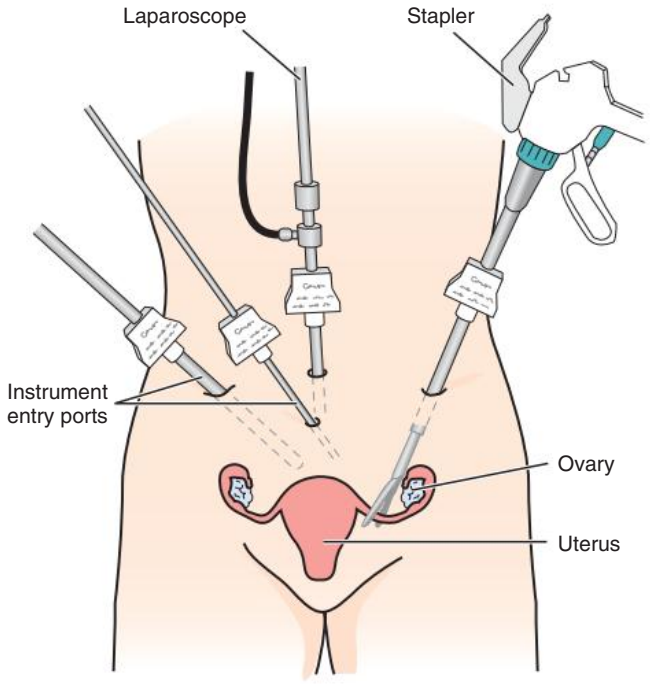
Intrauterine thermal balloon therapy is contraindicated for women who wish to have future pregnancies. The thermal process destroys the endometrial lining that supports the placental attachment during pregnancy. As per all latex devices, use of a latex balloon is contraindicated for patients sensitive to latex products.

Vaginal Hysterectomy

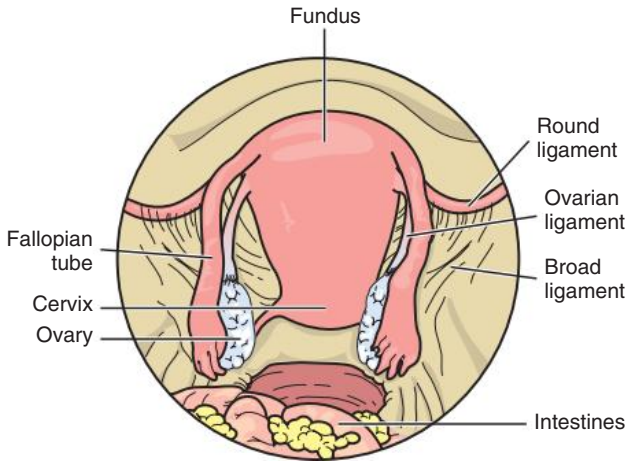
Vaginal hysterectomy is performed for severe uterine prolapse or prolapse accompanied by stress incontinence and for patients with pelvic relaxation or a history of myomas, irregular uterine bleeding, or a treated premalignant lesion. The procedure can be done totally through the vagina or by laparoscopic-assisted methods. In laparoscopy the abdominal attachments are taken down via the laparoscopic instruments and the uterus is removed through the vagina.



• **Fig. 34.11** Endometrial thermal ablation with balloon.



• **Fig. 34.12** Access portals for laparoscopically assisted vaginal hysterectomy.



• **Fig. 34.13** Laparoscopic view of the uterus.

The uterus is removed through the vagina with incision of the vaginal wall and the pelvic cavity. Urinary incontinence caused by an enterocele and/or a rectocele may be simultaneously repaired by anterior and posterior colporrhaphies and with reconstruction of the pelvic floor. Advantages of the procedure include restoration of a normal anatomic relationship and preservation of vaginal function. The ovaries are not always removed. Contraindications are immobility of pelvic organs, a large uterus, a pathologic condition such as an ovarian mass, or pelvic cancer.

The vaginal wall is incised anteriorly, and the bladder is separated from the cervix. The incision is continued around the cervix. The peritoneal cavity is entered through the posterior cul-de-sac and the anterior uterovesical pouch. Ligaments supporting the uterus and uterine vessels are ligated and cut. The fundus is delivered, the upper pedicles are sutured, the uterus is removed, and the peritoneum is closed. Suturing the cardinal and uterosacral ligaments together and to the vaginal vault supports the vault and prevents prolapse of the vagina.

Potential complications include injury to the ureters, bowel, or bladder and massive hemorrhage from the uterine vessels. An unopened laparotomy setup should be available in case it is necessary to open the abdomen.

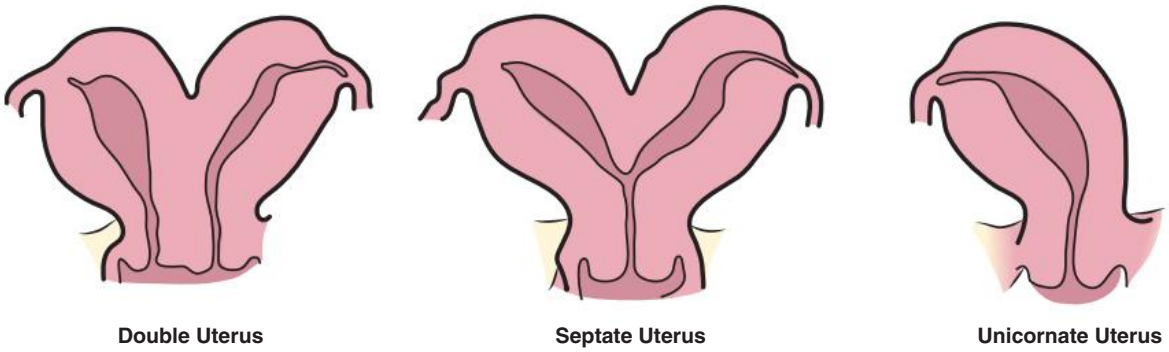
Radical Vaginal Hysterectomy

A surgical approach to early carcinoma of the cervix, radical vaginal hysterectomy (i.e., the Schauta procedure) does not permit pelvic lymph node dissection but is useful in select patients (e.g., obese patients). It includes vaginal removal of the uterus, upper third of vagina, fallopian tubes, and ovaries. Damage to the ureters or bladder is a potential complication.

Laparoscopic-Assisted Vaginal Hysterectomy

In laparoscopic-assisted vaginal hysterectomy (LAVH) an abdominal endoscopic approach is used to dissect the uterus from its supporting ligaments and vasculature. Trocar placement is depicted in Fig. 34.12. Endoscopic clips, linear staplers, sutures, electrosurgery, or a laser may be used to enhance hemostasis. Once the intraperitoneal attachments of the uterus are ligated and divided, a vaginal approach is used to separate the bladder from the anterior aspect of the uterus as in a standard vaginal hysterectomy. Direct visualization of the bladder flap dissection through the endoscope from above enables the surgeon to avoid damage to adjacent structures (Fig. 34.13). The uterine vascular pedicles are ligated vaginally. In the Heaney technique the uterus is inverted and removed fundus-first through a posterior colpotomy. The uterosacral ligaments are sutured to the posterior aspect of the vaginal cuff, and the colpotomy is closed.

This method is used in moderate prolapse of the uterus. In the Döderlein technique a nonprolapsed uterus is inverted and removed fundus-first through an anterior colpotomy. This technique provides greater visibility of the uterine vessels and a more



• **Fig. 34.14** Uterine anomalies.

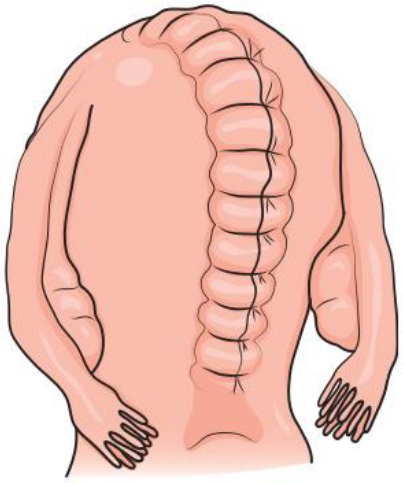
effective vaginal suspension. LAVH is the procedure of choice when a minimally invasive procedure is desired, when salpingo-oophorectomy may be necessary, and when the uterus is only moderately enlarged.

Abdominal Procedures

The open abdominal approach may be used for a fixed or enlarged uterus; exploration; inflammatory disease; and most malignant lesions of the uterus, fallopian tubes, and ovaries. This approach permits inspection of pelvic and abdominal organs and lymph glands for biopsy or treatment. Open laparotomy or minimally invasive endoscopic procedures are performed as appropriate to achieve desired outcomes.

Congenital Abnormal Uterine Development

The uterus can assume abnormal configurations during fetal development (Fig. 34.14). Abnormal uterine formation can include single cornu, double fundi, absent cornu or vagina, full or partial septum, or a complete duplication of the female reproductive tract. Ovaries may or may not be affected. Select patients may be candidates for uterine repair, or hysteroplasty. A uterine septum or bicornate uterus is sometimes repaired surgically. The uterine scar from hysteroplasty alters the integrity of the uterine wall and may necessitate cesarean delivery if the woman becomes pregnant (Fig. 34.15).



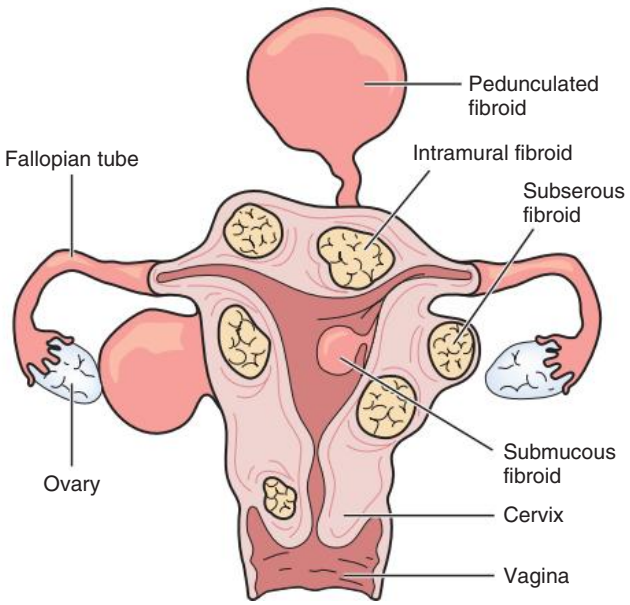
• **Fig. 34.15** Hysteroplasty.

Myomectomy

The most frequent indication for abdominal hysterectomy is **leiomyofibroma**, commonly known as benign fibroids or myomas. Fibroids are composed of coiled muscle and fibrous connective tissue. They may be single or multiple and most often are present in the wall of the uterus (intramural) (Fig. 34.16). Some may be attached by a pedicle (pedunculated) or protrude into and distort the uterine cavity (submucous).

In myomectomy, single or multiple fibroid tumors are removed from the uterine wall in premenopausal women who may still desire pregnancy. The procedure is especially adaptable to pedunculated tumors, which may become necrotic from interference with the blood supply. Removal of large submucous fibroids may require opening the uterus, which poses the significant risk for blood loss and potential for rupture during pregnancy (depending on location on the uterine body).

Fibroids, which are usually slow growing, are treated conservatively if they are small and present no problems. If



• **Fig. 34.16** Uterine fibroids.

symptoms such as **menometrorrhagia**, bladder or bowel pressure, pelvic discomfort, or rapid tumor growth develop, surgical treatment is essential. The tumor has no active growth during pregnancy and after menopause because of hormonal changes.

Fibroid Embolization through the Uterine Artery

Symptomatic uterine fibroids are sometimes treated with occlusion of the arterial blood supply, causing the substance of the fibroid to diminish.[4] An intravascular placement of guidewires and catheters in an interventional radiology suite facilitates delivery of embolization materials, such as hemostatic gelatin particles or sclerosing solution. The location of the target fibroid and its direct blood supply are carefully determined by x-ray during the procedure.

Decreasing the uterine blood supply can impair future childbearing, and other fibroid management options should be explored before uterine artery embolization is performed. Embolizing submucous fibroids can cause endometrial sloughing, infection, fever, and sepsis. Pedunculated submucous fibroids should be removed hysteroscopically.

Abdominal Hysterectomy

Medical, psychosocial, and sexual ramifications must be considered when contemplating hysterectomy (removal of the uterus). Medically, the procedure may be lifesaving in patients with a malignant lesion or severe hemorrhage. However, the gynecologist has an obligation to consider the individual patient's attitudes when another mode of therapy is available as an alternative to hysterectomy.

Because it signals the end of the patient's reproductive potential, a hysterectomy may cause psychologic stress and a sense of incompleteness, even though sexual responsiveness is not dependent on the uterus. Patients whose families are complete, however, may welcome reproductive sterilization.

The uterus is removed through an abdominal incision and opening of the peritoneal cavity.

Differential diagnoses include dysfunctional uterine bleeding caused by disturbed endocrine function, tubal or ovarian masses, and pelvic cancer. In addition to these indications, hysterectomy is performed for uterine prolapse, extensive endometriosis, and cervical or uterine cancer. Various types of hysterectomies are performed.

Total Abdominal Hysterectomy

The entire uterus, including the cervix, is resected. Normal ovaries are preserved for hormone production whenever possible in women younger than 45 years. Studies have shown that after hysterectomy, women have a 20% increased risk for ovarian cysts within 5 years of the surgical procedure. Bilateral oophorectomy followed by hormone replacement therapy has eliminated the need for subsequent surgery for ovarian pathologic conditions.

The abdominal peritoneal cavity is entered through a vertical midline or a transverse Pfannenstiel incision. Vertical incision facilitates exploration. The patient is placed in a deep Trendelenburg's position. Incision through the uterine peritoneum is carried out laterally.

The abdominal organs are retracted and protected with laparotomy packs moistened with warm sterile normal saline solution. The fallopian tubes and round and broad ligaments are clamped, cut, and ligated. The ovaries, when not removed, are suspended to avoid adherence to the vaginal vault. With the uterus forward, posterior sheets of the broad ligaments are incised, the ureters are identified, and the uterine vessels and uterosacral ligaments are clamped, divided, and sutured. All uterine-supporting ligaments must be divided and ligated. The bladder is mobilized from the cervix and vagina, the vaginal vault is incised, and the cervix is dissected from the vagina.

After the uterus is removed, the connective tissue ligaments are anchored to the vagina. The vaginal mucosa and muscular wall are approximated by absorbable sutures or staples, and the bladder, vault, and rectum (i.e., pelvic floor) are reperitonealized (i.e., covered with peritoneum). Abdominal layers are closed as for laparotomy. The following considerations apply:

1. When the surgeon is closing the vaginal vault after removal of the uterus, the needle, suture, needle holder, or stapler and all instruments used on the cervix and vagina are considered contaminated and isolated from the main instrumentation. Separate instruments are used for abdominal closure.
2. Complications of hysterectomy include injury to the ureters with possible fistula formation or renal failure, injury to the bladder or bowel with fistula formation, and massive hemorrhage from damage to major vessels.
3. Some surgeons have a urologist place ureteral catheters before the hysterectomy begins so that they are easily identified during the procedure. This is referred to as ureteral stenting and requires the use of a separate cystoscopy setup. The cystoscopy setup should remain sterile in the room after the stenting procedure in case an adjustment is necessary during the case. This saves creating another setup mid procedure.

Radical Hysterectomy with Pelvic Lymph Node Dissection

A radical Wertheim procedure, essentially a hysterectomy with pelvic lymph node dissection, may be performed for early stages of invasive cervical cancer and sometimes for endometrial cancer. It involves wide en bloc removal of paracervical and uterosacral tissues (uterus, tubes, ovaries, ligaments) and at least the upper third of the vaginal canal. Bilateral pelvic lymph nodes and channels surrounding the external iliac artery and vein, the hypogastric artery and vein, and the obturator fossae are also dissected and removed. Some surgeons perform a modified Wertheim procedure for microinvasive carcinoma. This is somewhat less extensive than the radical procedure and may omit lymphadenectomy.

Because radical hysterectomy involves excision of paracervical and paravaginal tissue, bladder innervation is disrupted. This results in bladder dysfunction postoperatively, sometimes for as long as 6 months. Bladder complications are related to the extent of dissection.

Salpingo-oophorectomy

Fallopian tubes and ovaries are removed along with the uterus. This procedure may be done for endometrial, tubal, or ovarian cancer; excessive vaginal bleeding; or large fibroids. In postmenopausal women for whom total hysterectomy is indicated, bilateral salpingo-oophorectomy is often performed to avoid future ovarian pathologic conditions.

Pelvic Exenteration

An ultraradical procedure for invasive, persistent carcinoma, exenteration is not performed for palliation but rather only when a possibility of cure exists. The extent of the disease determines the amount of exenteration.

In anterior exenteration the reproductive organs, the distal part of the ureters, the bladder, and the vagina are removed. This modification is performed for cancer of the cervix, vagina, or vulva with extension to the bladder. The ureters are diverted to an ileal conduit, whereas the bowel remains intact.

Posterior exenteration removes the reproductive organs, sigmoid colon, and rectum. It is done for cervical carcinoma involving the rectum or advanced rectal carcinoma involving the uterus

and posterior vaginal wall. The urinary system remains intact; fecal diversion is by colostomy.

Total or complete exenteration, rarely performed, involves en bloc dissection of the bladder, reproductive organs, perineum, rectum, and pelvic lymph nodes. Two setups are needed: abdominal and perineal. These procedures affect structure, function, body image, and sex life and should be preceded by intensive physical and psychologic preoperative preparation.

Numerous complications may occur involving any major system. Anesthesia and procedure times are long. Blood replacement and extensive monitoring are essential. Multiple stomas and gross pelvic defect with much dead space predispose the woman to infection; therefore several wound drains are used. Vascularized omental and myocutaneous flaps are used to fill pelvic defects.

Fallopian Tube Procedures

The fallopian tubes are also referred to as the uterine tubes, oviducts, and salpinges.

Tubal Ligation for Reproductive Sterilization

Tubal ligation should be considered a permanent method of reproductive sterilization because reversal cannot be guaranteed. Thorough preoperative counseling of the patient and her husband or partner should preface this procedure.

Various open surgical techniques can be used for tubal ligation. They are essentially similar, involving (1) removal of a portion of the middle part of the fallopian tube on each side for pathologic confirmation and (2) ligation of both the distal and proximal ends to prevent the cut ends from growing together. Frequently performed by laparoscopy, tubal ligation by open abdominal approach may be done alone, in conjunction with other abdominal surgery, immediately postpartum, or for patients in whom laparoscopic technique is contraindicated.

Ligation may be performed through a small transverse incision in the pubic hairline area. An infraumbilical incision is used for postpartum patients. This is referred to as minilaparotomy. Tubal ligations are often performed immediately after cesarean delivery and closure of the uterine wall. No additional instruments are required other than those used for the cesarean section.

The Pomeroy technique of ligation is the most reliable, provides a surgical specimen of each tube, and causes minimal tubal destruction. The tube is tied with suture material, and a section is removed. The tube eventually pulls apart, destroying the passage between the ovary and uterus.

Sterilization also may be performed after vaginal delivery, on the first to third postpartum day, through an infraumbilical incision. In the cauterization technique the bipolar electrosurgical electrode transects and seals the ends of the fallopian tube or excises a section of the tube and seals the ends.

Laparoscopic application of a stretchable Silastic band (Falope ring) or spring-loaded ligating clips (Hulka or Filshie) also produces occlusion. In some patients, however, the Pomeroy and other occlusion techniques may be reversible by a subsequent reparative procedure. An estimated 1% of sterilized women will seek reversal because of sterilization at an early age, remarriage, or death of a child.

Tuboplasty

Removal of an obstruction may restore tubal patency to reverse infertility caused by diseased, damaged, or occluded tubes. Microsurgical techniques with fine suture materials and lasers have vastly improved results of tubal reconstructive procedures. Success depends on the extent of abnormal tissue or tubal destruction and/or the site of obstruction. The location of the previous ligation and normality of tissues at the severed ends of the tubes will influence the reversibility of a tubal ligation.

Although tubal patency may be restored, abnormal function may persist in tubes scarred by previous surgery or ectopic pregnancy or damaged by pelvic inflammatory disease (PID). The chance of successful uterine pregnancy may remain limited. The risk for a tubal pregnancy can increase after tuboplasty.

Preoperative assessment may include a hysterosalpingogram to determine the length and patency of tubal segments and/or laparoscopy with tubal dye perfusion or ultrasound imaging with instillation of sterile normal saline solution to demonstrate patency. Contraindications for tuboplasty include active infection or disease and a tube that is less than 3 cm long.

Tuboplasties are microsurgical procedures performed through an abdominal incision. They include the options described in the following sections.

Salpingolysis

Adhesions caused by an inflammatory process, such as a ruptured appendix or ovarian cyst, may surround the fallopian tubes. The tubes may function normally after lysis of adhesions.

Salpingostomy

Tubal mucosa and/or fimbriae may become occluded secondary to PID or other infectious process. A salpingostomy creates an opening in a distally obstructed tube. A CO_2 laser may be used through the microscope to open fimbriated ends and to divide adhesions in blocked tubes. An incision in a tube also may be performed to evacuate an early small tubal pregnancy (ectopic pregnancy).

Tubal Anastomosis

A proximal obstruction in the tube is resected. The remaining patent segment is then reimplanted into the uterus and anastomosed at the cornu. Salpingitis usually occludes the tube near the cornu, which may need to be shaved to reach healthy tissue. A previous sterilization procedure usually occludes the midisthmus. This anastomosis will be midtubal in the ampulla.

Salpingectomy and Salpingo-oophorectomy

Salpingectomy (removal of a fallopian tube) is often performed in association with salpingo-oophorectomy (partial or total removal of the corresponding ovary). Procedures may be unilateral or bilateral. Indications are extensive damage from PID or endometriosis, cysts, primary adenocarcinoma of the tube, and ectopic pregnancy.

Total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed for bilateral disease. Removal of a large tubo-ovarian abscess is essential to prevent rupture and dissemination of pus in the abdominal cavity.

Ovaries

Ovarian pain usually is referred to the lower abdomen just above either groin, making differential diagnosis from abdominal disease pertinent. Pelvic endoscopy, ultrasonography, and computed tomographic (CT) scans assist diagnosis. An ovarian mass requires exploration for evaluation. The mass may be a cyst or a tumor. Ovarian tumors may be benign or malignant, cystic or solid. Epithelial ovarian cancer begins as a cystic intraovarian growth. It usually is asymptomatic until malignant cells have spread into the peritoneal cavity.

Ovarian cancer is usually confined to the peritoneal cavity and retroperitoneal lymph nodes, but advanced ovarian carcinoma can obstruct the urinary and intestinal tracts. Ovarian cancer is the leading cause of gynecologic cancer deaths in the United States.

Screening for Ovarian Cancer

This disease is particularly deadly because 80% of symptomatic women present to their physician with advanced disease. Screening modalities include ultrasound, CT, pelvic ultrasound, serum CA125, and physical examination. Unfortunately, early diagnosis does not ensure a decrease in mortality.

Benign cysts, more common than tumors, may arise from the graafian follicle, corpus luteum, or epithelium (dermoid). As they grow, ovarian cysts can cause menstrual disturbances, pain, and abnormal uterine bleeding. They may leak contents into the peritoneal cavity, causing irritation, or they may rupture, causing massive bleeding that necessitates immediate laparotomy.

Cysts or solid tumors, even if asymptomatic, should be removed as a precaution because they may degenerate into a malignant lesion, increase in size, or lead to twisting of the pedicle. The type of procedure depends on the type of cyst or tumor, the age of the patient, and the importance of childbearing potential.

Excision or Biopsy

The surgeon examines the ovaries. If a cyst or tumor is found in one ovary, the surgeon inspects the other ovary to rule out a neoplasm. Pelvic washings may be obtained and tested for cancer cells. If ovarian cancer is highly suspected, the entire ovary is removed for tissue sampling to avoid dissemination of cancerous cells throughout the pelvis. Biopsy specimens also may be taken from paraaortic and pelvic lymph nodes.

Ovarian Cystectomy

A procedure to remove an ovarian cyst may be scheduled as an oophorocystectomy, cysto-oophorectomy, or ovarian cystectomy. Many benign ovarian cysts and tumors are treated by local excision with preservation of the ovary. A large cyst may be aspirated before removal. Immediately after removal, the surgeon incises the cyst for examination to determine its character because gross appearance and frozen section are both important. If there is reasonable assurance that the lesion is benign, removal of only the cyst or resection of a diseased portion (e.g., endometrioma) is justified, with preservation of normal tissue.

Oophorectomy

The most frequent indications for oophorectomy (removal of an ovary) are benign ovarian tumors. Many gynecologists believe that cystadenomas and all solid benign ovarian tumors should be treated by unilateral salpingo-oophorectomy because of the difficulty of clean dissection and the questionable assurance of their benign nature. In postmenopausal women, both ovaries, both tubes, and the uterus are removed to avoid future cancer.

If there is a strong probability or proof of malignancy in any ovarian cyst or mass, total hysterectomy and bilateral salpingo-oophorectomy are usually performed, regardless of age. Partial or complete omentectomy may be included because the rich blood supply of omentum contributes to rapid metastases. The extent of the surgical procedure is determined by the lesion. In malignant tumors a differentiation is made between primary and metastatic ovarian cancer, which influences treatment.

As much tumor as possible is removed—a procedure referred to as *debulking*—for management of advanced ovarian cancer. An ultrasonic aspirator may be used for debulking. The procedure may require resecting parts of small and large intestines and the urinary tract.

After debulking, most patients receive chemotherapy. This often is followed by a "second-look laparotomy" to reassess the peritoneal cavity for further palliative or therapeutic therapy.

Intraoperative Intraperitoneal Chemotherapy

Ovarian cancer is primarily a peritoneal disease that is sensitive to chemotherapy. The goal of intraperitoneal instillation is to expose the greatest number of ovarian cancer cells with the least amount of systemic toxicity. Earliest used agents include 5-fluorouracil and methotrexate in large quantities of irrigant to cover the greatest surface of the peritoneal cavity; however, cisplatin infusion is most commonly used today. The best results have been seen with minimal extensions of the disease, but it does seem to prolong life in advanced disease. Great care is taken when handling chemotherapeutic agents.

Muscles and Ligaments of the Pelvic Floor

Urinary Stress Incontinence Procedures

Urinary stress incontinence is the sudden, involuntary, and intermittent release of urine as a result of muscular changes around the proximal urethra, bladder neck, and bladder base. Differential diagnosis from fistulas, bladder neuropathies, and primary lesions is established by urethroscopy, a cystometrogram, and urodynamics. Surgical correction attempts to restore support. Three basic approaches are used. Anterior colporrhaphy with plication (i.e., reducing the size of the bladder neck) often is satisfactory. In a urethral sling procedure a musculofascial sling is placed beneath the bladder neck and urethra; usually this is a combined vaginal and abdominal procedure.

Urethral suspension procedures reposition the urethra and bladder neck retropubically by suspending the urethra in a plane with the symphysis pubis through a transverse abdominal incision. Sometimes a combined abdominoperineal approach is necessary for urethral suspension. Variations of these procedures have been devised, including an endoscopic suspension of the bladder neck.

Marshall-Marchetti-Krantz Vesicourethral Suspension

After mobilization through an extraperitoneal abdominal approach into the prevesical space, the urethra and bladder neck are suspended to the posterior border of the symphysis pubis. Sutures are placed through the anterior vaginal wall on each side of the urethra and brought through the periosteum on the posterior surface of the symphysis pubis. Sutures also may be placed adjacent to the bladder neck and through the rectus muscle fascia to suspend the bladder neck.

This procedure may be performed in conjunction with other pelvic surgery. It is 85% effective in the treatment of stress incontinence in women. A suprapubic catheter may be used for bladder drainage for 48 to 72 hours postoperatively. Urinary retention is a common complication for up to 7 days.

Perioperative Obstetrics

Diagnostic techniques such as ultrasonography, specialization in fertility problems, and techniques of fetal monitoring and management have brought significant changes in the field of reproductive biology. Perioperative personnel become involved in the

TABLE 34.2 Altered Laboratory Values of Pregnancy

Test	Nonpregnant Females	Change in Pregnant Females	Gestational Timing
Hemoglobin (Hgb)	12-16 g/dL	↓ 1.5-2 g/dL	Drops to lowest point between 30th and 34th weeks, then stable
Hematocrit (Hct)	37%-47%	↓ 4%-7%	Drops to lowest point between 30th and 34th weeks, then stable
White blood cells (WBCs)	5000-10,000/cm^3	↑ 3.5 × 10^3	Gradual increase throughout pregnancy
Platelets	150,000-400,000/mm^3	↓ Slightly	Gradual decrease throughout pregnancy
Fibrinogen	200-400 mg/dL	↑ 50%	Gradual increase throughout pregnancy
Calcium (Ca)	9-10.5 mg/dL	↓ 10%	Gradual decrease throughout pregnancy
Sodium (Na)	136-145 mEq/L	↓ 2-4 mEq/L	Decreases before 20th week, then stable
Chloride (Cl)	90-110 mEq/L	↑ Slightly	Gradual rise, almost negligible
Potassium (K)	3.5-5 mEq/L	↓ 0.2-0.3 mEq/L	Decreases before 20th week, then stable
Creatinine clearance	95-125 mL/min	↑ 40%	Rises through 20th week, then stable
Blood urea nitrogen (BUN)	5-20 mg/dL	↓ 50%	Drops during first trimester, then stable
Glucose (fasting)	70-115 mg/dL	↓ 10%	Gradual decrease throughout pregnancy
Uric acid	2-6.6 mg/dL	↓ 33%	Decreases during first trimester, then stable
Albumin	3.2-4.5 g/dL	↓ 1 g/dL	Rapid drop before 20th week, then stable

care of obstetric patients, in both elective and emergency procedures, for both obstetric and nonobstetric procedures. The pregnant woman experiencing trauma or an acute surgical disease, such as appendicitis, presents challenges to the perioperative team. The well-being of the fetus depends on maternal physiologic factors. Anesthesia and positioning are especially critical concerns. The anatomic changes of pregnancy alter the appearance and location of commonly identified surgical landmarks. Laboratory values are altered as a result of the growing fetus within the mother's uterus (Table 34.2).

Planning care for the surgical obstetric patient includes determination of the expected date of confinement (EDC). The size of the uterus, competency of the placenta, and condition of the growing fetus are prime considerations.

Considerations for the Care of the Pregnant Patient

Oxygen consumption increases about 20% during pregnancy and as much as 100% above normal during labor in response to the increased metabolic demand. Hypoxia and hypercapnia develop rapidly. Fetal oxygenation varies in direct relation to that of the mother in normal and abnormal situations. In treating fetal distress, continuous 100% oxygen is administered to the mother until delivery or relief of the distress. Hypoventilation and hyperventilation are potentially harmful because they induce hypoxemia and hypercapnia in both the mother and the fetus.

Maternal hypotension and hypovolemia diminish uterine blood flow and fetal perfusion. Hypoxia and acidosis threaten fetal well-being. The mother is safeguarded by appropriate anesthetic technique and selection of drugs. The fetus is protected by adequate uteroplacental perfusion and fetal monitoring by trained personnel. The patient should not be left alone in the holding area or OR. The fetal heart rate and uterine contractions are monitored continually. The procedure involves the care of two patients.

Positioning the Pregnant Patient

Uterine displacement to the left during transport and until after delivery is necessary to shift the uterus away from the large abdominal vessels. The positional effect on cardiac output is of major importance in avoiding maternal hypotension and maintaining fetal well-being. In the supine position the enlarged uterus compresses the inferior vena cava and aorta, resulting in diminished venous return to the heart, stroke volume, and cardiac output. This is further complicated if the patient is obese with a large central body habitus.

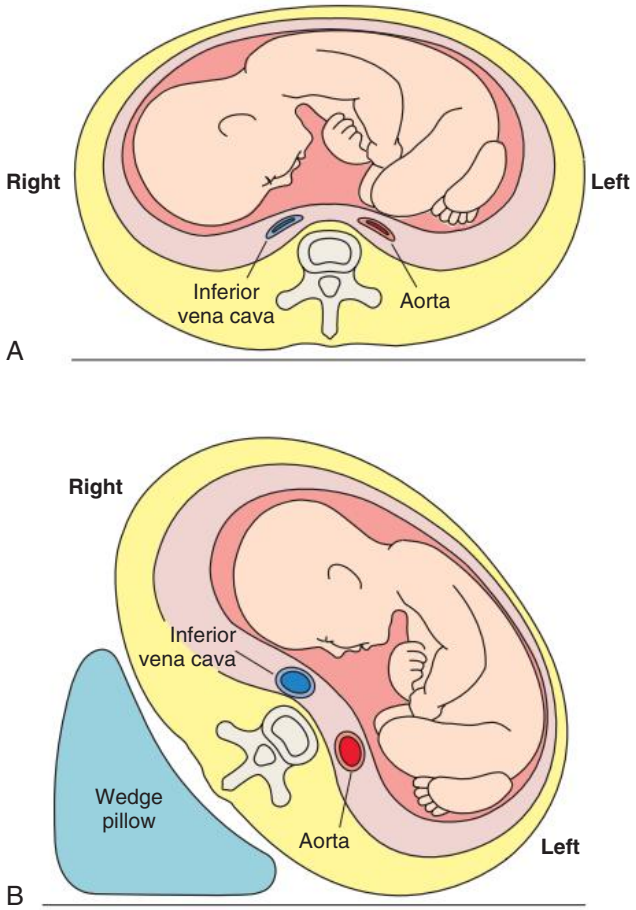
The patient is positioned supine with the right side slightly elevated by a wedge or small roll to tilt the uterus to the left (Fig. 34.17). The OR bed may be tilted 30 degrees to the left. A slight Trendelenburg's position assists venous return in the patient.

Anesthesia

Anesthesia is selected on an individual basis. Regional anesthesia, such as spinal or epidural, is preferred because it has a lesser effect on the physiology of the mother and her fetus. It is advantageous in patients with diabetes because of reduced metabolic expenditure, low incidence of vomiting, and earlier return to oral intake. General anesthetic is administered when the mother or fetus is in jeopardy and delivery is crucial, as in the presence of hemorrhage or severe fetal distress. The choice also depends on the reason for the surgical procedure, degree of urgency, and the patient's condition and preference. A cesarean section can be done with local anesthesia in an extreme emergency when an anesthesia provider is not immediately available.

The anesthesia provider chooses the method safest for the mother and fetus. Gastric motility and emptying are inhibited by fear, pain, labor, and narcotic administration. Patients requiring emergency surgery may have eaten recently. A pregnant patient should always be regarded as having a full stomach.

Spinal or epidural anesthesia allows the mother to see her newborn in the OR. It also reduces neonatal depression and risk for



• **Fig. 34.17** **A,** Pressure on aorta and vena cava caused by gravid uterus. **B,** Pressure is relieved by placing a wedge under right hip.

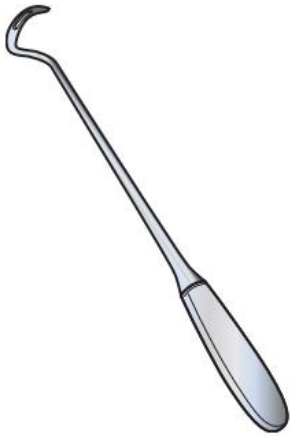
maternal aspiration. Hypotension is treated with IV fluid infusion and/or IV ephedrine given to increase blood pressure. Ephedrine, mephentermine (Wyamine), and metaraminol (Aramine) do not cause undesired uterine vasoconstriction. Other vasopressors can cause fetal hypoxia.

Placentally transmitted drugs depressant to the fetus are avoided. A single injection of morphine may be given through the epidural catheter at the conclusion of the surgical procedure. With injection into the pain path, the drug significantly reduces postoperative pain for 24 to 36 hours with minimal side effects. General anesthesia provides more rapid induction, less hypotension, greater cardiovascular stability, and better control of the airway and ventilation.

Preoxygenation Precedes Induction

Rapid-sequence induction and intubation are used if general anesthesia must be administered. Cricoid pressure during intubation occludes the esophagus to prevent regurgitation. Induction-to-delivery time is directly related to fetal hypoxia. Intervals greater than 3 minutes may lead to a lower pH of blood (metabolic acidosis) and respiratory depression of the infant from altered uteroplacental perfusion.

All efforts are made to deliver the newborn as rapidly as possible, consistent with safety, to minimize anesthesia and surgical time and to protect the fetus. With general anesthesia, all preparations, such as patient skin preparation, insertion of an indwelling Foley catheter, draping, gowning, and gloving, are done before induction of anesthesia.



• **Fig. 34.18** Suture passer.

Threatened Abortion

Cerclage

Patients with painless dilation and effacement of the cervix during the second trimester may be at risk for preterm delivery caused by cervical incompetence. The pregnant patient at risk should be assessed for a history of previous preterm rupture of membranes or spontaneous abortion. The initial primipara cervical incompetence is rarely evident before 16 weeks' gestation.

Diagnosis of **threatened abortion** for cervical incompetence is commonly made between 18 and 26 weeks' gestation. Gestational ages appropriate for elective treatment of known cervical incompetence range between 12 and 16 weeks' gestation, before the cervix has dilated beyond 2 to 3 cm. Some patients may be suitable for this procedure up to 20 weeks' gestation.

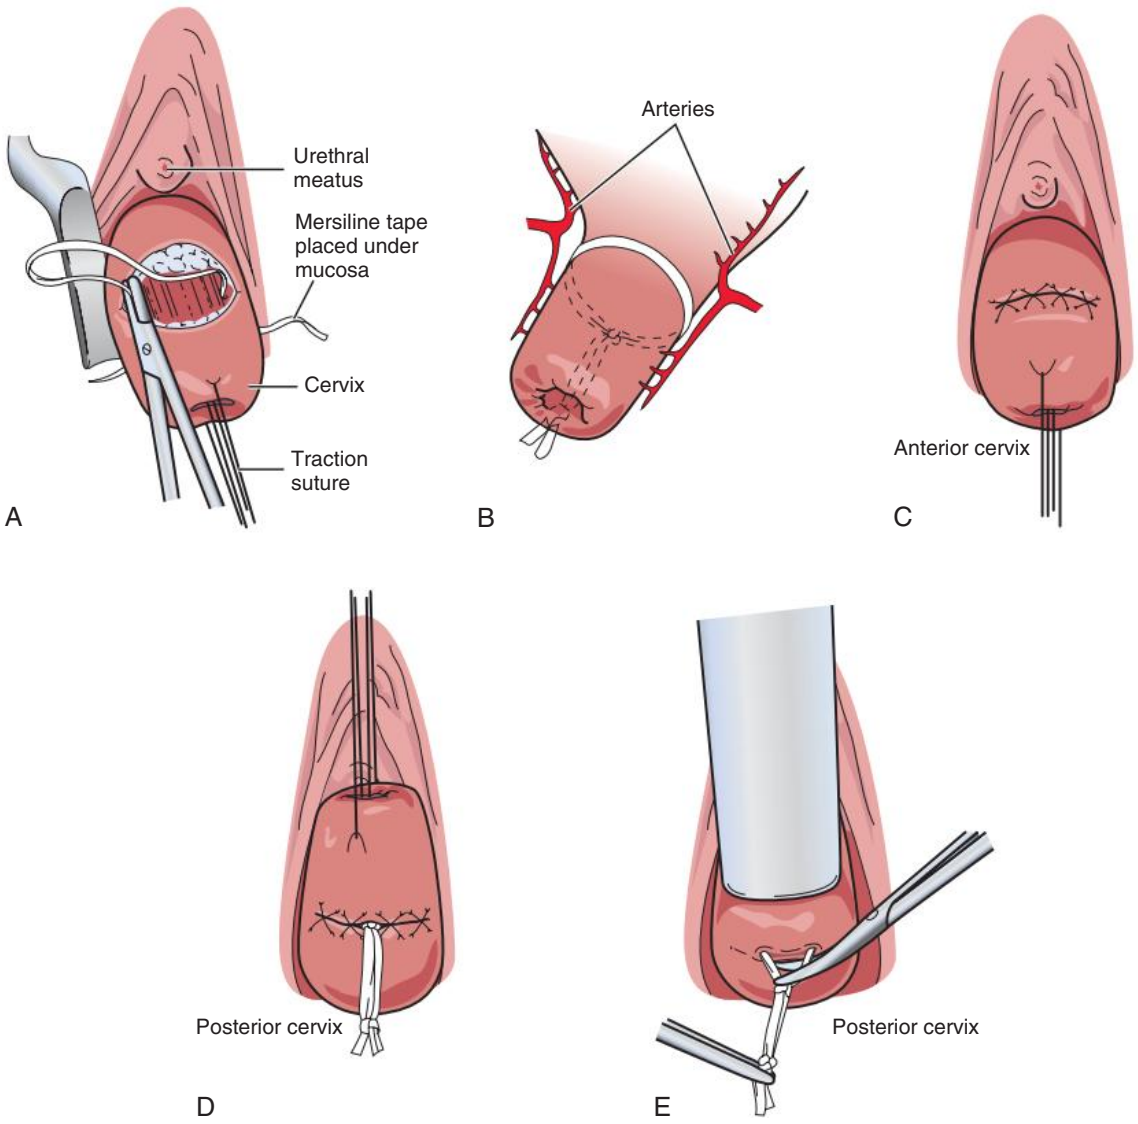
Cerclage is not usually performed after 26 weeks' gestation because the cervix is often too short to support suturing. Most cerclage is performed as an ambulatory procedure.

Occasionally, cerclage may be performed as an emergency procedure when the cervix is dilating and membranes are bulging, as long as the membranes have not ruptured or premature labor has not begun. The patient is placed in a deep Trendelenburg's position to take the uterine pressure off the cervix. No vaginal prep is performed, to prevent accidental rupture of the membranes. It may be necessary to simultaneously perform transabdominal amniocentesis to decompress the membranes for the cerclage procedure. A sterile amniocentesis set up will be required.

General anesthesia is commonly used to provide relaxation of the uterine muscle. Cerclage is contraindicated in active infection, ruptured membranes, bleeding, or active labor. Cerclage is performed with ligature tape and a suture passer (Fig. 34.18).

Rarely, transabdominal cervicoisthmic cerclage (TCIC) may be performed as an open pelvic procedure for patients who have had severe cervical lacerations, congenital malformations of the cervix, or multiple failed cervical cerclage procedures. In some patients, laparoscopy is used for cervical banding to support the uterus for a pregnancy.

TCIC can be performed as early as 11 weeks' gestation after ultrasonographic documentation of a viable pregnancy. A 5-mm Mersilene tape is sutured around the cervical isthmus in an avascular plane. This procedure has been successful in preventing pregnancy loss characterized by painless cervical dilation and pregnancy loss during the third trimester.



• **Fig. 34.19** Steps in the Shirodkar Procedure for Closure of an Incompetent Cervix. **A,** A ligature is placed below the mucosa circumferentially around the neck of the cervix. **B,** The uterine arteries are preserved and the ligature is tied on the posterior aspect of the cervix. **C,** The mucosal tissue is approximated with absorbable suture. **D,** A short length of ligature tape is left in place as a grasping tail. **E,** At term the ligature tape is clipped to permit the cervix to open for the delivery of the fetus.

Shirodkar Procedure

A small incision is made in the anterior vaginal mucosa at the level of the bladder reflection and at the posterior cervix–cul-de-sac junction (Fig. 34.19). A tunnel under the cervical mucosa is then made to join the anterior and posterior incisions. A polyester (Mersilene) tape is drawn around the internal os and tied. The knot is secured posteriorly to prevent erosion into the bladder. The suture tail is cut long so it can be located and released at 37 to 38 weeks' gestation or if active labor begins (before delivery). Mucosal incisions are closed. A cesarean section may be necessary at term.

McDonald Procedure

The polyester suture tape is placed around the cervix with a circumferential running stitch without mucosal dissection. Cervical scarring is less, and the procedure is quicker to perform. The tape can be removed at term for vaginal delivery.

Aborted Pregnancy

Termination of pregnancy may be spontaneous or induced. The procedure will depend on the gestational age of the fetus. Ultrasonography may be used to determine the stage of intrauterine pregnancy and the implantation site of the placenta.

Some patients are psychologically repulsed by the word **abortion**. They may associate the word with elective termination (elective voluntary abortion) regardless of natural causes or therapeutic need. Religious or personal beliefs may influence decision making about a pregnancy that cannot continue to full term. In some circumstances the patient may accept and understand the word *miscarriage* and feel freer to select appropriate treatment options without fear of reprisal or rejection.

Consideration for the support of psychologic coping mechanisms of the patient in crisis is more important than using absolute words such as *abortion*. Females with Rh-negative blood types

are candidates for immune globulin (RhoGAM) injections to prevent sensitization from the potentially Rh-positive fetus and complications with other pregnancies.

Suction Curettage

Intrauterine contents can be aspirated for **elective abortion** or for **incomplete abortion** (spontaneous abortion) within the first 20 weeks of pregnancy.

Uterine Evacuation

A small, flexible plastic tip or cannula is inserted into the uterus in the first 8 weeks of pregnancy. Suction created by drawing back on the plunger of a large syringe attached to the cannula is sufficient to evacuate the contents of the uterus. Disposable equipment for suction curettage not requiring dilation or anesthesia is commercially available.

Dilation and Evacuation

For pregnancies of 8 to 16 weeks' duration, dilation and evacuation (D&E) must be performed. Cervical dilation is adjusted to the stage of pregnancy and the necessary cannula. A laminaria tent (i.e., a cone-shaped expansion plug) may be inserted preoperatively to gradually dilate the cervix, usually for 4 to 24 hours. Dilation with the laminaria, which is removed before the procedure, is gentler than instrument dilation, which can cause cervical tearing. Some instrument dilation may be necessary.

A vacuum aspirator–cannula is inserted into the uterine cavity and connected by tubing to an adjustable electric vacuum pump. With gentle suction, the uterine contents are collected in a vacuum canister. Additional curettage with uterine curettes may be necessary to completely remove the remaining uterine contents (**retained secundus**). The curetted contents are sent to the pathology department for gross examination. After an incomplete spontaneous or **missed abortion**, it is vital to remove all retained products of conception to prevent infection, especially from anaerobic bacteria, which may progress to septic shock.

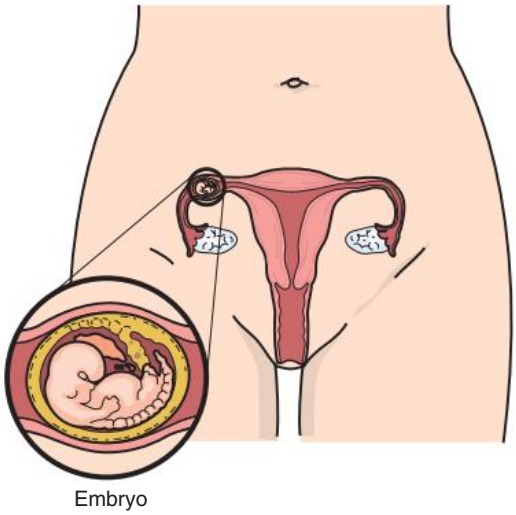
A D&C setup and suction curettage are used. The tissue is sent for culture and pathologic examination. Some patients may request baptism of an aborted fetus for religious reasons. Perioperative personnel may perform this function or request hospital clergy to assist. This has deep meaning for many patients.

Ectopic Pregnancy

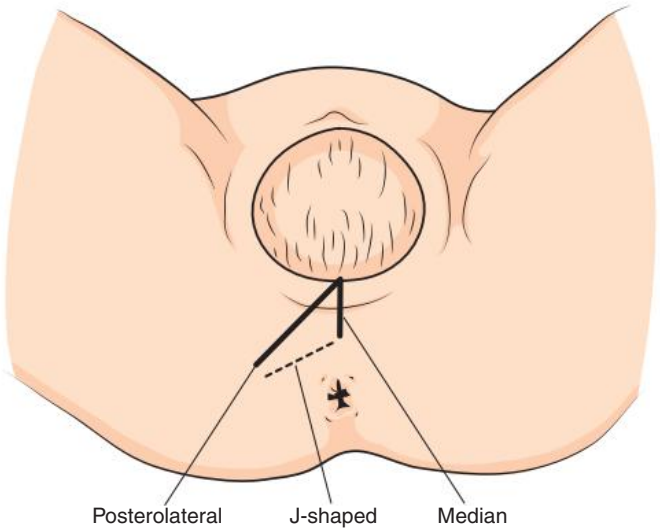
A fertilized ovum may become implanted outside the uterine cavity. Referred to as an **ectopic pregnancy**, rarely does this fetus develop to full term. This type of pregnancy usually involves the fallopian tube (95%) but can develop in the uterine cervix, on the ovary, or intraabdominally (Fig. 34.20).[5]

Symptoms of ectopic pregnancy are irregular growth patterns of the uterus, abdominal pain, and vaginal bleeding. Diagnosis is made by ultrasonography, by laparoscopy, or by detection of blood in the cul-de-sac by aspiration. Hemorrhage results from extensive trauma to the tube and mesosalpinx. The patient often goes into severe shock. Immediate surgical intervention is necessary.

Ruptured ectopic pregnancy is a true obstetric-gynecologic emergency. The affected tube is opened, and the products of conception are removed; hemostasis is attained; and the pelvic cavity is irrigated. The surgeon may attempt to repair the affected tube. Removal of the associated tube and possibly the ovary depends on the extent of damage from the rupture.



• **Fig. 34.20** Ectopic pregnancy.



• **Fig. 34.21** Episiotomy.

If an ectopic pregnancy is diagnosed by ultrasound or laparoscopy before rupture, conservative surgery may be able to restore fertility. Tubal pregnancy can be removed through a linear salpingostomy or by segmental resection, followed by tuboplasty. Laparoscopic techniques may be used. Some ectopic pregnancies can be managed through a vaginal colpotomy incision or abdominal minilaparotomy.

Complicated Birth

Difficult Vaginal Delivery

Routine episiotomy allows for vaginal delivery in some parturient mothers (Fig. 34.21). The obstetrician uses scissors to cut the vaginal outlet to make room for the presenting part of the fetus. An episiotomy helps prevent lacerations into the rectum or urethra that could later develop into a fistula. Perineal tears can still happen, and the team needs to know how to assist with repairs. Complicated deliveries can include a torn cervix that later requires surgical reconstruction. If the obstetrician suspects a potential complication, the surgical team will be set up and on standby.

Placental Problems

Placental implantation problems can complicate birth. The placenta normally implants into the inner third of the myometrial layer and separates at the decidual layer during birth. Predisposition for implantation problems increases in patients with a history of previous placental problems, uterine deformity, or previous uterine surgery.[6,7] Improper placental implantation can be diagnosed with ultrasound.

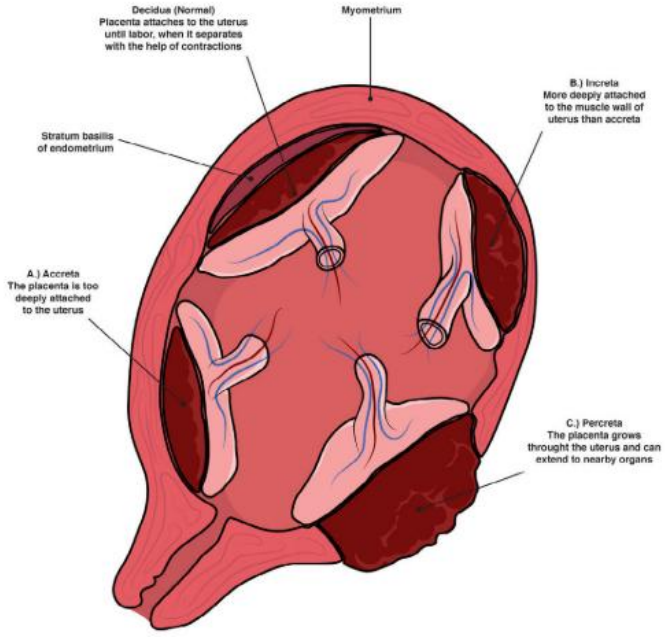
When the placenta implants improperly and the chorionic villi invade beyond the normal implantation depth, the placenta cannot separate during delivery. This is known as *placenta accreta*. Extremely deep implantation is known as *placenta increta*.[6,7] As the placenta tries to separate during delivery, there is uncontrolled maternal hemorrhage. Further complications arise if the placenta invades through the myometrium to the level of the serosa, which is known as *placenta percreta* (Fig 34.22)

The depth of placental implantation is negatively affected by uterine contractions. The blood supply to the placenta is impeded by myometrial compression during labor contractions, depriving the fetus of oxygen. Other organs, such as the bladder, can be affected by an invasive placenta. Placenta percreta can invade the bladder wall as it grows through the serosal layer of the uterus.

In severe cases the mother may present with intractable hemorrhage necessitating a cesarean hysterectomy to stop the bleeding. The team should have a cystoscopy setup available for the placement of ureteral catheters and inspect for bladder damage. The hysterectomy should be performed with the patient in the low lithotomy position for rapid access to the bladder with the cystoscope.

Difficulties arise when the uterus unexpectedly ruptures along a previous cesarean section (C-section) scar. The fetus is delivered as quickly as possible. If the bleeding cannot be controlled, the uterus can be removed totally or supracervically if the placenta has not invaded the cervical tissue.

Perimortem C-section (at the death of the mother after longer than 5 minutes) is not usually successful before 24 weeks' gestation. The surgeon may elect to try to save the fetus by immediately cross-clamping the aorta (to conserve placental blood) and quickly performing a hysterotomy for delivery.



• **Fig 34.22** Abnormal placental implantation that can cause serious hemorrhage during delivery and necessitate hysterectomy

Cesarean Birth

A cesarean section is a method of delivery by abdominal and uterine incisions. Cesarean delivery may take place in the labor and delivery department or in the OR. Pregnancy and labor produce many physiologic alterations. Both the mother and the newborn have specific needs requiring comprehensive care. To promote a positive experience, the perioperative team should be cognizant of these physiologic and psychologic needs and of the reasons for transabdominal delivery.

A C-section is a significant family event. Partners or support persons may be permitted in the OR, and mothers are given regional anesthesia and are usually awake.

The frequency of cesarean delivery is attributed mainly to diagnosis and management of uterine dystocia (ineffective labor), failure to progress, and fetal distress detected by fetal monitoring. A C-section is performed when safe vaginal delivery is questionable or immediate delivery is crucial because the well-being of the mother or fetus is threatened.

Indications for C-section include hemorrhage, placenta previa (low implantation), abruptio placenta (premature separation), invasive placenta (accreta, increta, or percreta), toxemia, fetal malpresentation, cephalopelvic disproportion (CPD), chorioamnionitis, genital herpes in the mother within 6 weeks of delivery, fetal distress, or prolapsed umbilical cord.[7] The multiparous pregnant patient who has had previous cesarean delivery may attempt vaginal delivery or may elect to schedule a planned cesarean birth.

Severe, unanticipated complications, such as bleeding or fetal distress during late pregnancy or labor, adversely affect the mother and/or fetus, creating an emergency. For these patients, preparations for immediate delivery are rapid. The patient easily senses a loss of control, especially if she participated in a childbirth education program for vaginal delivery. She needs special support. Most mothers fear more for the survival of the fetus than for themselves.

An elective patient is admitted the morning of surgery. The patient is taken to the delivery suite. An emergency patient will go directly to the delivery room from the labor area. The pediatrician and neonatal personnel from the nursery are notified before the procedure so they will be available to resuscitate and care for the infant in the delivery room. Sterile pediatric resuscitation equipment and supplies are made available.

Setup

Routine abdominal skin prep, draping, and setup are used for C-sections. Instruments are essentially those for a major gynecologic laparotomy with the addition of delivery forceps, a cord clamp, and a mucus aspiration bulb for infant suctioning on the field. A Foley catheter is inserted to decompress the bladder and monitor urinary output. The patient is placed supine with the right side of the OR bed elevated or a small pillow under the right hip to displace the uterus from the inferior vena cava.

All preparations are made for the setup before the anesthetic is administered to the patient. If regional anesthesia is planned, the setup, counts, and preliminary routines can be performed simultaneously with the anesthesia procedures. The patient is prepped, catheterized, and draped after the anesthetic has taken effect. If general anesthesia is to be used, the setup, prep, catheterization, and draping are performed before the anesthetic is administered to prevent prolonged depression of the fetus.

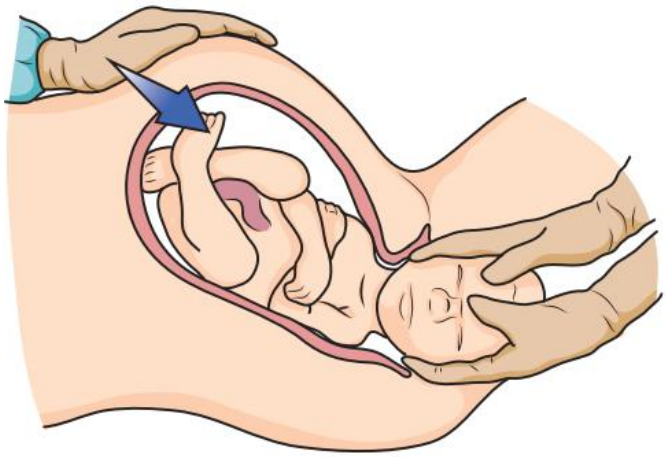
Incision and Delivery

A low transverse Pfannenstiel, or low midline vertical, incision is made in the skin and underlying tissue layers. The skin incision and uterine incision may be made in different anatomic planes.

The length varies with the size of the fetus. Dissection is expeditious. As the uterus is incised, the amniotic sac will be opened. The amniotic fluid will escape rapidly, requiring suction. Retractors are removed, and the fetal head or the presenting part is delivered as gentle fundal pressure is applied (Fig. 34.23).

The uterine incision is made by one of the following methods (Fig. 34.24):

- *Low transverse (Kerr incision)*. The bladder is dissected off the uterus and retracted gently downward. The lower uterine segment is entered through a low horizontal curvilinear incision. This approach causes less intraoperative blood loss and a decreased chance of rupture with subsequent pregnancies. Some patients will be able to have vaginal deliveries in future pregnancies.
- *Low vertical midline (Kronig incision)*. An 8-cm vertical incision is made in the lower uterine segment after the bladder is separated and retracted away. This incision is used when the fetus is small, preterm, and in the breech position. It is also used when cesarean hysterectomy may be performed after delivery.
- *Classic uterine incision*. The uterus is incised vertically above the attachment of the bladder. The bladder is not dissected off the lower uterine segment. This approach is rarely used but may be necessary for a fetus in transverse presentation or for multiple fetuses. It may be indicated for a low anterior placenta, varicosities of the lower uterine segment, or cervical cancer. A major disadvantage is the high incidence of rupture with subsequent pregnancy.



• **Fig. 34.23** Fundal pressure.

Immediately on emergence of the head, the nares and mouth are aspirated with a bulb syringe to clear them of amniotic fluid (Fig. 34.25). Newborns delivered by C-section have respiratory secretions. Delivery is completed, and the umbilical cord is double-clamped and cut between the clamps with sterile scissors. The newborn is transferred via a sterile sheet to the neonatal resuscitation team.

The circulating nurse or neonatal team member who receives the newborn should wear protective eyewear, a gown, and gloves until all blood and amniotic fluid are wiped off the infant. The risk for exposure to blood and amniotic fluid warrants the same adherence to standard precautions as with any other contact with blood and body fluids. The neonate is placed under a radiant warmer for resuscitation.

Oxytocin 10 to 20 units is administered IV to the mother to promote uterine contraction, minimize blood loss, and facilitate expulsion of the placenta and membranes. The placenta is delivered, visually inspected, and placed in a specimen basin. The uterine fundus is palpated for firmness and massaged as necessary to prevent hemorrhage from relaxation. Intrauterine injection of 10 units of oxytocin may be necessary to firm up an atonic uterus.

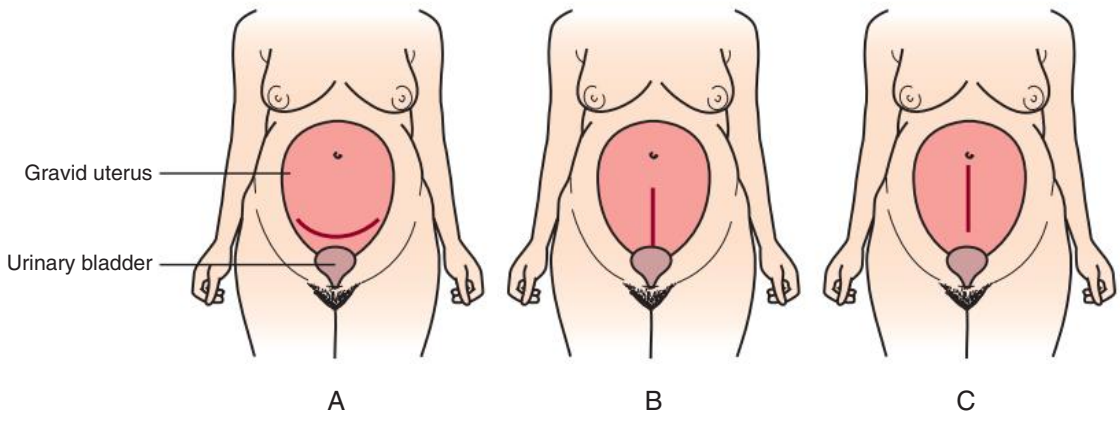
The patient is returned to a horizontal supine position. The uterine incision is closed in layers with absorbable sutures, and hemostasis is ensured.[8] Clots and excess intraperitoneal fluid are evacuated. After inspection of the pelvic organs and possible tubal ligation, the peritoneum and abdominal incision are closed.

Intraoperative assessment is the same as for any surgical patient. Sponges, tapes, and needles are counted before closure of the uterus and again before closure of the peritoneum, fascia, and skin.

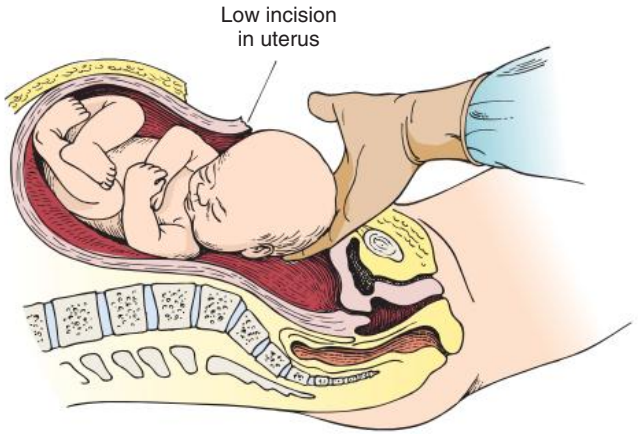
Postpartum surveillance of the patient is essential. Lochia is observed. Abnormal bleeding, such as rapid saturation of the perineal pad, is immediately reported to the physician and recorded. Nurses' notes should include the mother's contact with the infant, the mother's emotional reaction to the surgical procedure, and personnel in attendance, in addition to physical assessment data.

Neonate

Immediate postdelivery care is given in the OR by the neonatal team. The infant is taken to the nursery after careful examination by a pediatrician. The neonate traditionally has been evaluated by



• **Fig. 34.24** Uterine Incisions for Cesarean Birth. **A,** Low transverse Kerr incision is the most commonly used. **B,** Low midline Kronig incision may be used for smaller or preterm fetus. **C,** Higher midline incision is referred to as a classic C-section and is used only in extreme circumstances. This method has a higher incidence of rupture in subsequent pregnancies.



• **Fig. 34.25** Cesarean delivery after incising uterus and fetal membranes. As head is lifted through low uterine incision, pressure usually is applied to fundus of uterus through abdominal wall to help expel fetus.

the Apgar score, acid-base status, and neurobehavioral examination. The Apgar score, first published by American anesthesiologist Virginia Apgar (1902–1974) in 1953, is an excellent screening tool for vital functions immediately (at 1 and 5-minute intervals) after birth, but the subtle effect of drugs may be overlooked. The Neurologic and Adaptive Capacity Score does not use noxious stimuli but emphasizes neonatal tone. Drugs that will produce significant neurobehavioral changes in the newborn must be avoided during labor and delivery.

In the newborn the apical pulse is the most accurate. Oxygenation is extremely important. Hypoxia (too little oxygen) can lead to intracranial hemorrhage, brain damage, or necrotizing enterocolitis. Hyperoxia (too much oxygen), administered at a rate in excess of 40% concentration, can cause bronchopulmonary dysplasia or retrolental fibroplasia.

Father or Support Person in the Delivery Room

Paternal or support-person participation in the birthing process is well established for vaginal delivery to provide support to the mother, a family-centered birth, and immediate bonding with the infant. However, the presence of the father or support person in the OR during cesarean delivery is not universal and requires the surgeon's consent. Hospitals adopting this policy report favorable experiences. This person is informed of the conditions permitting and excluding his or her presence. Those who have attended a structured childbirth education course have more understanding of pregnancy and birth. In compliance with hospital policy, donning of OR attire and supervised handwashing with an antimicrobial soap before entrance to the OR are stressed.

The father or support person sits by the mother's head. He or she may accompany the infant to the newborn examining area after delivery. If the newborn and the mother's conditions permit, the father or support person may rejoin the mother in the OR for bonding.

Prenatal Testing

Potentially useful for management of some congenital developmental disorders or genetic defects, prenatal diagnostic studies are performed during pregnancy in select patients. Fetal anomalies are found in 2% of all women tested. Disorders in the fetus may be cause for induced abortion, elective cesarean delivery, or intrauterine fetal surgery.

Ultrasonography

Ultrasound is the standard tool for fetal imaging in utero. Ultrasonography, a noninvasive technique, permits accurate location of the placenta, determination of the gestational size of the fetus, assessment of fetal heart activity, and reliable diagnosis of structural defects (e.g., hydrocephalus, spina bifida). Other defects, such as missing limbs or conjoined twins, may be diagnosed.

Blood and Chorionic Villus Sampling

Ultrasound is also used for catheter or cannula guidance to obtain percutaneous umbilical blood samples or transcervical chorionic villus samples. Through direct fetal blood samples, anemia and some metabolic and chromosomal abnormalities can be diagnosed and treated in utero. Intravascular blood transfusions can be given to correct fetal anemia. Chorionic villi are a source of fetal genetic information. When obtained between the eighth and twelfth weeks of gestation, chorionic villi can aid in accurately diagnosing some enzymatic defects and in detecting the sex of the fetus.

Amniocentesis

Amniotic fluid is aspirated from the amniotic sac under ultrasound direction at 16 to 20 weeks' gestation for chromosomal analysis. This highly accurate test is indicated for known or suspected risk for chromosomal abnormality because of advanced maternal age, known parental translocation carrier, or a history of previous pregnancy with chromosomal defect in the fetus or infant. Maternal serum alpha-fetoprotein (AFP) measurement can predict neural tube disorders (e.g., myelomeningocele) or other defects in the fetus.

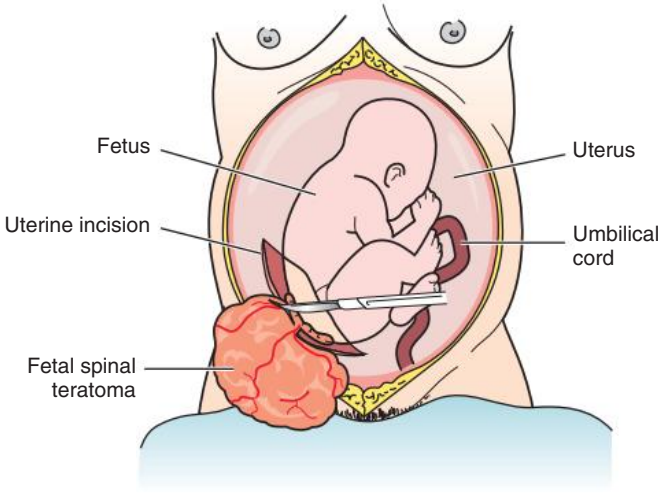
Fetoscopy

Fetoscopy permits direct visualization of the fetus. A fiberoptic needle scope (fetoscope) is inserted into the amniotic cavity to view fetal parts, to obtain a biopsy of skin, or to sample fetal blood. The fetoscope is 1.7 mm in diameter with a visual field of 70 degrees. To ensure an adequate volume of amniotic fluid, fetoscopy is done after 16 weeks of pregnancy. Because of the intent to view specific structures, the position of the fetus must first be determined and the procedure performed under sonographic-assisted visualization.

Placental localization is important, especially in the area of umbilical cord insertion. Hemoglobinopathies and coagulation problems (e.g., hemophilia) may be rapidly diagnosed by aspiration of fetal blood from the placenta or umbilical cord. Congenital skin disorders and albinism may be detected through biopsy. Direct viewing of the fetus may reveal characteristic abnormalities of various congenital syndromes. The procedure is not without complications and should be performed only by trained physicians when genetic information is critical.

Intrauterine Fetal Surgery

Improvement and expansion in prenatal diagnosis have led to rapidly developing antenatal surgical intervention–intrauterine fetal surgery. Diagnostic screening by ultrasound, AFP, or some other method during gestation reveals abnormalities heretofore diagnosed after delivery. Some disorders can be treated in utero. Other conditions fall within the province of the surgeon. Prerequisites for fetal therapy include accurate diagnosis, known pathophysiology, workable treatment, and technical capability. Fetal surgery teams are composed of radiologists, perinatologists, pediatric surgeons, anesthesia providers, obstetric nurses, perioperative nurses, and surgical technologists.



• **Fig. 34.26** Intrauterine fetal surgery.

Most correctable malformations may be detected in utero but are best remedied by a surgical procedure after delivery at term. A full-term infant is a better surgical risk than is the fetus. Surgical treatment in utero is reserved for fetuses in whom continuing organ development could be normal if surgically treated (e.g., diaphragmatic hernia, spina bifida, tracheal stenosis, hydronephrosis caused by urinary tract obstruction).

Minimally invasive procedures facilitate the placement of shunts and catheters. Highly invasive procedures require hysterotomy (opening of the uterine wall) (Fig. 34.26). Preoperative preparation includes the administration of tocolytic drugs (indomethacin suppository) to prevent the onset of labor caused by uterine manipulation. An irritable uterus requires cancellation of the procedure.

The procedure is performed in the late second trimester with the patient under general anesthesia, using isoflurane because it is considered less hazardous to the fetus.

The uterus is exposed through an abdominal incision, and a cannula is inserted through the uterine wall to decompress some of the amniotic fluid. The uterine anterior fundal incision is carefully extended down to the amnion. The sac is opened, and the edges are secured to the uterine edges with Raney clips. Meticulous hemostasis is necessary. ESU use is avoided. Small doses of fentanyl and pancuronium are administered to the fetus for anesthesia. A sterile pulse oximeter and electrocardiographic (ECG) leads are sutured to the fetus to monitor oxygenation and cardiac activity.

Great care is taken to avoid manipulation of the placenta or cord. Warmed sterile saline irrigation is continuously perfused through the amniotic cavity during the procedure. After the repairs are complete, a small, wireless transducer is placed in the fetal chest for continued postoperative monitoring of the fetus in utero. This transducer is removed after birth. If fetal repairs require thoracotomy and diaphragmatic patching, the pleural space is maintained with warmed lactated Ringer's solution to allow for continued lung growth.

On completion of the procedure the amnion is sutured closed and fibrin glue is applied. The uterus is sutured, and the abdominal incision is stapled. The fetal wound healing is nearly scarless because of decreased inflammatory response and neotissue generation associated with continued fetal development. The pregnancy continues as long as possible after the open procedure, preferably to a minimum of 32 to 36 weeks' gestation. Lung maturity is the key issue for success.

Preterm labor usually precipitates cesarean birth. Vaginal delivery is contraindicated because a classic uterine incision of the fundus is used for open intrauterine fetal surgery and may predispose the uterus to rupture during contractions.

Assisted Reproduction

Infertility, the inability to conceive a child after a year or more of repeated attempts, can be emotionally devastating. Both partners undergo extensive testing to determine possible organic or functional causes. These may include a structural defect in either partner, past or present infections, genetic and/or immunologic abnormalities, or an endocrine imbalance or deficit. In the woman a hostile cervix, antibodies to sperm, endometriosis, or exposure to DES in utero may prevent conception.

Tubal occlusion is the most frequent cause of infertility. A male partner may have an inadequate number, quality, or mobility of sperm or an absence of live spermatozoa in semen. When conventional infertility therapy has failed to produce a pregnancy, other options are available to assist in achieving pregnancy and birth of a mature, live infant.

In Vitro Fertilization

The term *in vitro* means "in glass." Fertilization literally takes place in a culture dish or test tube. In vitro fertilization (IVF) refers to removal of ova from the prospective mother via endoscopy, fertilization with the husband's or a donor's sperm, and incubation in the laboratory with subsequent embryo transfer to the uterus. Ovulation may be stimulated by administration of hormones. Multiple follicles may mature, and several ova are procured. The first documented birth from IVF and embryo transfer, performed by Dr. Robert Edwards and Dr. Patrick Steptoe, took place in England in 1978 by cesarean section. The first "test tube" baby has since grown and had a child of her own. The first IVF clinic in the United States using the Edwards-Steptoe method was established in Virginia in 1980.

IVF is most successful in women younger than 30 years. In women younger than 34 years, the success rate is 30% to 40% for delivery per ovum retrieval. The success of this technology for pregnancy in women older than 42 years is less than 10%. However, reports of a live birth by this method to a woman 60 years of age are found in the literature.

Patient Selection

IVF is accepted therapy for women with severely damaged or nonfunctioning fallopian tubes, for men with scarce or absent sperm, or for infertility of unknown cause. Contraindications include a uterine myoma, single uterine cornu, or bicornate or septate uterus. The woman is evaluated preoperatively for a normal uterine cavity, an accessible ovary, and evidence of ovulation. These parameters are measured by pelvic ultrasonography and serum estrogen levels. A laparoscopy, endometrial biopsy, and hysterosalpingogram may be part of preoperative testing. Semen analysis is done to check the sperm condition and count of the male partner.

Some patients may be unable to provide an ovum, conceive, or carry a fetus to full term. In select situations a surrogate mother will carry the developing fetus to term, surrendering the neonate at birth to the adoptive mother. Family members, such as a sister

or other, may participate. Ethics and legal issues surround this event. Patient confidentiality is protected.

Induction of Ovulation

IVF is coordinated with timing of the ovulatory cycle. The medical protocol is prescribed for the individual couple. From day 2 or 3 of the menstrual cycle through day 6 or 7, the woman takes fertility drugs to stimulate growth and maturation of ovarian follicles. These drugs are a combination of clomiphene citrate (a synthetic hormone) and human luteinizing and follicle-stimulating hormones. Follicular growth is monitored daily, beginning about the eighth day, by ultrasonography and serum estrogen levels. The fluid-filled follicles on the surface of the ovaries contain ova (oocytes). When follicles reach a diameter of 15 to 20 mm, the woman is given human chorionic gonadotropin (HCG) intramuscularly to stimulate maturation of the ova.

Ovum Retrieval

The patient is scheduled for retrieval of mature ova about 35 hours after HCG injection. Ovum retrieval may be accomplished through ultrasound-assisted transvaginal, transvesical, or transabdominal approaches. The procedure is performed with the patient under general anesthesia or IV sedation. Transvaginal ovum retrieval is the procedure of choice, but the approach depends on accessibility of the ovary.

With the patient in the lithotomy position, the ultrasound probe with an aspiration needle guide attached is advanced through the cervix, uterus, and fallopian tube to the ovary. The needle guide is directed toward the follicle, as seen on a monitoring screen. The follicle is punctured with a 14-inch × 17-gauge needle. Follicular fluid is aspirated into a 5-mL syringe. Ova procured from the graafian follicle are placed in sterile solution designated by the treating gynecologist.

Extensive scarring in tubes may make ovaries inaccessible via the transvaginal approach. For a transvesical approach the ultrasound probe is inserted through the urethra and posterior bladder wall to the ovary. With the patient positioned supine, a retrieval probe can be inserted percutaneously through the abdominal wall to reach the ovary in the pelvic cavity.

Ova can be retrieved by laparoscopy. The surgeon visualizes the ovaries. The follicle is punctured with an 8-inch × 14-gauge needle and aspirated directly into a test tube through a catheter attached to the needle. All instruments and solutions used for retrieval are kept at a normal physiologic temperature of 98.6° F (37° C). After completion of aspiration, the syringe or test tube is carefully handed to the circulating nurse using aseptic technique.

To avoid contamination, fluid should not be exposed to the environment, including light. Dimmed room light also enhances the surgeon's view on the video monitor. The circulating nurse labels the specimen and sends it immediately to the laboratory for confirmation of ovum retrieval while instrumentation is still in place. If the report is negative, the search for another ovum continues until the laboratory gives a positive response of retrieval. The procedure may be repeated on the contralateral ovary. Many surgeons prefer to retrieve at least three to five ova for fertilization. Other women can be suitable volunteer donors of ova for women who have been unable to provide a suitable ovum.

Fertilization

The aspirated ova are placed in a culture dish containing a nutrient mixture similar to tubal secretions at midcycle, which prepares the ova for fertilization. Fresh semen obtained an hour or so before the woman undergoes ovum retrieval, or previously collected frozen sperm from a partner or donor, is added. Care is taken to confirm identification of the ovum and sperm to prevent error.

The culture dish is incubated for 40 to 48 hours for fertilization to take place. Cell division is detected by microscopic examination. When the embryo reaches the 4 to 8-cell stage of development, it is ready for transfer to the uterus.

Multiple oocytes can be fertilized, and embryos can be stored frozen for a period of up to 3 years for later implantation if desired. Embryos frozen at the 2-, 4-, 8-, or 16-cell stage, after thawing, have a viability rate of 60% to 80%. The embryo is transferred during a natural ovulatory cycle for the best results.

Embryo Transfer

Approximately 48 hours after retrieval, the woman returns for embryo transfer. She is placed in the knee-chest position. Anesthesia is unnecessary. A catheter prepared in the laboratory, containing the embryo in culture medium, is inserted into the uterus. The patient remains in the knee-chest position for at least an hour to allow the embryo to gravitate to the upper uterine fundus. Immediately after embryo transfer, an injection of progesterone is given. Necessary for implantation, injections are given daily for the next 12 to 15 days. Implantation is necessary for progression of the cell mass to an embryo. The woman's own ovarian function sustains early gestation, as confirmed by ultrasonography.

Failure to implant may result from escape of the embryo from the uterus with removal of the catheter, excess uterine contractility, inadequate luteal phase affecting the endometrium, mechanical disturbance of the endometrium, or encapsulation of the embryo in blood or mucus.

Gamete Intrafallopian Transfer

The procedure for gamete intrafallopian transfer (GIFT), developed in 1984, is similar to IVF but is always done laparoscopically. The woman must have at least one patent, functional fallopian tube. Ovulation is induced as described for IVF. Laparoscopy is scheduled 34 or 35 hours after injection of HCG. Fresh semen is obtained from the partner at least an hour before this procedure and is centrifuged and incubated at body temperature until use.

Ovum retrieval via laparoscope is accomplished as described for IVF. The follicular fluid is sent immediately to the laboratory, where an embryologist selects two or three ova. These and the sperm, along with the culture medium, are loaded into a catheter and sent back to the OR. The surgeon passes the catheter through the laparoscope and injects fluid into the ampulla of the fallopian tube. One or both tubes may receive an injection.

Other procedures, such as laser vaporization of endometriosis or lysis of adhesions, may be performed while the surgeon waits for the catheter. Additional ova may be inseminated and cryopreserved for IVF if GIFT is unsuccessful. Many implants may precede conception; it may never be successful.

Artificial Insemination

In vivo fertilization by artificial insemination of sperm may provide a reproductive option for a fertile woman. Homologous insemination deposits the partner's sperm into the upper vagina, cervical canal, or uterine cavity. Whole ejaculate is used when the man is unable to deposit sperm into the partner's vagina because of psychologic or physiologic factors. Washed sperm are used for intrauterine injection. Semen or sperm may be frozen and stored in a sperm bank for future use if reproductive capacity is

threatened, such as by illness. Artificial insemination is coordinated with the recipient's ovulation for conception to occur.

Donor insemination involves the same techniques, but sperm are obtained from a donor. Donors are screened for STIs, including infection with human immunodeficiency virus (HIV) and hepatitis B virus (HBV). Genetic screening also may be required. Donor sperm may be sought when the partner has a genetically transmitted disease or defect. The couple may have concerns about donor selection.

Uterus Transplants

The first successful uterine transplants were performed in 2014 at the Sahlgrenska University Hospital in Gothenburg, Sweden, by Dr. Mats Brännström. Uterine transplants in humans became possible after 10 years of research using animals. The early studies concluded that living donors were preferred, because cadaver organs would possibly have a prolonged ischemic time. With the living donor the ischemic time was approximately 2.5 hours. With a cadaver uterus the ischemic time would be greater. The procurement and the transplant were performed simultaneously to minimize the time element.

Of the first nine women who received living donor uterine transplants, four of the recipients were successfully impregnated with previously frozen embryos from their own ova and husband's sperm. As of 2019, 12 babies have been born after uterine transplants. Ten babies were the result of living donor transplants, and two were cadaver donors. One of the women has successfully carried two pregnancies.

The original recipient women were O positive blood type and ranged from 30 to 36 years in age. They were categorized as "absolute uterine factor infertility" because they did not have a uterus. Most of the women were born with vaginal-uterine dysgenesis, and one had a hysterectomy for cancer in her twenties. The condition is known as Mayer-Rokitansky-Küster-Hauser syndrome (MRKH). The condition presents as a congenital absence of a uterus and in some cases the upper segment of vagina. Functional ovaries are present, but not located in the pelvis. They are located higher in the abdomen, having failed to descend during fetal development. Mature ova are retrieved transabdominally, fertilized in vitro, grown to a four-cell stage, and frozen in preparation for transfer to the transplanted uterus.

The donor organs were procured from family members in all but one case; the donor uterus used in the first birth was from a friend aged 61 years. The postmenopausal donor was given hormones to stimulate the endometrial lining in preparation for donation. Criteria for uterine donation include good general health, previous childbearing, nonsmoking, and appropriate tissue matching. The donation surgery can take 8 to 10 hours in some cases. The donated organs were taken complete with long pedicles of round ligament, sacrouterine ligament, paravaginal tissue, uterine arteries, and veins. There is no innervation of the transplanted uterus.

The implanted uterine vasculature was attached end-to-side with the internal iliac arteries and veins with 7-0 and 8-0 nonabsorbable monofilament suture. Perfusion was quickly evident. The ligamental tissue was secured for support. A tiny Doppler probe was attached to the uterine artery for postoperative monitoring of the blood supply. The end of the thin probe cable was exteriorized through the abdomen and was extracted by the third postoperative day. The recipient uterus transplant procedure took around 5 hours.

The recipients were given immunosuppressant drugs and seven of the nine uteri were still viable at 6 months after implantation. **Menstruation** began within 43 days in the first patient and began to regularly cycle within 3 months. The other recipients also began to have regular menstrual cycles. Periodic cervical biopsies were done to monitor the viability of the tissue. The first embryo was transferred 1 year after the transplant. Pregnancy tests returned positive 3 weeks after the first embryo transfer. Fetal heartbeat was present 2 weeks later.

Criteria for the uterus recipient patients include the informed consent that only one fertilized embryo will be implanted, only two pregnancies would be permitted per patient, the births would be by cesarean section 1 month preterm, and the uterus will be removed to prevent the need for long-term immunosuppression. Transplanted uteri are not considered a "life-long" organ, but rather a temporary means to have a baby when absolute uterine factor infertility is the diagnosis.

Nonobstetric Surgical Procedures and the Pregnant Patient

The pregnant surgical patient who is brought to the OR for reasons other than childbirth presents a unique challenge to the perioperative team.[3] The plan of care includes consideration for two patients: the mother and her developing fetus. The effects of surgical intervention can be disastrous to a pregnancy, but in some situations it is necessary to save the mother and/or the fetus. A developing fetus is intolerant of hypovolemia and hypoxemia. These considerations apply to all pregnant patients.

The average gestation, or duration of pregnancy, is 38 to 40 weeks, or 9 calendar months. This gestation period is divided into trimesters (3-month segments). Each trimester represents a specific developmental and viability concern (Box 34.1). Maternal anatomic and physiologic changes occur during each trimester of pregnancy (Table 34.3). Modifications to the plan of care vary according to these changes.

Risks associated with surgical intervention may be specific to the fetus. During the first trimester, spontaneous abortion of the developing embryo (until the end of the eighth week) or fetus (from the eighth week) can occur. Preterm labor and/or delivery may be precipitated during the second and third trimesters. The surgeon and anesthesia provider should discuss the risks, benefits, and potential outcome with the patient and her family.

Nonobstetric surgical procedures on pregnant patients are usually performed for an urgent or emergent reason, such as cholecystitis, appendicitis, or trauma. Urgent surgical procedures are delayed until the second or third trimester, if possible. Emergency procedures are performed immediately, regardless of gestational stage. If the maternal condition is critical, the primary concern is to save the mother. Elective surgical procedures should be deferred until after delivery of the neonate and when the anatomic and physiologic changes of pregnancy have returned to normal.

Anesthesia Considerations in Pregnancy

The surgeon and anesthesia provider collaborate closely because the risks of anesthesia and surgical procedures are high for both the mother and the fetus. Perinatal morbidity and mortality are affected by maternal health, fetal viability, the type of anesthetic, and the surgical procedure. The incidence of preterm labor, low birthweight, and fetal death increases if a general anesthetic agent

• BOX 34.1 Stages of Fetal Development and Viability Concerns

First Trimester (1-3 months, 1-12 weeks)

- Zygote implants in uterine wall by 14 days.
- Communication of venous sinus and arterial supply of maternal circulation is completed at 17 days.
- Teratogens can impair organogenesis until 14th week.
- Primitive placental system with umbilical cord is established by 7th week.
- Heart rate is detectable on ultrasound at 10-12 weeks.
- Facial features and external genitalia are present by 12th week.
- Crown-to-rump length is 6-7 cm by 12th week.

Second Trimester (4-7 months, 13-27 weeks)

- Arms and trunk grow rapidly.
- Little muscle tone.
- Scalp hair, tiny nipples, and external ears develop by 20th week.
- Meconium is present in intestine.
- Body weight is 300 g.
- Skeletal calcification is seen on x-ray.
- Sucks thumb and moves freely at will.
- Fetal heart rate is audible with fetoscope at 120-160 beats/min at 20th week.
- Fingertip pressure causes ballottement (fetal rebound) in amniotic sac during 16th-32nd week.
- Teratogens may cause minor structural and functional abnormalities, especially endocrine, brain, and special senses, from 10th week to term.
- Body is covered with vernix (gray-white cheeselike substance) and lanugo (soft, downy hair).
- Eyebrows and eyelashes are present.
- Body weight is 454-630 g (1-1.4 lb) by 24th week. May be viable.

Third Trimester (7-9 months, 28-38-40 weeks)

- Subcutaneous fat begins to develop.
- Crown-to-rump length is 25 cm.
- Testes are descended in males
- Body weight is 1100 g (2½ lb).
- Surfactant is present in alveoli of lungs by 28th week.
- Increased chance of survival.
- Body weight is 1361-1814 g (3-4 lb) by 32nd week.
- Body is fuller and rounded.
- Muscle tone is good.
- Less vernix and absence of lanugo by 36th week.
- Body weight is 3402-3629 g (7½-8 lb) by 38-40 weeks.
- Crown-to-rump length is 36 cm.

must be administered. The objectives of anesthesia management in the pregnant surgical patient include, but are not limited to:

1. *Maternal safety:* The pregnant patient always should be treated as if she has a full stomach. Nausea and vomiting are common and place the patient at risk for aspiration of regurgitated stomach contents during induction of anesthesia, intubation, and extubation. The condition of the mother directly affects the outcome of the pregnancy.
2. *Avoidance of teratogenic drugs:* Many anesthetic drugs cross the placenta and enter the fetus through the uteroplacental circulation. Some drugs that adversely affect the fetus during the first trimester are nitrous oxide, halogenated agents, sedatives, tranquilizers, antidepressants, and amphetamines.
   - Halogenated agents and nitrous oxide have been given without teratogenicity in emergency situations during the second and third trimesters. Only short-acting drugs should be used. The fetal liver is immature and metabolizes tranquilizers and other narcotics slowly. Neonatal respiratory depression is common if these drugs have been used.
   - Agents used in local and regional anesthesia have not shown teratogenicity in animal studies and may provide a safer anesthetic alternative than those agents used for general anesthesia when a surgical procedure must be performed.
3. *Prevention of fetal asphyxia*. Maternal hypoxia rapidly affects the oxygenation of the fetus. The oxygenation capability depends on the hemoglobin content and arterial oxygen tension of maternal blood and uteroplacental perfusion. Maternal hypotension and decreased uterine blood flow cause fetal hypoxia.
4. *Prevention of preterm labor*. Studies have shown no association of any single anesthetic agent with an increase or decrease in preterm labor. Manipulation of the **gravid** uterus can cause preterm labor. The use of halogenated agents in advanced pregnancy decreases uterine tone and prevents uterine contractions. Vasopressors and drugs used to reverse muscle relaxants may stimulate the uterus to contract and initiate preterm labor.

Special Considerations

Intraoperative Care of the Pregnant Patient

Both the mother and the fetus should be monitored during the surgical procedure. The mother's physiologic and psychologic condition rapidly affects the well-being of her fetus. Changes in the fetal condition may be the first indicators of a physiologic change in the mother. Intraoperative care and monitoring of the pregnant surgical patient include special considerations regarding the following objectives:

1. *Minimize the patient's time under anesthesia*. Skin preparation and draping should be done before induction of general anesthesia. Devices for electronic fetal and uterine monitoring should be in position and in proper working order.
2. *Monitor maternal oxygenation*. Pulse oximetry is useful for noninvasive measurement of oxygenation in hemoglobin. Readings should remain above 94% to prevent fetal hypoxia. Continuous oxygen is usually administered.
3. *Monitor the fetal heart rate*. An electronic fetal heart monitor (EFM) should be used by appropriately trained personnel for continuous monitoring. Fetal tachycardia may be the first indicator of maternal hypoxia. EFM is most effective after 16 weeks' gestation. Personnel qualified in EFM should be assigned this role.
4. *Monitor the uterine tone*. The uterus should be palpated frequently during the surgical procedure to detect contractions. Uterine manipulation, bladder stimulation, and several anesthetic drugs may cause preterm labor.
5. *Prevent aspiration*. Assist the anesthesia provider during intubation by providing cricoid pressure (Sellick's maneuver) as directed.
6. *Prevent maternal hypotension*. If the uterus is enlarged to the level of the umbilicus or above (17 to 20 weeks' gestation), place a small pad or folded sheet under the right hip to laterally displace the uterus to the left. This redistributes the weight of the gravid uterus off the vena cava and abdominal aorta and facilitates a normotensive state. Renal perfusion is also improved.
7. *Monitor urinary output.* Minimum urinary output should be 25 mL/hr. Palpate the bladder every 30 minutes. Bladder distention can cause uterine irritability and preterm labor. The bladder is displaced above the pelvis during the second and third trimesters and is easily injured. An indwelling Foley catheter should be inserted if the surgical procedure is anticipated to exceed 1 hour.

TABLE 34.3 Maternal Anatomic and Physiologic Changes of Pregnancy

System	First Trimester (1-3 Months, 1-12 Weeks)	Second Trimester (4-7 Months, 13-27 Weeks)	Third Trimester (7-9 Months, 28-38-40 Weeks)
Cardiovascular	Cardiac output begins to increase at 6th week.	Cardiac output increases 30%-50% by 16th week.	Cardiac output decreases slightly by 30th week.
	Plasma volume begins to increase.	Plasma volume continues to increase. Hypervolemic and hemodiluted.	Plasma volume increase peaks 50% at 32-36 weeks.
		Red blood cell (RBC) production increases 20%. White blood cell (WBC) production increases 30%-40%.	RBC increases, peaks at 33%.
	Breast veins dilate.	Capillary engorgement can cause epistaxis (nosebleeds) and epulis (bleeding gums).	May develop hemorrhoids, varicosities in leg veins. Increased risk for venous thrombosis.
	Vasculature increases to vulva and vagina.	Heart rate increases 15-20 beats/min.	Factors VII, IX, X increase, causing hypercoagulative state. Plasma fibrinogen increases 40%-50%.
		Slight hypotension caused by decreased peripheral vascular resistance.	Normotensive by 26th week
		Uterus presses on vena cava when supine.	Uterine circulation is 1 L/min by 38th-40th weeks.
		Physiologic anemia: hemoglobin, hematocrit, and platelets decrease.	
Pulmonary			
Lung compliance and pulmonary diffusion remain constant throughout pregnancy.	Vital capacity and partial pressure of oxygen (Po_2) are unchanged.	Diaphragm is displaced upward by rising fundus; thoracic circumference increases by 6 cm.	Diaphragm is displaced 4 cm by rising fundus; thoracic breathing replaces abdominal breathing.
		Tidal volume increases 30%-40%.	Venous stasis increases risk for thrombus formation and pulmonary emboli.
		Respiratory rate increases 15% to accommodate increasing metabolism.	
		Mild dyspnea. Chronic state of compensated respiratory alkalosis.	
		Nasal congestion caused by estrogen-induced edema.	
Gastrointestinal	Nausea and vomiting.	Nausea and vomiting diminish.	Gastric emptying time is decreased.
	Constipation.	Incidence of cholecystitis is increased.	
	Salivation increases.	Progesterone causes decreased gastrointestinal motility. Esophageal sphincter tone is decreased; at risk for gastric reflux.	Gallbladder sluggish, gallstones frequently develop.
Neurologic	May feel some slight Braxton Hicks contractions starting at 8th week.	Intraocular pressure decreases. Some temporary visual changes develop; vision returns to prepregnant state after delivery.	Braxton Hicks contractions increase and become regular.

Continued

TABLE 34.3 Maternal Anatomic and Physiologic Changes of Pregnancy—cont'd

System	First Trimester (1-3 Months, 1-12 Weeks)	Second Trimester (4-7 Months, 13-27 Weeks)	Third Trimester (7-9 Months, 28-38-40 Weeks)
Endocrine	Human chorionic gonadotropin hormone secreted by corpus luteum of ovary is present in serum 9 days after conception.	Protein binding causes increase in circulating hormones. Thyroid and adrenal hormone levels are elevated. Insulin production increases.	Prolactin increases and peaks at delivery.
	Progesterone production increases.	Erythropoietin increases by 20th week.	
	Basal metabolic rate decreases. Blood glucose level decreases.	Metabolism increases.	
Genitourinary			
Ureters and renal pelves and calyces dilate, increasing risk for urinary tract infection. Dilation is present throughout pregnancy.	Urinary frequency is caused by uterine pressure on bladder.	Bladder pressure decreases as fundus elevates. Bladder is displaced superior to pelvis.	Lateral position facilitates renal blood flow and increases urinary output.
		Glomerular filtration rate increases 30%-50%. Drugs are excreted faster.	Frequency is increased as presenting part enters pelvis.
Integumentary	No appreciable change.	Striae gravidarum (stretch marks) appear on breasts and abdomen.	Dark line (linea nigra) appears between umbilicus and pubis.
			Increased pigmentation of face (chloasma).
Musculoskeletal	Feels fatigue.	Feels energetic.	Energy declines.
	Weight loss first few weeks caused by nausea and vomiting. Average weight gain 2.2 lb (1 kg) by 10-12 weeks.	Weight gain 1 lb (0.45 kg) per week; desirable weight gain between 12th and 20th week is 8 lb (3.62 kg). Gains 0.5-1 lb (0.24 kg-2.2 kg) per week between 20th and 38th week.	Ideal weight gain 25-30 lb (11-13.6 kg) total for entire pregnancy.
		Progressive lordosis to compensate for shifting center of gravity causes backache.	Increased lordosis as uterus expands and protrudes forward.
	Leg cramps.	Leg cramps increase by 24th week.	Pelvic joints relax, and slight separation of symphysis pubis can be seen on x-ray.
Reproductive	Menstruation ceases.	Uterine fundus elevates halfway between symphysis pubis and umbilicus by 12th-16th week but rises above umbilicus by 24 weeks.	Uterine fundus elevates halfway between umbilicus and xyphoid process by 28th week and reaches xyphoid by 32nd week. Fundus decreases in height (caused by uterine weight) by 38th week. Uterine weight at term is 1100 g.
	Progesterone causes uterine lining to thicken.	Fetal movement is felt by 18th-20th week.	
	Estrogen causes uterine body to hypertrophy, anteflex, and become globular; by 3rd month, fundus reaches pelvic brim.		
	Cervix softens, and vulva and vagina appear blue (caused by increasing vascularity). Vaginal discharge increases.	Lower uterine segment elevates in pelvis.	
	Breast tissue enlarges and becomes sensitive.	Areolae darken.	Breasts feel full and tender. May secrete colostrum (precursor to milk).

8. *Maintain a normothermic environment*. Warm the room to 75° F (24° C) and maintain a consistent temperature during the surgical procedure. Maternal hypothermia causes decreased uteroplacental perfusion and can cause fetal bradycardia. Use prewarmed blankets and irrigating solutions. Keep the mother's head covered.
9. *Prepare for emergency cesarean birth or preterm delivery*. In the event of untimely rupture of the membranes, preterm labor, or fetal distress, it may be necessary to perform a cesarean section or precipitous delivery in an effort to save a viable fetus. A preterm fetus requiring immediate delivery after 24 weeks' gestation or 1 lb (500 g) weight may be considered viable. Fetal viability is individualized by measurement of lung maturity, body weight, and ability to sustain life after removal from the uterus.
10. *Protect the fetus from hazards in the environment*. The pregnant uterus at any stage of gestation should be shielded from ionizing radiation. During the first trimester, radiation may cause teratogenic damage. This may be unavoidable in trauma surgery.
11. *Reassure the mother*. Explain that she and her fetus will be monitored closely and that they will be carefully protected.

Intraoperative Risks

The enlarging uterus displaces abdominal organs and distorts anatomic landmarks, making diagnoses of trauma or a pathologic condition complex. A motor vehicle accident (MVA) is a common cause of abdominal trauma. A seat belt (lap belt) without a shoulder restraint can cause compression injury to the enlarged uterus. Spontaneous laceration and/or rupture can occur. Peritoneal lavage, if used to assess for intraabdominal bleeding, should be done through an incision above the umbilicus to avoid injuring the uterus.

Surgical procedures for reasons other than trauma, such as pathologic causes, require careful differential diagnosis.[3] Anatomic and physiologic changes of pregnancy must be considered. For example, the appendix is displaced to the upper right quadrant and may mimic cholecystitis. In advanced pregnancy, chest drainage tubes should be inserted one or two intercostal spaces higher, if needed. Diagnosis is complicated because laboratory tests are altered by the progressing pregnancy and results vary according to the gestational stage.

Assessment of the patient's condition is difficult because compensatory mechanisms of pregnancy cause alterations in vital signs. The arterial blood pressure is lower than prepregnant values, and the pulse is elevated to accommodate an increase in circulatory volume. Decreased peripheral vascular resistance prevents overt physiologic signs of shock, such as cool, clammy skin.

Circulating blood volume can be reduced 30% to 35% before the patient shows any signs of hypovolemic shock, such as lowered blood pressure and increased pulse rate. In hypovolemic shock, blood is shunted away from the uteroplacental circulation at the expense of the fetus. The fetus becomes hypoxic. Fetal demise rate is 80% in maternal hypovolemic shock.

An EFM can detect early signs of fetal hypoxia and uteroplacental insufficiency. Use of a fetal monitor is recommended during surgical procedures after 16 weeks' gestation. Personnel appropriately trained in fetal monitoring should perform this assessment throughout the perioperative period, including during the surgical procedure and postanesthesia recovery.

In the immediate postoperative period the pregnant patient must be assessed for uterine irritability, vaginal bleeding, and/or ruptured membranes. Any combination of these signs may signal impending labor and possible preterm delivery and must be reported to the physician immediately. Bladder distention can cause uterine irritability and stimulate preterm labor. The bladder should be palpated frequently. A distended bladder is felt as a bulge above the symphysis pubis that is slightly cooler than the surrounding skin.

Psychologic Considerations

For most patients and their families, pregnancy is a time of joy and excitement. Their happiness is shattered when they are faced with the prospect of a surgical procedure and its inherent risks. In urgent and emergency situations the family has little time to adjust to the pending procedure.

The outcome is uncertain, and the risks to the mother and her fetus are great. The patient and family are also facing the possibility of a preterm delivery.

The perioperative team should consider the special needs of the pregnant patient and her family and provide as much reassurance as possible. Preterm emergent C-section after 25 weeks' gestation has a 45% fetal survival rate.

35 Urologic Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify the organs of the male genitourinary system.
- Compare the differences between male and female urinary systems.
- Describe the procedures performed for urinary incontinence.
- Describe the procedures performed for prostate cancer.

KEY TERMS AND DEFINITIONS

Diversion Redirection of urine flow into a neobladder or stoma.
Extraperitoneal Outside the peritoneal cavity.
Hemolyze Blood cells dissolve, releasing hemoglobin.
Hyponatremia Low salt concentration of the blood.
Impotence Inability to have an erection.
Incontinence Inability to control bladder or bowels.
Isosmotic Solution having the same osmotic pressure as blood.
Litho- Stone; calculi.
Meatotomy Incising the meatus (distal opening) of the urethra.
Neobladder A urine collection reservoir fashioned from a segment of bowel.
Neurogenic Caused by the nerves within the area. Loss of bladder control caused by nerve injury or malfunction.
Orthotopic Autologous tissue used to create a structure or a replacement structure within the body. Used here to describe the creation of a bladder reservoir from bowel tissue that communicates with the urethra.
Retroperitoneal Behind the peritoneal cavity.
Transurethral Through the urethral canal.

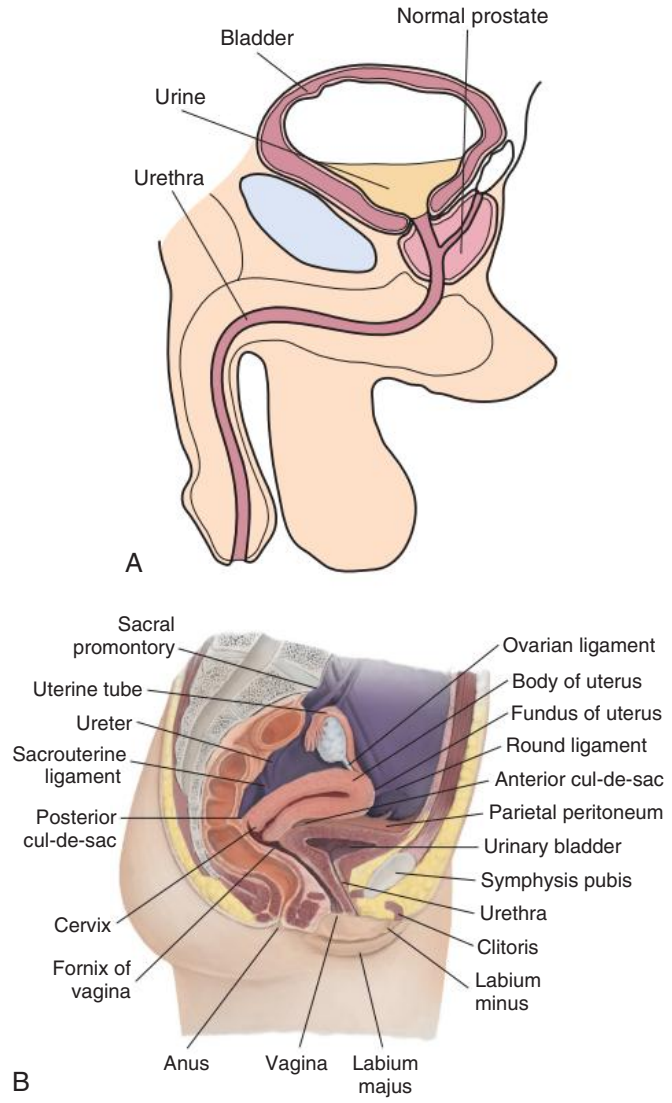
Anatomy and Physiology of the Urinary System

The urinary system provides the vital life-sustaining functions of extracting waste products from the bloodstream and excreting them from the body. Organs of this system include bilateral kidneys and ureters, the bladder, and the urethra (Fig. 35.1). An obstruction to blood flow in the renal arteries or any part of the urinary system can cause renal damage, which ultimately results in uremia (a biochemical imbalance) or renal failure if left undiagnosed and untreated. Vascular hypertension, hypotension, obstruction, tumors, infection, trauma, and other systemic or **neurogenic** disorders are of major concern to a urologist.

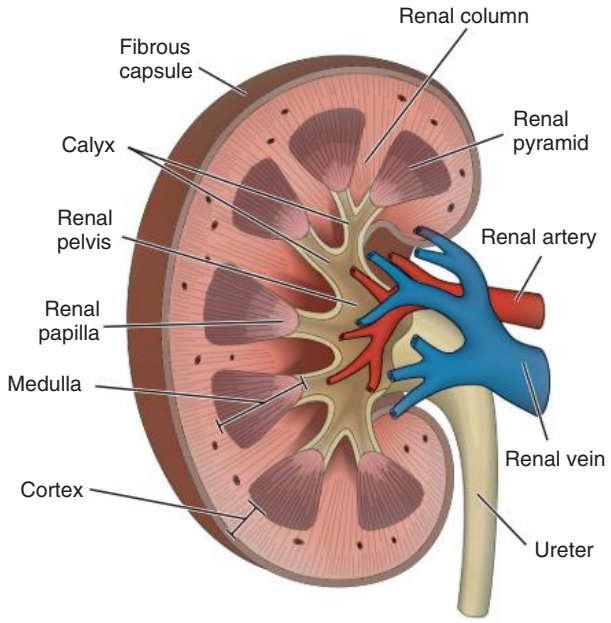
Kidneys

The kidneys are large, bean-shaped, glandular organs located bilaterally in the **retroperitoneal** space of the thoracolumbar region behind the abdominal cavity. The arterial blood supply (renal artery) of the kidney originates from the aorta and enters the hilum on the medial aspect. Venous drainage flows through the renal vein and into the inferior vena cava. The lymphatics drain into the lumbar nodes. Innervation is from the autonomic nervous system originating in the lumbar sympathetic trunk and vagus nerve.

Each kidney is enclosed in a thin, fibrous capsule referred to as Gerota's fascia. The renal parenchyma, the substance of the kidney within the capsule, is composed of an external cortex and internal medulla. The medulla consists of conical segments called renal



• **Fig. 35.1** Anatomy of the urinary tract. **A,** Male urinary tract. **B,** Female reproductive organs and urinary system. (*B,* From Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 5, St. Louis, 2007, Mosby.)



• **Fig. 35.2** Cross-section of the kidney. (From Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 5, St. Louis, 2007, Mosby.)

pyramids. Each pyramid and its surrounding cortex form a lobe. Within these pyramids are the essential components of renal function: the nephrons (Fig. 35.2). As the urine forms, it drips from the papillae at the tips of the pyramidal structures.

Ren is the Latin word for kidney—hence the adjective *renal* and combining forms of *ren-* and *reno-* in terms pertaining to the kidney as part of the renal system. The purposes of the kidney are as follows:

- To remove metabolic waste, excess substances, and toxic substances from the blood
- To regulate and maintain body fluid and pH balance
- To help regulate and respond to blood pressure by producing the hormone renin
- To produce the hormone erythropoietin to control the rate red blood cells are produced by the bone marrow
- To assist in the production of water-soluble vitamin D, which is important for the metabolism of calcium

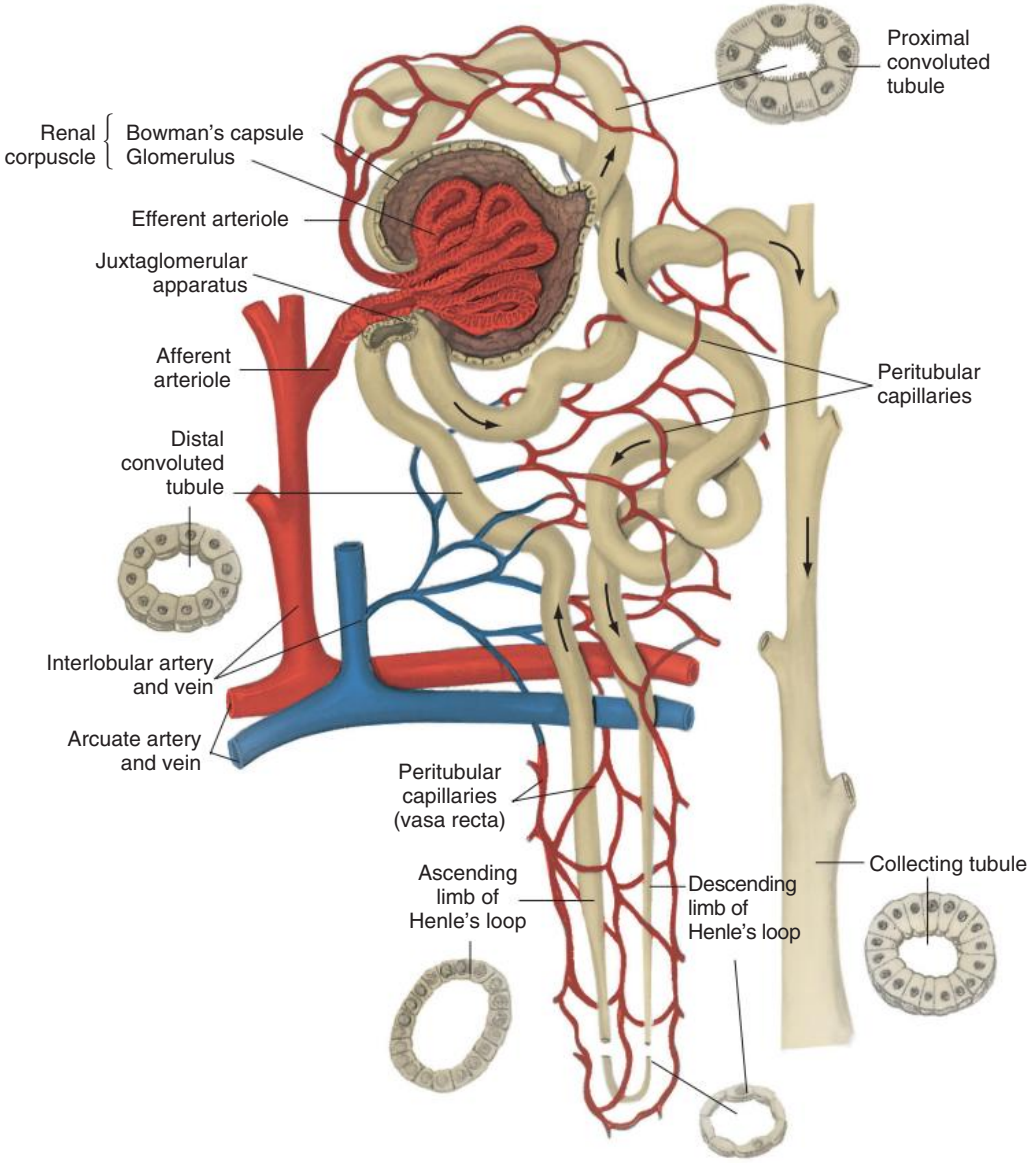
Each nephron consists of a glomerulus, glomerular capsule, and tubules. A glomerulus is an aggregation of capillaries formed by an afferent branch of the renal artery. These capillaries unite to form an efferent vessel. This capillary network is enclosed in a glomerular capsule (capsule of Bowman), which is the dilated beginning of the renal tubule. From the capsule, the tubule becomes tortuous and forms the proximal convoluted tubule. The distal portion forms the descending and ascending limbs of the medullary loop (loop of Henle) (Fig. 35.3).

Nitrogenous wastes, salts, toxins, and water filtered from the capillary network form urine, which flows through the medullary loop and into the collecting tubule. The collecting tubules converge at the papilla (apex) of each renal pyramid. Urine flows continuously from each papilla into a calyx. Each kidney has between 4 and 13 minor calyces that lead into 2 or 3 (rarely 4) major calyces that form the renal pelvis. The renal pelvis forms the dilated proximal end of the ureter.

Urine forms at the glomerulus by filtration. Hydrostatic pressure forces the plasma minus the blood cells and large molecules through the system. The amount of blood filtered is approximately 1700 quarts, from which is derived 200 quarts of filtrate. As this filtrate passes through the tubules, 99% of the water is resorbed and approximately 1 to 2 quarts of urine are produced. Cardiac function is closely related to the perfusion of the kidneys. Every time the heart beats a small drop of urine is formed. Cardiac failure leads to renal failure. Failure of both kidneys to function is followed by death within a few weeks.

Ureters

The ureters are connecting tubes between the kidneys and bladder; they are 4 to 5 mm in diameter, have a 0.2 to 1-cm lumen, and are approximately 12 inches (25 to 30 cm) long. They lie bilaterally beneath the parietal peritoneum and descend along the posterior abdominal wall to the pelvic brim. From there, they pass along the lateral wall of the pelvis and curve downward, forward, and inward along the pelvic floor to the bladder.



• **Fig. 35.3** Cross-section of the nephron. (From Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 5, St. Louis, 2007, Mosby.)

The wall of each ureter is continuous with the renal pelvis and is composed of mucous membrane, longitudinal and circular muscles, and an outer layer of fibrous and elastic tissue. Slow, rhythmic, peristaltic contractions carry urine from the kidneys to the bladder in response to filling of the renal pelves.

Urinary Bladder

The bladder is a hollow muscular reservoir lined with mucous membrane; it is located extraperitoneally in the anterior pelvic cavity behind the symphysis pubis. The ureters enter the bladder wall obliquely on each side. The triangular area between the ureteral and urethral orifices is called the *trigone*. Folds of mucous membrane in the bladder wall act as valves to prevent the backflow of urine into the ureters. Urine collects in the bladder until an autonomic nerve stimulus from the sacral reflex centers causes micturition (urination) through the urethra. This stimulus opens the muscle fibers that form an internal sphincter at the bladder neck, the vesicourethral junction.

The arterial supply of the urinary bladder is derived from the hypogastric arteries that branch from the internal iliac arteries. The venous drainage empties into the hypogastric veins. The lymphatics drain into the internal and common iliac nodes.

The autonomic innervation of the bladder controls filling and emptying of the bladder. The parasympathetic fibers from S3 to S5 promote emptying by contraction of the detrusor muscles. The sympathetic nerve fibers that originate from L1 to L2 cause relaxation of the detrusor muscles and closure of the internal urinary sphincter, allowing the bladder to fill. Somatic innervation of the external urinary sphincter responds to somatic fibers arising from S2-S4 and is voluntarily controlled to contract the musculature. Spinal cord injury at or below the level of L5 can result in inability to empty the bladder.

Urethra

The male urethra is approximately 25 to 30 cm long and has a diameter of 7 to 10 mm. It consists of two segments (proximal and distal) that are further subdivided into three segments referred to as the *prostatic*, the *membranous*, and the *cavernous* urethral segments. The proximal (posterior) prostatic urethra passes from the bladder orifice, through the prostate gland, and to the pelvic floor. The membranous urethra passes from the pelvic floor to the base of the penis. The distal (anterior) segment consists of parts of the membranous, bulbous, and anterior urethral segments that pass through the penis to the external urethral orifice at the meatus. The membranous and anterior urethras also serve as a passageway for secretions from the male reproductive system (see Fig. 35.1, *A*). The urethra is lined with urothelium that is continuous with the lining of the bladder.

The female urethra is approximately 3 to 5 cm long and 6 to 8 mm in diameter. It is firmly embedded posterior to the clitoris and anterior to the vaginal opening. The Skene glands are situated bilaterally near the opening of the urethral meatus. Females are predisposed to urinary tract infections because the urethra is anatomically located near the vagina and the anus, both of which have resident flora that can cause infection if introduced into the urethra. Mechanical injury during coitus and the use of a pessary for vaginal support or diaphragm for contraception may be contributing factors to chronic urinary tract infection (see Fig. 35.1, *B*).

Special Features of Urologic Surgery

Urologic Endoscopy

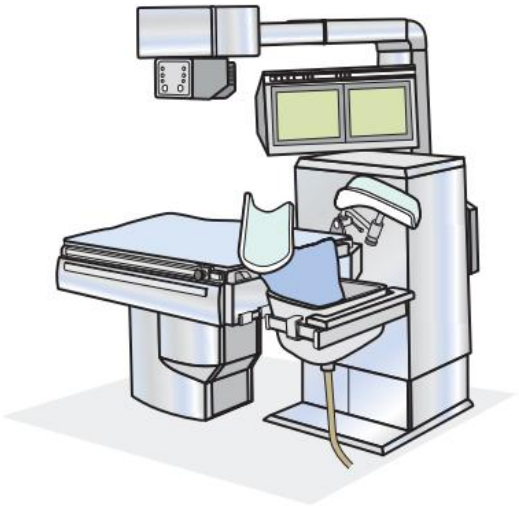
Cystoscopic diagnostic procedures and some conservative urologic procedures approached through the urethra are performed in a specially designed and equipped area that is often referred to as the cysto room or suite. This area may be located within the operating room (OR) suite or in the urology clinic. X-ray control booths, developing units, and digital imaging are located adjacent to or within the area. Because x-ray procedures are often performed, the walls and doors of the room should be lined with lead and personnel remaining in the room with the patient during x-rays or fluoroscopy should wear lead aprons. Patients should be protected with gonadal and thyroid shields whenever feasible.

To protect the welfare of the patients and personnel, all safety regulations apply in the cysto room as they do elsewhere in the OR suite. All lighted instruments and electrical equipment should be checked for proper function before and after each use. Excess fluid should not be permitted to accumulate on the floor.

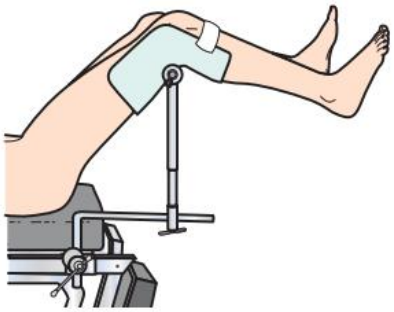
Proper OR attire is worn by all personnel entering the room. Personal protective equipment such as eyewear and masks should be worn if there is a possibility of splash or aerosolization. Many urologists don a water-repellant apron before scrubbing. It is recommended that the urologist wear a sterile gown and sterile gloves. Procedures performed in the cysto room should be performed as in a sterile field to prevent introducing microorganisms into the patient. Adherence to the principles of aseptic technique should be practiced to prevent urinary tract infection.

Urologic Bed

A urologic bed differs from the standard OR bed in that it provides an x-ray–compatible base, a drainage system, and lithotomy knee supports with safety belts (Fig. 35.4). Some urologic beds incorporate electrosurgical units (ESUs). Urologic radiographic studies use conventional x-rays, fluoroscopy and image intensification, and tomography. The imaging system is an integral part of the urologic bed. Some beds have a built-in automatic x-ray film–handling system, others have a film cassette holder, and others adapt to a C-arm.



• **Fig. 35.4** Urologic bed.



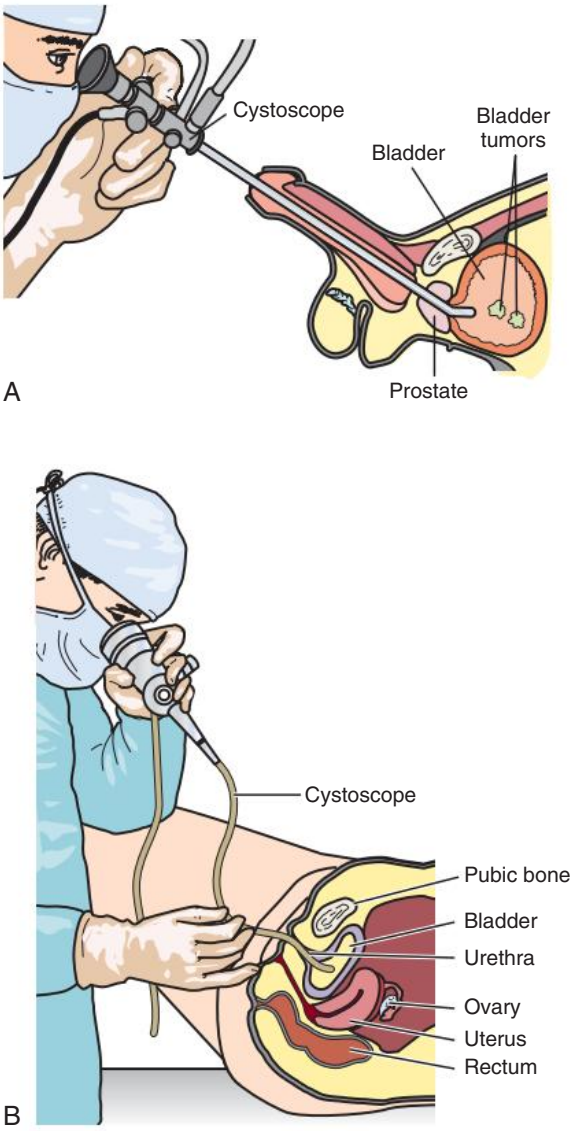
• **Fig. 35.5** Knee crutch stirrup commonly used with urologic table.

The drainage system may have a drainage pan with tubing to drain port or single-use drainage bags. Under-knee/calf supports with gel pads and Velcro straps provide patient comfort in the lithotomy position (Fig. 35.5). Urologic beds are equipped with hydraulic or electric controls to adjust height and tilt. Some have tray attachments for the light source and auxiliary equipment such as an ESU or laser, as well as hooks for irrigating solution bags.

Patient Preparation for a Cystoscopic Examination

1. Unless the procedure will be performed with the patient under general or regional anesthesia, the patient may be encouraged to drink fluids before coming to the cysto room. Fluids ensure rapid collection of a urine specimen from the kidneys. Some tests require the ability to void for bladder strength studies or while contrast medium passes through the urinary system. Electromyographic (EMG) data may be gathered during the process.
2. Intraurethral procedures are often performed with topical agents or local infiltration anesthetics. The patient should be reassured that the procedure usually can be performed with only mild discomfort. Respect the patient's modesty by providing appropriate drapes and keeping the cysto room door closed.

3. The patient is assisted into the lithotomy position with the knees resting in padded knee supports or stirrups. Gel pads behind the legs and knees help avoid undue pressure in popliteal spaces. Velcro straps are used to secure the patient's legs. Some cystoscopic procedures are performed with the male patient in the supine position.
4. The drainage area is located under the lower break of the urologic bed. The drainage area is visible for draping after the patient's legs have been positioned on knee supports and the foot of the bed has been lowered or removed,
5. The pubic region, external genitalia, and perineum are mechanically and chemically cleansed with an antiseptic agent according to routine skin preparation procedure. Scrub soaps can be diluted with warmed sterile saline or water for the comfort of the patient.
6. Topical anesthetic agents are instilled into the urethra at the end of the prep procedure. A viscous liquid or jelly preparation of lidocaine hydrochloride, 1% or 2%, may be used. This medium remains in the urethra rather than flowing into the bladder.
   a. *For the female:* The female urethra is most sensitive at the meatus. A small, sterile cotton-tipped applicator dipped into the anesthetic gel and placed in the meatus is sufficient anesthesia for local urethral procedures. The applicator is removed when the urologist is ready to introduce an instrument. Cone-shaped syringes are commercially available for intraurethral instillation of local lidocaine 2% jelly.
   b. *For the male:* A disposable cylinder with an acorn tip can be used for intraurethral insertion. The agent is injected into the urethra, and the penis is compressed with a noncrushing spring-loaded penile clamp for a few minutes to retain the drug.
7. A sterile filter screen is placed over the drainage pan. The patient is draped as for other perineal procedures in the lithotomy position. The urologist may need to have access to the rectum. The perineal sheet has two fenestrations: one exposes the genitalia, and the other fits over the screen on the drainage pan. A mesh filter is incorporated into this latter fenestration to capture resected tissue. Tissue specimens are collected as irrigating fluid passes through a collecting basket. The sterile mesh filter collects any specimen that is missed by the collection basket.
8. The urologist may prefer to wear a sterile disposable plastic apron over his or her gown.

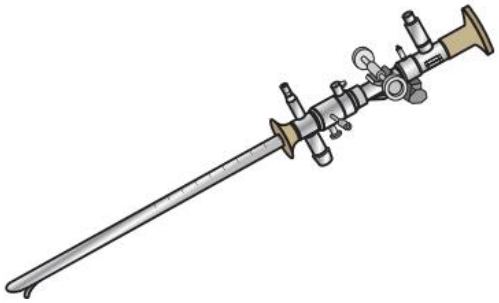


• **Fig. 35.6** **A,** Rigid cystoscopy. **B,** Flexible cystoscopy.

Urologic Endoscopes

Urologic endoscopic instruments and catheters are available in sizes to suit infants, children, and adults. The sizes of these instruments and catheters are measured on the French (Fr) scale: the diameter in millimeters (mm) multiplied by 3. The smallest ureteral catheter is 1 mm in diameter, or 3 Fr; the largest is 14 Fr.

Each type of procedure requires specific endoscopic equipment. All rigid urologic endoscopes have the same basic components, which are discussed in the following sections (Fig. 35.6).



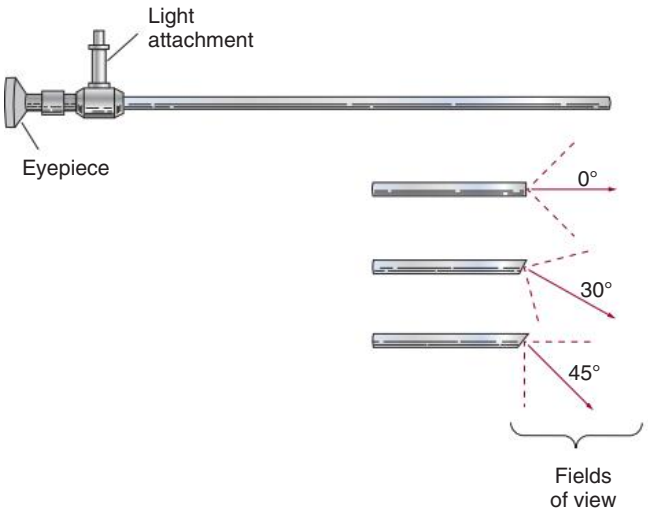
• **Fig. 35.7** Cystoscope, bridge, and sheath.

Sheath

The hollow sheath, through which the urologic endoscope passes, may be concave, convex, or straight in configuration at the distal end (the end inserted into the urethra) (Fig. 35.7). The other end has a stopcock attachment for irrigation. Sheath sizes range from 11 Fr for infants to 30 Fr for adults. Space is provided within the sheath to accommodate instruments for work in the bladder or urethra. Other instruments and catheters can be inserted through the sheath into the ureters and/or kidneys for diagnostic or therapeutic procedures.

Obturator

The stainless steel obturator, which is inserted into the sheath, occludes the opening of the sheath and facilitates introduction into the urethra without trauma to the mucosal lining.



• **Fig. 35.8** Viewing angles of telescopes.

Telescope

Telescopes are complex precision optical systems; they are costly, delicate instruments that are handled gently at all times. Each telescope contains multiple finely polished optical lenses that relay the image from the distal end inside the bladder or urethra to the ocular (eyepiece) used by the urologist to view internal structures. Additional rod-shaped elements (i.e., field lenses) are located between each pair of relay lenses. Properly spaced throughout the length of the telescope, the lenses provide undistorted and clear vision at the desired angle and with some magnification. All telescopes are stainless steel and have a Bakelite or heat resistant plastic ocular. Some telescopes have operating or working elements incorporated into them.

The optical systems provide several angles of vision (Fig. 35.8):

- Direct forward or 0-degree vision is useful for viewing the urethra and for use with the optical urethrotome (an instrument for sharp resection of tissue in the urethra).
- Right-angle or 30-degree vision is most suitable for viewing the entire bladder and insertion of ureteral catheters.
- Lateral, which deviates 70 degrees but includes an additional visual field at a right angle in the line of vision, is used for wide-angle viewing within the bladder.
- Foroblique, which is a forward vision with an oblique view somewhat in front of a right angle, is used to examine the urethra and for **transurethral** surgical procedures.
- Retrospective, which provides an approximate 55-degree angle of retrograde vision, is used to inspect the bladder neck.

Light Source

The light source is a fiberoptic bundle and may be an integral part of the sheath or the telescope. A cable connects the instrument to a fiberoptic light source.

Types of Urologic Endoscopes

Many different types of urologic endoscopes and accessories are used, including nephroscopes introduced into the kidney and cystoscopes introduced through the urethra into the bladder. Before instrumentation is placed on the sterile instrument table, the preferred type and size of the endoscope for the examination and/or treatment should be verified with the urologist. The endoscopes and accessories most commonly used in the cysto room are described in the following sections.

Brown-Buerger Cystoscope

The stainless steel sheaths of the Brown-Buerger cystoscope range in size from 14 to 26 Fr. Size 21 Fr is the size most often used in adults; it has a right-angle examination telescope for routine inspection of the bladder. Size 24 or 26 Fr is used to accommodate larger instruments and catheters that cannot be used through size 21 Fr. The sheath contains the light carrier.

A Brown-Buerger cystoscope set usually consists of two sheaths—one concave and one convex, each with its own obturator—and two or three right-angle telescopes. Along with the basic examination telescope, the set may have a combination operating and double catheterizing telescope (i.e., a convertible telescope), or the operating and double catheterizing functions may be in separate telescopes. The convertible operating and catheterizing telescopes have a small, deflectable lever on the distal end to aid in directing ureteral catheters or flexible stone baskets into the ureters. All corresponding parts of each set must be the same French size.

Blue Light Video Cystoscope

The blue light cystoscope uses photodynamic diagnostic (PDD) technology. Cystoscopes are available in both rigid and flexible styles. The blue light system is used specifically for the diagnosis of bladder cancer after instillation of a photoactive substance. Hexaminolevulinate (HAL) is instilled into the bladder 1 hour before the procedure. Tumor cells absorb the drug because they have less ferrochelatase enzyme. The blue light (375 to 440 nm) from the cystoscope is absorbed by the drug and gives the tumor cells a pink or red color. The surgeon can distinguish the normal cells from tumor cells, which could have been missed with white light cystoscopy.[1]

McCarthy Panendoscope

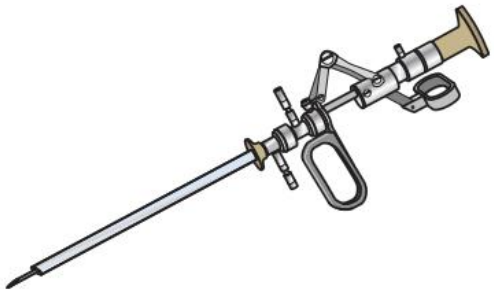
The stainless steel sheaths of the McCarthy panendoscope range in size from 14 to 30 Fr. These are used most often with the Foroblique telescope for viewing the urethra. Other telescopes are available for bladder visualization. The telescopes are interchangeable with all sizes of sheaths. A bridge assembly is required to fit the telescope properly to the sheath. The light is supplied through the telescope.

Wappler Cystourethroscope

The Wappler cystourethroscope combines the functions of the Brown-Buerger cystoscope and the McCarthy panendoscope. The stainless steel sheaths range in size from 17 to 24 Fr. The Foroblique and lateral telescopes, which also supply the light, are interchangeable with all sheaths. A visual obturator may be used to permit visualization and irrigation during the introduction of the sheath into the urethra.

Resectoscope

The resectoscope uses electric current to excise tissue from the bladder, urethra, or prostate (Fig. 35.9). Components of this instrument include the sheath, obturator, telescope, working element, and cutting electrode. The sheath, usually 24 to 28 Fr, is made of Bakelite or fiberglass to prevent a short circuit of the electric current. If the short beak post sheath is used with a wide-angle telescope, a Timberlake obturator is used to introduce the sheath into the urethra.



• **Fig. 35.9** Resectoscope.

The working element of the resectoscope, which is inserted through the sheath, has a channel for the telescope and cutting electrode. The types of working elements differ by the method in which the cutting electrode moves:

- The Iglesias resectoscope uses a thumb control on a leaf spring–lock mechanism. The working element can be adapted for simultaneous irrigation and suction to control hydraulic pressure in the bladder.
- The Nesbit resectoscope uses a thumb control on a spring.
- The Baumrucker resectoscope uses finger control on a sliding mechanism.
- The Stern-McCarthy resectoscope uses a rack and pinion to move the loop forward and back. This requires two hands.

The cutting electrode is the most critical component of a resectoscope. Because it cuts and coagulates tissue, the electrode must be stabilized in the working element so it retracts properly into the sheath after each cut. The electrode has a cutting loop from which electric current is passed through tissue, an insulated fork, an insulated stem, and a contact that is inserted into the working element. Several loop sizes are available; the stem is usually color-coded by size. Loop size corresponds to the French size of the sheath. The electrode is malleable and therefore is checked before use to be certain the insulation is intact and the loop is not broken. Disposable styles are preferred.

Electric current is applied only when the loop is engaged in tissue, and it is inactivated after a cut is completed. The sheath can be charred if electric current is maintained after the cutting loop has been retracted into it. Conductive lubricants may provide a pathway for electric current and therefore should never be used on the sheath. Cleanliness of the sheath and all other components is essential to proper function.

Endoscopic Accessories

Ureteral catheters, bougies, filiforms and followers, stone baskets, and sounds are commonly used by urologist-endoscopists. Other accessories, such as retractable baskets and graspers, are used to remove tissue or calculi (stones).

Electrodes

In addition to the cutting loops used with the resectoscope, primarily for transurethral resection (TUR), other types of electrodes with tips of various shapes are used in the bladder. One type, referred to as a *Bugbee,* is inserted through the operating telescope of the Brown-Buerger cystoscope or Wappler cystourethroscope. The Bugbee is used mainly for fulguration of bladder tumors, coagulation of bladder vessels to control bleeding after biopsy, and ureteral meatotomy. More electric current is needed when working in solution (as in the bladder) than when working in air.

A spark-gap generator is commonly used for transurethral resection and fulguration. A spark-gap ESU requires high-voltage arcing, which is described as spray coagulation. Spark-gap generator use requires the patient to be grounded with a return electrode. The power control settings on the ESU should be as low as possible. Recommended practices as suggested by AORN (The Association of periOperative Registered Nurses) for the use and care of electrosurgical equipment (e.g., return electrodes) apply also to urologic procedures. Additional information about ESUs can be found in Chapter 20.

Lasers

Argon, neodymium:yttrium aluminum garnet (Nd:YAG), and holmium:yttrium aluminum garnet (Ho:YAG) lasers can be adapted for use with urologic endoscopes. These are particularly useful for the ablation of hemangiomas and vascular tumors in the bladder and kidneys. The argon-pumped tunable dye laser is used for photodynamic therapy on solid bladder tumors. A flash lamp–pulsed dye laser will fragment a calculus in a ureter.

Lasers used through endoscopes require most of the same equipment as needed for standard urologic endoscopy. The bladder expansion medium can be either saline or water to create the working space because, unlike with the ESU and electrodes, no ionic charge is emitted from the laser.

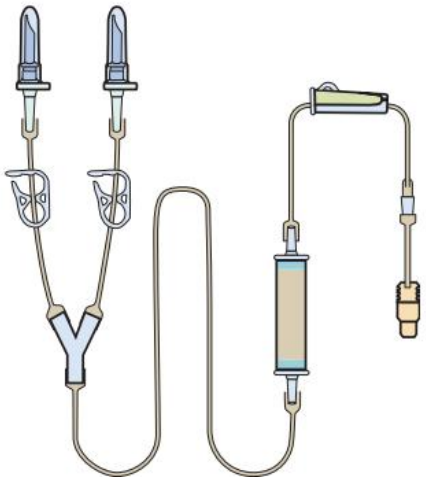
Irrigating Equipment

Continuous irrigation of the bladder is necessary during cystoscopy (cysto) to do the following:

- Distend bladder walls to create a working space so the urologist can visualize them.
- Wash out blood, bits of resected tissue, or stone fragments to permit continuous visibility and collection of specimens.

A sterile, disposable, and closed irrigating system is used because it prevents airborne contamination of the solution. The tubing is Y shaped (Fig. 35.10). Two or more liters of sterile irrigating solution may be needed for a single examination. Disposable tandem sets may be used to connect several containers together. Tandem sets allow for a continuous flow and replacement of containers without interruption of flow.

Sterile disposable irrigating tubing is connected to the irrigating solution container before it is hung on a hook on the urologic bed, in the ceiling, or on a stand placed beside the bed. The solution container should be at a level 2½ feet (0.75 m) above the bed; a



• **Fig. 35.10** Y-tubing for cystoscopy.

lower level decreases flow, and a higher level increases hydraulic pressure with consequent fluid absorption by the tissues of the patient. Tubing should be filled with solution before being attached to the sheath of the cystoscope or resectoscope. The plastic tubing from the container to the instrument is for individual patient use only and is discarded after use.

Sterile **isosmotic** irrigating solutions that are nonhemolytic and nonelectrolytic are generally preferred by most urologists. Sterile distilled water may be used for visualization procedures and during resection or fulguration of bladder tumors with an ESU. Water may **hemolyze** red blood cells if a sufficient amount enters the circulation through open blood vessels. As much as 3 to 6 L of solution may be absorbed during a transurethral prostatectomy.

Saline is contraindicated for use with a monopolar ESU because the electrons in saline act as a conductor and disperse the current when the ESU is used. Newer bipolar resectoscopes use saline irrigation without problems.

Isosmotic solutions of 1.5% glycine (an amino acid) or sorbitol (an inert sugar) premixed in distilled water are commercially available in 1.5 and 3-L containers.

Glycine solution is sometimes used for TUR with an ESU; however, it can cause serious complications in some patients. Overabsorption of glycine can occur during TUR, causing water intoxication with resultant **hyponatremia** and acid-base imbalance (acidosis). This process has been called transurethral resection syndrome and is hallmarked by dilutional hyponatremia.

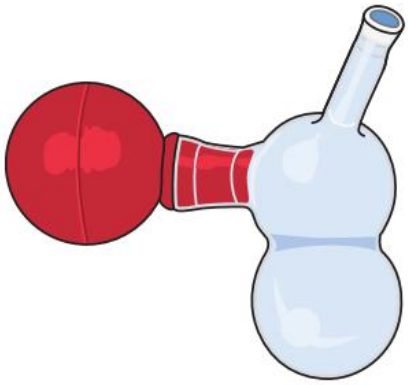
During a cysto procedure, the flow of solution into the endoscope is controlled by the stopcock on the sheath where the tubing attaches. Rubber tips or sealing caps are used to seal other openings on the instrument to prevent solution from escaping during a procedure. The openings through which catheters or instruments are to be inserted are closed with rubber sealing caps that have a central hole. The accessory can be inserted through this hole with the seal maintained. Silicone caps should be used instead of rubber caps if the patient or surgeon has a latex sensitivity.

The irrigating solution flows away from the instrument and into the drainage pan through the filter screen when the urologist needs to divert the flow. Solution drains from the pan, through the tubing, and into a collecting container that is emptied after each patient use. Fluid collection receptacles can provide the surgeon with accurate patient fluid output. Some older cysto rooms have floor drains, which are a source of environmental contamination unless cleaned thoroughly. If large quantities of solution are used, the level of drainage into the container should be observed to prevent overflow onto the floor or around the foot pedal of the ESU, which can be an electrocution hazard.

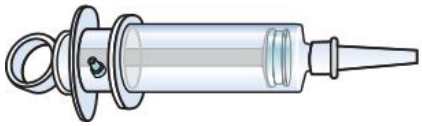
Evacuators

Evacuators may be attached to the endoscope to irrigate the bladder and aspirate stone fragments, blood clots, or resected tissue. Stone or tissue fragments collected in the evacuator are retrieved and sent to the pathology laboratory. The two most commonly used types are the Ellik evacuator and the Toomey evacuator, as follows:

- *Ellik evacuator.* The Ellik evacuator is a double bowl-shaped glass or firm disposable plastic receptacle (Fig. 35.11). It contains a trap for fragments so they cannot be washed back into the sheath of the endoscope during irrigation with pressure on the compression-bulb attachment.
- *Toomey evacuator.* The Toomey evacuator is a syringe-type evacuator with a wide opening into the barrel (Fig. 35.12). It may be used with any endoscope sheath. A metal adapter permits its use with a catheter.



• **Fig. 35.11** Ellik evacuator for flushing prostate tissue from the bladder during transurethral resection of the prostate (TURP).



• **Fig. 35.12** Toomey irrigator.

Care and Preventive Maintenance of Urologic Endoscopes

1. Sterilization is recommended before use. The bladder is considered a sterile space. Endoscopes and reusable accessories must be free of debris and residue for sterilization and/or high-level disinfection techniques to be effective.
   a. Disassemble all parts and open all outlets.
   b. Clean all parts in an appropriate liquid detergent solution. Clean the interior of sheaths and openings with a soft brush.
   c. Rinse in clean water, and dry thoroughly.
   d. Wipe lenses gently with a soft, dry cloth.
2. After cleaning, place endoscopes on a towel to drain. With air, blow-dry the lumens. Moisture in the channels can dilute chemical sterilants and, if ethylene oxide is used, will form ethylene glycol, which is toxic to tissues.
3. Check the function of all moving parts, the clarity of vision through telescopes, and the patency of channels through instruments and catheters.
4. Keep sets of sterile sounds, bougies, and filiforms and followers together so the urologist has a complete range of sizes readily accessible.
5. Wrap items for sterilization after cleaning. Flexible instruments should be protected by a rigid container.
6. Clean and dry stone baskets before sterilizing by low-temperature sterilization methods, such as plasma vapor, peracetic acid, or ethylene oxide. Retractable stone baskets are sterilized in the open position.
7. The principles and methods of sterilization apply to urologic endoscopy equipment.
8. Endoscopic processors and sterilizers are useful for sterilizing instrumentation between patient uses. The instrumentation is used immediately after processing and is not stored in the processing tray.
9. Because the interior of the bladder is considered sterile the recommended practice is to use only sterile instrumentation.

Surgical Procedures of the Genitourinary System

Most patients commonly seen by urologists are in the preadolescent or older age-groups. Congenital and common pediatric problems are discussed in Chapter 8. This chapter focuses on adult problems, most of which occur in men older than 50 years who have prostatic disease and women who have urinary **incontinence**. Female bladder problems are addressed in Chapter 34.

An open surgical procedure is performed only after conservative treatment fails or examination of the genitourinary tract (GU) confirms a condition that does not yield to treatment. Fortunately, most urologic conditions can be diagnosed and treated conservatively through a urologic endoscope and its accessories. Some laparoscopic procedures are performed to remove a kidney (nephrectomy) or obtain lymph nodes for biopsy. When a congenital or acquired condition does not respond to conservative therapy, the urologist performs open surgical procedures to repair, revise, reconstruct, or remove organs.

Obstructive and neuromuscular disorders are common problems in the urinary tract. Renal calculous disease and tumors in the urinary tract are most commonly diagnosed in middle age. These conditions may cause obstruction and subsequent infection in the kidneys, ureter, or bladder.

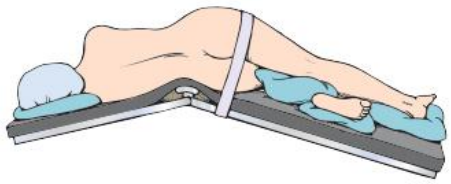
Kidney

Definitive renal surgical procedures are justified for the management of renal neoplasms, large cystic lesions that compromise renal function and/or produce obstruction, inflammatory diseases that necessitate drainage, or renal vascular disease. Chronic degenerative disease or severe traumatic injury can produce irreparable damage to renal cells. Computed tomography (CT) and magnetic resonance imaging (MRI) identify the site, size, and extent of tumor involvement.

Ultrasonography and intravenous (IV) urograms and pyelograms differentiate among solid tumors, stones, and cystic disease. A radionuclide scan may indicate renal function; arteriograms and venograms indicate the extent of renal vascular disease.

The kidney is usually approached posteriorly with the patient in a lateral position (Fig. 35.13). The kidney rest may be raised, and the bed flexed until the flank muscles become tense. After the patient is secured in position, the bed is tilted in Trendelenburg's position until the flank is horizontal to the floor. A flank incision is made parallel to and just below or over the eleventh or twelfth rib; the twelfth rib may be removed. The retroperitoneum is opened to expose the kidney. The peritoneal cavity is not entered.

The kidney can be approached anteriorly through a transverse, subcostal, or midline incision. A thoracoabdominal incision may be preferred in an obese patient or to reach a lesion in the upper pole of the kidney. These incisions, with the patient in the supine position, are often used for exposure of the aorta and vena cava for renovascular procedures. An anterior approach may be advantageous when prompt control of blood supply is important in renal trauma.



• **Fig. 35.13** Surgical position for open kidney procedure.

Nephrectomy

Removal of a lobe or the entire kidney is indicated when tumor, disease, or traumatic injury has resulted in the absence of renal function. The entire kidney can be removed during a laparoscopic procedure. Hand-assisted laparoscopy (HALS) can use used.[2] The organ is dissected, fragmented, and aspirated; vascular pedicles are stapled. This alternative technique is used primarily for benign renal disease.

Partial Nephrectomy or Heminephrectomy

Partial excision of the kidney may be sufficient when a lobe has been destroyed by localized disease or injury but the remainder of the kidney remains functional. The vascular supply to the segment to be removed must be identified, ligated, and divided. The parenchyma of the lobe is resected from the capsule by blunt dissection. The renal pelvis and remaining capsule are closed.

Radical Nephrectomy

In a radical nephrectomy, the renal vessels are dissected free, ligated, and divided. Prerenal fat and fascia are dissected to remove the kidney. The ureter is ligated and divided close to the bladder. The renal pedicle is ligated and divided, and the kidney is removed. Massive hemorrhage from the renal artery and veins is a potential complication, as is injury to adjacent structures (i.e., inferior vena cava, aorta, and duodenum on the right side or spleen on the left side).

A nephrectomy is performed in the OR on a living donor (unilateral) or a cadaver donor (bilateral) to procure the kidney(s) for transplantation. Meticulous dissection is necessary to free the kidney, its blood vessels, and the ureter with minimal trauma. The ureter is dissected free and transected while the renal blood supply remains intact to ensure adequate urinary output. A kidney from a living donor may last longer than a kidney from a cadaver, because the organ ischemic time is less and transplantation takes place sooner. A living donor kidney can be obtained by HALS.

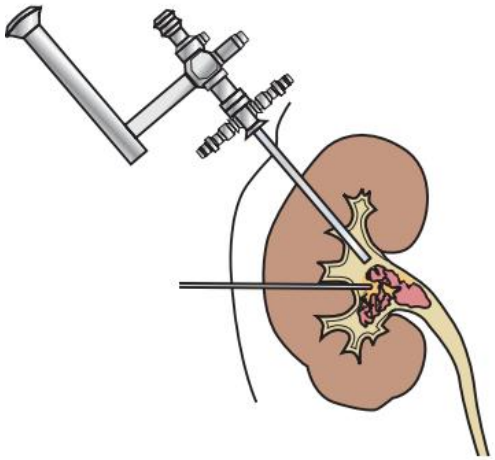
The left kidney is most commonly used for living donor transplant because it is easier to access. The anatomy is more complex on the right side because of the renal vein structure and requires a longer surgical time, causing a longer scar. Dr. Rizk El-Galley developed a special angled clamp that permits HALS right nephrectomy by excising a cuff of vena cava with the renal vein for added length of the vessel.

Bilateral Nephrectomy

Removal of both kidneys may be indicated before transplantation in a patient maintained on chronic dialysis who has severe hypertension. If rejection is uncontrollable after kidney transplantation, the donor kidney may have to be explanted and the patient returned to chronic hemodialysis. This is less likely after transplantation from a live donor than from a cadaver.

Nephrostomy or Pyelostomy

An incision through the renal parenchyma or into the renal pelvis may be necessary to establish temporary or permanent drainage when an obstruction prevents the flow of urine from the kidney (Fig. 35.14). A percutaneous tube is placed in the kidney through the skin. A cutaneous nephrostomy tube may be used to drain a



• **Fig. 35.14** Percutaneous nephrostomy.

kidney postoperatively during healing after renal reconstruction or revascularization. Silastic tubes placed internally through a cystoscope via the ureter eliminate the need for an open surgical procedure for a temporary urinary **diversion**.

More commonly, temporary urinary diversion is performed percutaneously under fluoroscopic or ultrasound guidance by a radiologist and/or urologist. A plastic disc is applied to the skin to secure the catheter, which is attached to a drainage bag in a manner to prevent tension. The tubing may be connected to a leg bag to avoid tension on the catheter during ambulation.

Pyeloplasty

Revision or reconstruction of the renal pelvis is performed to relieve an anatomic obstruction in the flow of urine by creating a larger outlet from the renal pelvis into the ureter. This may be performed to repair or excise damaged tissue so kidney function will be restored without a partial or total nephrectomy.

Either a rigid or a flexible fiberoptic nephroscope may be used to visually inspect the renal collecting system. A laser fiber may be used to ablate some tumors.

Renal Revascularization

Stenotic lesions of renal arteries are surgically correctable causes of hypertension. Renovascular reconstructive procedures (renal angioplasty) are designed to either improve blood flow through the stenotic area to the kidney or bypass the stenotic area.

Revascularization procedures may have a dual purpose: to correct hypertension and preserve renal function. The patient is placed in the supine position for these procedures because the renal arteries are approached through an abdominal incision.

In Situ Vascular Reconstructive Techniques

Obstruction of the renal artery most often occurs as a result of atherosclerotic stenosis at the origin of the artery or fibromuscular dysplasia (abnormal development) confined to the main renal artery. The obstruction is most often resected and replaced by an aortorenal saphenous vein bypass graft. A reversed segment of proximal saphenous vein, gently distended and irrigated, is anastomosed first to the aorta and then to the renal artery.

Prosthetic woven Dacron grafts may be used instead of an autologous vein graft for renal artery bypass combined with distal aortic replacement. Segmental resection of diseased arterial segments with primary end-to-end anastomosis may be performed. Thromboendarterectomy is more often performed than is the latter procedure. All of these procedures may be performed bilaterally or as staged bilateral renal artery reconstructions. Percutaneous transluminal angioplasty may be preferred to these open procedures.

Ex Vivo Extracorporeal Kidney Surgery

When stenotic disease or another obstructive lesion extends into the branches of the renal artery, in situ reconstruction may be difficult, hazardous, or impossible. In these patients, a temporary nephrectomy with microvascular repair followed by autotransplantation of the kidney may be performed; this is referred to as workbench surgery. The kidney is completely mobilized from the retroperitoneal space. If one kidney is to be reconstructed, the ureter can remain intact and reconstruction is performed on a sterile bench (Mayo tray) placed over the patient's lower abdomen.

For a bilateral reconstruction, one kidney is detached from its ureter to permit complete removal from the abdomen. A second team works on the contralateral kidney in situ while the other kidney is reconstructed at an adjacent dissecting bench (table) ex vivo.

Extracorporeal perfusion is necessary for renal preservation during reconstruction. This may be accomplished either with perfusion of cold lactated Ringer's solution or other hyperosmolar solution by gravity flow or with a continuous hypothermic perfusion through a Belzer pump machine. A simple cold storage in saline slush also may be used for renal preservation. Dry ice is never used.

A kidney may be autotransplanted into the patient's pelvis for revascularization of the kidney, removal of renal tumors or calculi, or repair of ureteral injuries.

Traumatic Injury

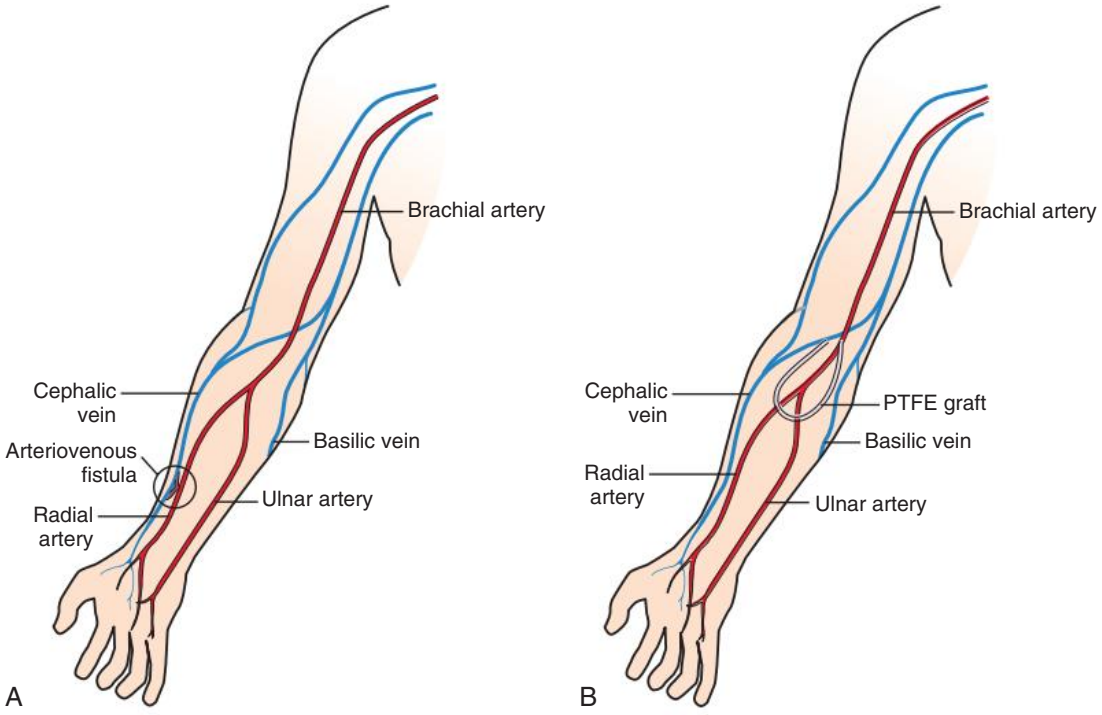
Serious hemorrhage may result if a kidney is ruptured or injured by blunt trauma or a bullet or stab wound. This requires an immediate surgical procedure. The surgeon makes every effort to save kidney tissue and the ureter. A Foley catheter is inserted to keep an accurate record of urinary output and check for the presence of hematuria preoperatively and postoperatively. Gross hematuria preoperatively usually indicates injury to the bladder or urethra. Kidney damage is diagnosed by the presence of blood seen microscopically.

Dialysis

End-stage renal disease and acute renal failure are potentially fatal conditions unless they can be controlled or reversed. Uremia and hypertension develop if renal failure is prolonged. Renal dialysis is the procedure of removing waste products and excess intravascular fluid from the body of a patient in acute or chronic renal failure by diffusion through a semipermeable membrane. This may be accomplished by either hemodialysis or peritoneal dialysis. The treatment modality alleviates the acute manifestations of uremia and controls many of the chronic long-term complications of end-stage renal disease.

Grossly undernourished and anemic patients with severe electrolyte imbalances must be adequately stabilized by dialysis before kidney transplantation. Some patients require dialysis for the remainder of their lives. Patients undergoing chronic dialysis must have a means of arterial-venous access established for long-term maintenance.

Patients with chronic renal failure can tolerate extensive surgical procedures with minimal complications. Their management in the OR must include strict attention to maintaining a patent hemodialysis access shunt, fistula, or catheter; careful monitoring of fluid and electrolyte balance; and avoiding postoperative infections.



• **Fig. 35.15** Dialysis access modalities. **A,** Arteriovenous fistula. **B,** Synthetic graft. *PTFE,* Polytetrafluoroethylene.

After kidney transplantation, the patient may require postoperative dialysis; thus access must remain patent during and after the surgical procedure.

Hemodialysis

In hemodialysis, waste products are removed from the blood through the semipermeable membrane of a dialyzer (artificial kidney machine). An arteriovenous (AV) shunt or fistula is created subcutaneously in either an arm or a leg to provide access to the patient's circulation (Fig. 35.15).

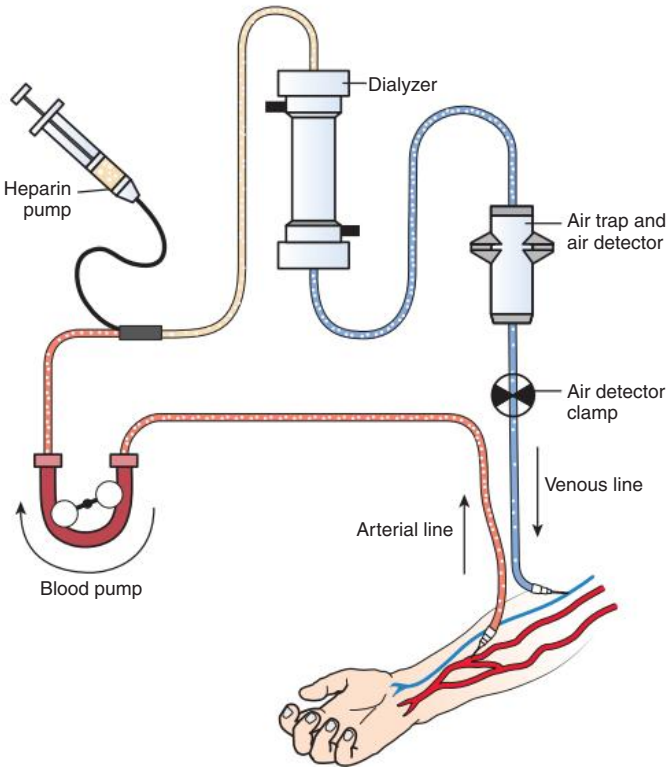
The Quinton-Scribner double-lumen shunt, developed in 1960, consists of two tips attached to tubing. One tip is placed in the artery and the other in a nearby vein. The tubing from each tip is exteriorized through a subcutaneous tunnel to form a loop. The arterial and venous blood mix in this shunt. Variations and modifications of this basic external shunt are used to create an AV conduit; some have self-sealing devices to minimize the potential problems of clotting and infection.

An anastomosis, usually between the radial artery and the cephalic vein in the forearm, creates an arterialized peripheral vein that permits dialyzer connections to be made by venipuncture. Needles are placed in the venous limb of the AV fistula for blood outflow and return (Fig. 35.16). The Brescia-Cimino radiocephalic AV fistula, first described in 1966, is easiest to construct and has the fewest complications. If creation of an AV fistula by direct anastomosis is not feasible, a biologic or synthetic graft may be interposed between the artery and the vein.

Cryopreserved human vein, saphenous or other autologous vein, bovine carotid artery heterograft, and polytetrafluoroethylene (PTFE) grafts are used.

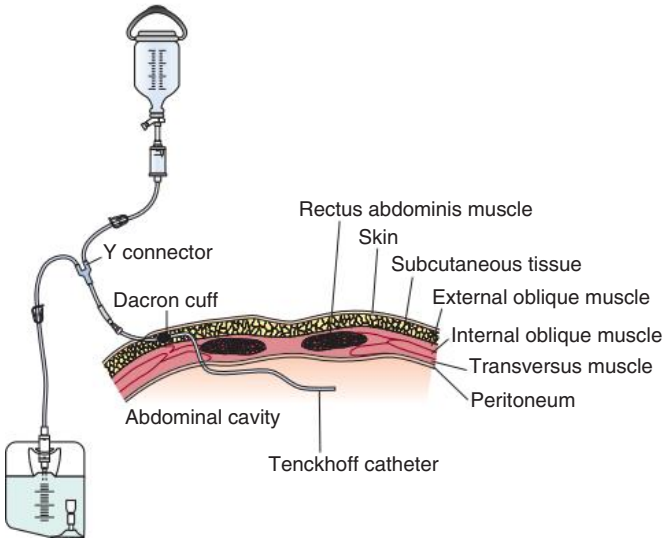
Peritoneal Dialysis

For acute, intermittent, or continuous peritoneal dialysis, a Tenckhoff silicone catheter is placed into the peritoneal cavity



• **Fig. 35.16** Arteriovenous fistula and dialysis machine.

(Fig. 35.17). A paramedian incision generally is used to place a section of the catheter in subcutaneous tissue. The catheter has one or two synthetic fiber cuffs to anchor it in subcutaneous tissue and block bacterial invasion along the catheter into the peritoneal cavity.



• **Fig. 35.17** Tenckhoff catheter for peritoneal dialysis.

Dialysate is instilled over time into the peritoneal cavity to draw solutes from body fluids into the dialyzing solution across the peritoneal membrane. This process selectively removes electrolytes, metabolites, toxins, and water normally excreted by the kidneys.

Dialysate that has been warmed to body temperature is instilled, allowed to remain for a specified number of hours, and then withdrawn by a cycling machine or by gravity drainage. A Y-set disconnect system attached to the catheter allows separation of inflow and outflow. Peritonitis is always a potential complication.

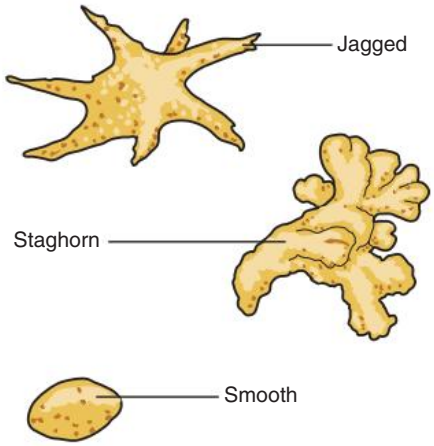
Infection is often treated by adding antibiotics to the dialysate. Heparin is added to prevent fibrin clots in the catheter. The patient may perform this routine at home several times per week, usually during the evening hours.

A patient being treated with peritoneal dialysis may come to the OR for an unrelated surgical procedure. Respiratory excursion may be impaired by pressure of retained dialysate under the diaphragm. A slight reverse Trendelenburg's position may alleviate respiratory discomfort. Additional suction containers should be available if the abdomen must be evacuated while the patient is in the OR. Fluid removed from the peritoneal cavity is measured, and the appearance and volume are recorded on the intraoperative record.

Urolithiasis (Urinary Calculus)

A renal calculus (kidney stone) is a solid deposit or deposits of minerals and salts (Fig. 35.18). These deposits are called calculi and accumulate in the renal collecting system. Kidney stones are more common in white males living in warm climates and nearly 30% to 50% experience recurrence 5 to 10 years after initial treatment. Diagnosis in adults is best made with CT scan. Ultrasound is best used to diagnose kidney stones in children. Calculi can be the result of cystinuria (amino acid metabolic disorder), hypercalcemia (immobility or hyperparathyroidism), oxalate (oxalic and glycolic acid in urine), and uric acid (dietary purines).

Renal colic is an intense pain caused when a calculus or fragments of calculi partially or completely obstructs the calyces or renal pelvis. Renal calculi often dislodge and move from the renal pelvis into the ureter. A nidus (e.g., an infection or an exposed suture postoperatively) can be the focal point for the formation of a calculus in the ureter. If calculi are small enough, they pass into the bladder and are voided. Those that remain lodged, causing obstruction to outflow from any part of the urinary tract, must be removed.



• **Fig. 35.18** Kidney stones.

Preservation of renal function is the primary objective of surgical procedures for urolithiasis. Lithotomy is removal of a calculus. Lithotripsy is fragmentation of a stone followed by removal. Chemolysis is dissolution with a chemical substance.

After removal from any location in the GU tract, urinary calculi should be placed in a dry container and sent to the pathology laboratory for chemical analysis.

Percutaneous Nephrostolithotomy or Nephrolithotripsy

With percutaneous nephrostolithotomy or nephrolithotripsy, a guidewire inside a transluminal angioplasty needle is introduced, under fluoroscopy, through the flank into the renal pelvis. The access point is carefully closed. This procedure may be performed in the radiology department with the patient under local anesthesia. In the OR, dilators are placed over the guidewire to enlarge a nephrostomy tract for introduction of a nephrostomy tube or nephroscope. The patient is placed in a modified prone position to elevate the surgical side slightly.

Renal calculi may be removed with stone forceps or baskets, or they may be fragmented with a lithotriptor. Lithotripsy is necessary for large calculi such as a staghorn calculus, which branches from the renal pelvis into the calyces and may extend into the ureter. Size, density, composition, and location influence the urologist's choice of lithotripsy.

Ultrasonic Lithotripsy. With ultrasonic lithotripsy, ultrasonic waves are used to shatter the calculus into fragments. This procedure is usually performed with the patient under spinal or general anesthesia. Either a rigid or a flexible fiberoptic nephroscope is inserted percutaneously; a hollow, metal ultrasonic probe, which emits high-frequency sound waves, is inserted through the nephroscope. The probe is visually placed in contact with a calculus that is localized in the renal pelvis as identified on x-ray or by fluoroscopy.

As the ultrasonic energy is absorbed, the calculus fragments and shattered particles are aspirated by suction through the probe. A nephrostomy tube may be placed in the renal pelvis for temporary drainage postoperatively; this tube is usually removed after 2 weeks.

Electrohydraulic Lithotripsy. With electrohydraulic lithotripsy, an electrohydraulic lithotriptor is used to create an electrical discharge in fluid; this discharge is transformed into a hydraulic shock wave. The calculus disintegrates when the probe is directed at it. Larger fragments may be removed with Randall stone forceps, and smaller ones are flushed out with irrigation.

A tube is left in the nephrostomy tract for continued irrigation for several days after lithotripsy. This procedure may be performed with a local anesthetic with IV sedatives and analgesics.

Nephrolithotomy or Pyelolithotomy

A large staghorn renal calculus that does not dislodge from the calyces or renal pelvis may need to be removed through an open incision. A nephroscope may be used during the surgical procedure for direct visual examination of the nephrons to locate and remove residual calculi. Ultrasound also may be used to identify retained fragments. Localized hypothermia provides the surgeon with a bloodless surgical field and lengthens the time in which the renal artery may be clamped safely without a loss of renal function during the search for and extraction of calculi.

Extracorporeal Shock-Wave Lithotripsy

Many patients are scheduled for x-ray immediately before a noninvasive extracorporeal shock-wave lithotripsy (ESWL) procedure. A ureteral stent may be inserted to facilitate the passage of stone fragments. The ureteral stone may be manipulated back up into the renal pelvis. An x-ray may be obtained to check the location of the calculus.

The long-term effects of ESWL are under study, but to date the results are inconclusive. Potential long-term effects may be related to the underlying organs adjacent to the location of the stone as it is fragmented. Shock waves delivered directly over the kidney may injure the renal tissue causing the development of hypertension or chronic renal disease. The proximal location of the pancreas in the retroperitoneum exposes the organ to shock waves. The question is raised as to the potential development of diabetes. Peripheral organ damage is an area for future research.

Water Bag Lithotripsy

With a water bag lithotripsy, the patient first receives a continuous epidural or general anesthetic and then is positioned against a large fluid-filled pad on the OR bed. The calculus is visualized by fluoroscopy and approximately 1500 ultrasonic waves are generated over a period of 60 minutes by rapid high-voltage sparks that are discharged from the bottom of the OR bed and transmitted through the water bag to enter the body. The shock-wave energy is generated electromagnetically and focused with an acoustic lens. The impact of the sonic waves against the calculus causes fragmentation.

After each series of 150 to 200 waves, the focus on the calculus is rechecked by fluoroscopy. Each shock wave is synchronized with the patient's respirations and resting phase of the heartbeat; an electrocardiogram (ECG) monitors the patient's R waves to avoid disrupting the cardiac rhythm. A loud report sounds in the room each time a spark is fired, and therefore both the patient and personnel must wear protective earplugs.

Shock waves also may be produced by piezoelectric transducers activated by an electronic generator. These transducers are mounted on a bowl-shaped spherical dish; a soft, fluid membrane over this dish maintains contact with the patient's skin. Ultrasound images produced from an ultrasound localization system are used to position the stone at the focal point of the shock waves.

Ureters

The ureters are the vital anatomic structures for the flow of urine from the kidneys to the bladder. An obstruction to urinary flow must be either corrected or diverted. The ureters may be approached through either an endoscope or an open incision.

Ureteroscopy

Both rigid and flexible, short and long, fiberoptic ureteroscopes allow direct visualization of the ureteral tumors, calculi, and strictures. These scopes are introduced percutaneously or cystoscopically. Biopsies of tumors can be performed, and strictures can be corrected by balloon dilation. Ureteral calculi can be extracted with stone baskets or forceps or fragmented using ultrasound or lasers.

Percutaneous endoscopic techniques can be used in conjunction with x-ray. A complete x-ray implies that the procedure extends beyond the bladder into the ureters. Another term for a single x-ray of the abdomen is *KUB* (kidneys, ureters, and bladder). Some surgeons refer to a KUB as a "flat plate." This procedure may be performed for the following reasons:

- Drainage of the renal pelvis for differential diagnosis or renal function
- Insertion of ureteral catheters to provide constant drainage for one or both kidneys or outline the ureters for a difficult pelvic surgical procedure
- Insertion of a ureteral stent for internal drainage of an obstructed ureter
- Transluminal dilation of a ureteral stricture
- Manipulation and removal of a calculus
- Ureteral **meatotomy** to enlarge the opening of one or both ureteral orifices into the bladder

Ureteral Catheters

Made of flexible woven nylon or other plastic material, ureteral catheters range in caliber from size 3 to 14 Fr and are approximately 30 inches (76 cm) in length. Sterile, prepackaged disposable catheters are available. Most are radiopaque so they can be visualized on x-ray.

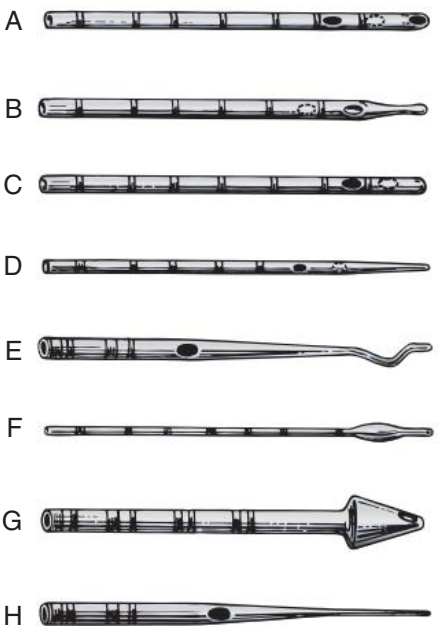
The urologist visualizes the ureteral orifice through the cystoscope. The catheter is inserted through the scope and introduced into the ureter.

The catheter has graduated markings in centimeters so the urologist can judge the distance that the catheter has been inserted. The urologist will request a size and style of catheter tip best suited for the intended purpose. The most common tips are shown in Fig. 35.19.

- *Whistle tips:* Used for drainage, as ureteral markers, or for the injection of a radiopaque contrast medium for retrograde pyelography. The largest sizes are used to dilate ureters to facilitate passage of a calculus.
- *Olive tips:* May be used for the same purposes as whistle tips.
- *Round tips:* May be preferred for drainage.
- *Flexible filiform tips:* May be used to bypass an obstruction for drainage.
- *Blasucci curved tips:* May be used to bypass a ureteral stricture more easily than straight tips.
- *Braasch bulb with whistle tips:* Preferred to dilate the ureter or to inject contrast medium for a ureterogram.
- *Acorn or cone tips:* May be preferred for a ureterogram.
- *Garceau tapered tips:* Used to dilate ureters.

Ureteral catheters that are left indwelling to provide drainage must be attached to a sterile, closed urinary drainage system. Because ureteral catheters are smaller in diameter than standard urinary drainage catheters, an adapter is used. This adapter may be a small rubber tip or nipple placed on one end of a straight connector or on both ends of a Y-connector. The catheters are put through the hole in the tip(s).

The distal end of the connector is attached to a constant drainage system with sterile tubing. A separate drainage system for each



• **Fig. 35.19** Ureteral catheter tips. **A,** Whistle. **B,** Olive. **C,** Round. **D,** Flexible filiform. **E,** Blasucci curved. **F,** Braasch bulb. **G,** Acorn/cone. **H,** Garceau tapered.

catheter is usually desired by the urologist. Each drainage container is labeled to identify the right and left ureteral catheters.

Ureteral Stent

An indwelling ureteral stent is inserted for long-term drainage in a wide variety of benign and malignant diseases that cause ureteral obstruction.

A stent also may be indicated for temporary drainage or marking a ureter for abdominal surgery. Placement of ureteral stents requires a cysto setup separate from the main surgical field. The table should be left intact for the duration of the abdominal procedure in the event a second cysto is necessary.

Several types of stents are used. They can be made of durable and biocompatible silicone, polyurethane, or another copolymer. The stent may have a collar, a double-J configuration, a pigtail, or a coil to minimize migration up into the renal pelvis or down into the bladder. The stent is passed through the cystoscope and over a guidewire into the ureter, and it remains fixed for internal urinary drainage. As described for ureteral catheters, some types of stents are used to identify ureters and provide external drainage intraoperatively.

Percutaneous Ureterolithotomy

As described for percutaneous nephrolithotomy and lithotripsy, a calculus lodged in the renal pelvis or upper tract of the ureter can be extracted or fragmented through a ureteropyeloscope.

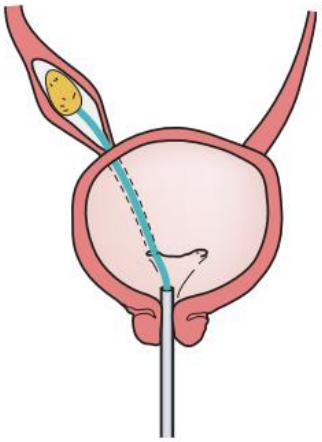
Transurethral Ureteroscopic Lithotripsy or Lithotomy

A urologic endoscope can be introduced transurethrally for direct visualization and lithotripsy or for extraction of a calculus that is obstructing a ureter (Fig. 35.20). Ultrasonic and electrohydraulic lithotripsy can be performed through a ureteroscope.[3]

Laser Lithotripsy

The use of laser technology has improved the minimally invasive treatment of calculi. A flash lamp–pulsed dye laser beam is directed through a flexible fiberoptic ureteroscope to a calculus in the lower tract. The fine tip of the laser fiber probe extends beyond the end of the scope and is placed in direct contact with the calculi to produce fragmentation without ureteral injury.

This pulsed laser has a green wavelength and is attracted to the yellow color of a calculus. The energy generated through the intermittent laser pulses fragments the yellow calculus by mechanical action without increasing its temperature to more than 50° F (10° C). This procedure may be performed with the patient under epidural or general anesthesia. Shattered calculi will pass with the patient's urine. An indwelling ureteral stent may be left in place for 48 hours and removed by the urologist in the office postoperatively.



• **Fig. 35.20** Ureteral stone removal.

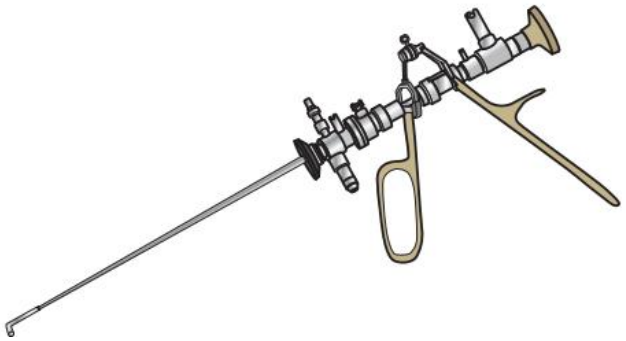
Ureteral Stone Extraction

A flexible-shaft, basket-type stone-capture device (stone basket) is inserted into the ureter through a cystoscope in the bladder for extraction of a ureteral calculus. Several types of stone baskets are available, including the Dormia, Johnson, Levant, Pfister-Schwartz, and Lomac. These instruments have a fine wire or nylon basket that can be expanded through the shaft to ensnare a calculus located in the lower third of the ureter. Specialized stone baskets have a laser fiber port for calculus fragmentation. The basket is used to retrieve the central core after the exterior portion of the calculus is shattered.

Stone baskets must be cleaned promptly after use in a nonresidue liquid-detergent solution to remove debris. Removable parts must be disassembled. Debris should be brushed away from the junction of the basket and shaft with a small, soft brush. Inspection of the basket wires is critical during cleaning. If the wires are cracked or broken at the end closest to the shaft, the basket may be passed into the ureter but cannot be withdrawn without trauma.

Ureterolithotomy

If a calculus fails to pass spontaneously through the ureter or cannot be removed with a stone basket, an open surgical procedure may be necessary. If the calculus is high in the ureter near the kidney, the patient is positioned for a lateral flank incision below the twelfth rib. An abdominal incision is used to reach a calculus in the lower segment near the bladder. The exposed ureter will be dilated proximal to the calculus and collapsed distal to it. The surgeon makes a small incision directly over the calculus and extracts it from the ureter with a stone forceps.



• **Fig. 35.21** Lithotrite for crushing bladder stones.

Litholapaxy and Cystolithotomy

Calculi usually can be removed from the bladder through the urethra. Crushing a urinary calculus in the bladder is referred to as *litholapaxy* or *lithotrity*. If a litholapaxy is unsuccessful or contraindicated, the removal of a calculus by incision into the bladder may be necessary; this surgical procedure is a *cystolithotomy*. For a litholapaxy, a lithotrite (Fig. 35.21) is introduced into the bladder through the urethra and is used to pulverize and remove calculi. The instrument used may be a lithotrite with hinged jaws, an ultrasound lithotriptor, or an electrohydraulic lithotrite. The electrohydraulic lithotrite generates energy shock waves at the tip of a flexible probe inserted through a cystoscope by direct vision. The stone fragments are then irrigated from the bladder.

Ureteroneocystostomy

Implantation of the ureters into the bladder wall can be performed to relocate the ureters into a different site for correction of ureterovesical reflux, reestablish urinary flow after temporary diversion or ureteral injury, or establish urinary flow from a kidney transplant after bilateral nephrectomy and ureterectomy.

Ureteroureterostomy

Anastomosis of two segments of one ureter is usually performed to reestablish ureteral continuity after traumatic injury. A ureteral catheter may be inserted as a stent and the ureter sutured over it. This procedure, a transureteroureterostomy anastomosis, may be indicated to bypass a ureteral stricture or to eliminate ureteral reflux that may be the result of trauma. Injury to a ureter can occur as a complication of pelvic or abdominal surgical procedures, as well as from external penetrating wounds.

Ideally, a transureteral anastomosis can be made 2 to 4 cm above the pelvic brim, because the ureters are close at this point and the recipient ureter has a straight course into the bladder.

Vesico-Psoas Hitch Procedure

The loss of a large segment of a middle or distal ureter can result from trauma or ureteral resection for tumor or stricture. A vesicopsoas hitch may be the procedure of choice when the length of the remaining ureter is insufficient for ureteroneocystostomy or ureteroureterostomy. The bladder is mobilized through an **extraperitoneal** approach into the retroperitoneal space. It is attached (i.e., hitched) to the psoas muscle to reposition the bladder cephalad. The segment of proximal ureter is brought through and sutured to the bladder wall. The kidney also may be mobilized and attached to the psoas muscle if too much tension will be placed on the ureterovesical anastomosis.

Urinary Bladder

The bladder may be opened through a suprapubic incision when a neoplasm, calculus, obstruction of the bladder neck, or traumatic injury is not amenable to treatment through the cystoscope. Diagnosis is usually established through urodynamics (the study of bladder function) and direct visualization via a cystoscope.

Cystometrogram

A cystometrogram measures voiding pressure within the bladder to determine muscle tone and check nerve supply. A calibrated recording tidal irrigator cystometer is used for this measurement. The patient should feel a desire to void when 350 mL of solution is put into the bladder. Carbon dioxide gas is used with some electronic transducers or radio pressure gauges. The normal maximum capacity of the bladder is 450 to 550 mL. Normal bladder pressure is 40 to 50 mL of water. If the problem is neurogenic, the cystometric findings are not higher than normal. If the problem is a hypertonic bladder, these measurements are higher than normal.

Cystoscopy

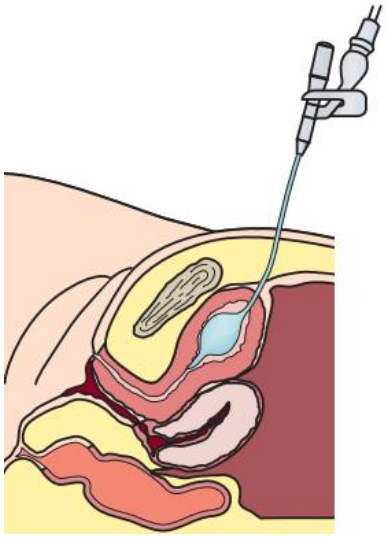
Cysto is a visual examination of the interior walls and contents of the bladder. This term is used broadly because various concurrent procedures may be carried out by using specially designed instruments through the cystoscope. Complete cysto and litholapaxy have been described. A plain cysto is a routine examination of the bladder. In conjunction with plain cysto, the following procedures also may be performed within the bladder:

- Biopsy of a tumor with a flexible-shaft biopsy forceps to obtain specimens
- Cystogram for diagnostic x-rays after injection of a contrast medium into the bladder
- Blue light cystoscopy with hexaminolevulinate (Cysview)[1]
- Fulguration of a tumor by use of an electrode to destroy tissue
- Resection of or incision into a bladder neck obstruction with a resectoscope
- Coagulation of a hemangioma with an argon laser, vaporization of a superficial tumor of the bladder wall with an Nd:YAG laser, or photodynamic therapy to a solid tumor with an argon-pumped tunable dye laser
- Removal of a foreign body with a flexible-shaft, foreign-body forceps
- Insertion of interstitial radionuclide seeds

Suprapubic Cystostomy

With a suprapubic cystostomy, urinary drainage from the bladder is established via a catheter inserted through a suprapubic incision or trocar puncture into the bladder (Fig. 35.22). If the bladder or urethra is injured by trauma associated with bony and soft tissue injuries of the pelvis, the bladder may be drained with a catheter placed above the pubic arch. This method of drainage is also preferred after some ureteral, bladder, prostatic, and urethral surgical procedures to decrease tension on sutures, ensure a patent route for urinary drainage, and minimize urinary retention.

A suprapubic catheter also can be used when the surgeon wants the patient to void some urine voluntarily via the urethra to maintain urethral function and tone, such as after bladder or vaginal repairs. Suprapubic catheters are connected to a sterile, closed, constant drainage system before the patient leaves the OR.



• **Fig. 35.22** Suprapubic cystostomy for urinary drainage.

The following are the most commonly used catheters for cystostomy drainage:

- Foley, 30-mL balloon, sizes 20, 22, or 24 Fr
- Foley, 5-mL balloon, 24 Fr, three-way irrigating catheter (third lumen can be used for continuous irrigation)
- Bonanno suprapubic catheter

Cutaneous Vesicostomy

In a cutaneous vesicostomy, urinary drainage is established directly from the bladder into a collecting device affixed on the abdomen rather than through a suprapubic catheter. The bladder is opened through a transverse suprapubic incision, and a flap is raised at the dome. A skin flap is raised in the midline of the abdomen below the umbilicus. The bladder flap is sutured to the defect created in the skin and then covered with the skin flap. A transparent adhering skin dressing and collection device form a seal around the resultant bladder stoma. A cutaneous vesicostomy may preserve renal function and/or improve upper urinary tract structure in patients with a neurogenic or atonic bladder, urinary incontinence, or bladder outlet obstruction.

Cystotomy and Cystoplasty

An incision into the urinary bladder through a suprapubic incision (cystotomy) may be performed to repair (cystoplasty) a bladder laceration or rupture as a result of trauma or a defect in the bladder wall.[4] Various techniques are used to restore the capacity and function of the bladder. Free fascial grafts, seromuscular grafts, myouterine flaps, and segments of stomach, ileum, or sigmoid colon are used to close defects.

To stimulate regeneration of tissue, the defect may be covered with peritoneum, omentum, lyophilized human dura, gelatin sponge, or a biodegradable or synthetic material. The bladder is also incised to perform a Y-V–plasty to relieve a stricture or contracture of the bladder neck by broadening the outlet of the bladder into the urethra.

Cystectomy

In a cystectomy, the bladder is removed for invasive malignant disease. The bladder can be removed by an open procedure or by robot-assisted laparoscopy. A radical total cystectomy with en bloc pelvic lymph node dissection is usually performed. The neurovascular bundle, which is required for penile erection, may be preserved in a male patient as possible, or a penile prosthesis may be implanted during a subsequent surgical procedure.

A salvage or partial cystectomy with intraoperative radiation therapy may be an alternative to a total cystectomy. If a urinary diversion procedure (previously described) has not been performed before removal of the bladder, transplantation of the ureters into the skin or into the intestinal tract for urinary drainage is required at the time of cystectomy. A gastrocystoplasty may be the procedure of choice after a partial cystectomy, especially in a patient with impaired renal function.

Continent Urinary Diversion Procedures

The ureters may be permanently or temporarily transplanted to maintain the patency of urinary excretion from the body. The bladder may be bypassed or absent. Bilateral transplantation for permanent urinary diversion is performed when bladder function is impaired by neoplasm, chronic infection, congenital anomaly, trauma, or other cause.

The procedure follows completion of a total cystectomy (removal of the bladder), a radical cystoprostatectomy in a male patient, or radical hysterectomy with salpingo-oophorectomy and cystectomy in a female patient, with or without pelvic lymphadenectomy. The ureters may be implanted into the intestinal wall, but more commonly they are transplanted to an isolated loop or detubularized segment of intestine that becomes a reservoir for urine. Ideally, a urinary reservoir collects and stores urine and expels it under voluntary control (i.e., functions as the lower urinary tract).

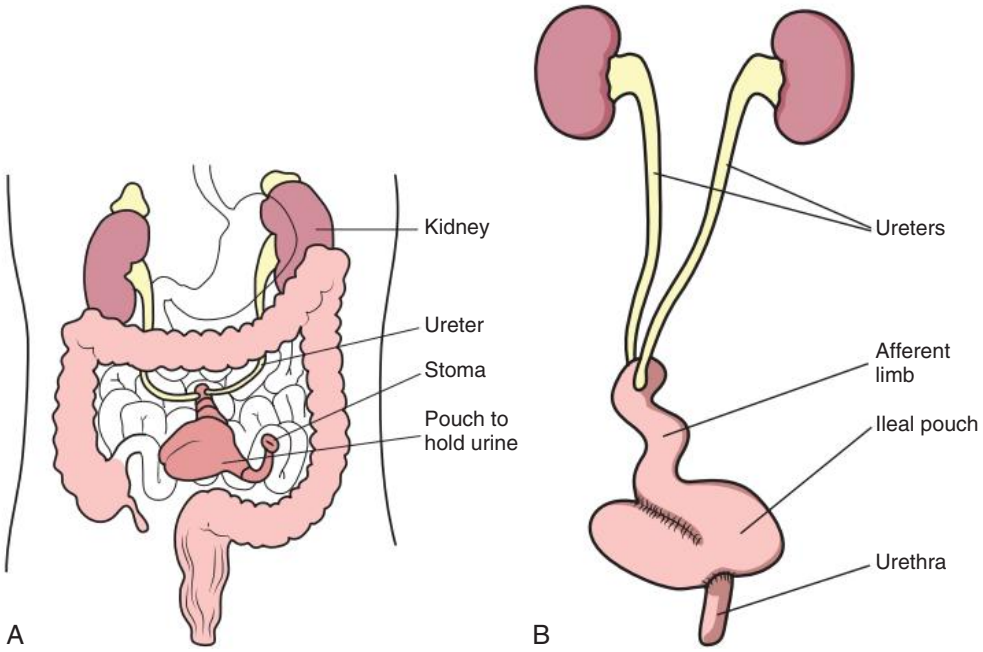
The upper urinary tract should be protected from urine reflux, which can lead to kidney infection. Normal renal function and electrolyte balance also must be preserved. These objectives are not easily attained. Various procedures are used for urinary diversion.

With a continent reservoir, an intestinal pouch is created with bilateral antirefluxing ureteroenteric anastomoses. This high-capacity (up to 800 mL), low-pressure pouch provides an intraabdominal reservoir (**neobladder**) for the storage of urine. A one-way outflow valve provides continence (i.e., the ability to control function). A cutaneous stoma also may be created to empty the reservoir (Fig. 35.23, *A*). The procedure is performed through a low midline incision.

Several techniques are used to create the reservoir from a segment of ileum. Anastomoses may be stapled or sutured to reestablish intestinal continuity. Some types use the appendix as the external conduit. For some procedures, the umbilicus can be used as the stoma site. This is done for cosmesis, particularly in children.

Although creating a continent reservoir is a lengthy surgical procedure, the resultant quality of life for the patient makes this procedure, which prevents involuntary urinary leakage, the procedure of choice unless contraindicated by the patient's tolerance or pathologic condition. Two components are important to the creation of a continent reservoir: (1) a urinary collection reservoir is created from segments of bowel and (2) a catheterizable stoma is fashioned on the abdomen or in the umbilicus.

Indiana Pouch. The Indiana pouch, developed in 1987, is constructed by mobilizing a segment (6 to 8 inches [15 to 20 cm]) of terminal ileum, cecum, and ascending colon. The ureters are anastomosed to the colonic segment, inferiorly on each side of the pouch, to prevent reflux. The terminal ileum is exteriorized to form a continent stoma for self-catheterization. This is the most common form to date and demonstrates a 93% continence rate during the day.



• **Fig. 35.23** Urinary diversion. **A,** Continent ileal reservoir with stoma. **B,** Studer pouch connected to urethra (orthotopic).

Kock Pouch. With a Kock pouch, developed in 1982, a U-shaped pouch is created from a segment (28 to 32 inches [70 to 80 cm]) of ileum. Nipple valves are created on two sides by intussusception (i.e., a portion of ileum is ensheathed in another portion). The afferent inflow valve prevents reflux. The ureters are anastomosed end-to-side distally near this inflow valve. The efferent outflow valve provides continence.

Absorbable staples and/or mesh are used to help stabilize the valves. The reservoir will gradually increase in capacity to as much as 750 to 800 mL of urine. The patient does not wear a collection device, but must use a catheter every 4 to 6 hours to empty the reservoir through the exteriorized cutaneous stoma. This form can have as high as a 25% failure rate.

Mainz II Pouch. With a Mainz pouch, a reservoir is formed by mobilizing a segment (4 to 8 inches [10 to 20 cm]) of cecum and ascending colon and detubularizing two small segments of equal length of terminal ileum. The walls of the pouch are formed by anastomoses of the ascending colon and cecum with the ileal segments. The ureters are implanted into the ascending colon in an antirefluxive manner. To increase capacity, this pouch can be anastomosed to the urinary bladder remnant after partial cystectomy.

Mitrofanoff Technique. Continent diversion can be achieved by inverting the appendix into the cecum and exteriorizing the intussuscepted appendiceal mucosa to form a continent stoma for self-catheterization. In the absence of a healthy appendix, an additional segment of ileum (3 to 5 inches [8 to 13 cm]) can be used to create a continent umbilical stoma.

Ureterosigmoidostomy. With a ureterosigmoidostomy, the ureters may be anastomosed to a nonrefluxing segment of sigmoid colon. Urine diverted into the colon may cause physiologic complications, making this alternative for permanent urinary diversion the least desirable therapeutically. The transverse colon is commonly used. However, the patient does retain an intact body image.

Orthotopic Neobladder. Orthotopic neobladder is constructed from a segment of ileum or colon and anastomosed directly to the urethra. Care is taken to preserve the urethral musculature. To empty the bladder, the patient increases the abdominal pressure while relaxing the external sphincter.

Studer Pouch. First introduced in 1989, it is commonly used today as a neobladder that is anastomosed to the urethra. This type of pouch works well with short ureter segments (Fig. 35.23, *B*).

Camey Pouch. An orthotopic ileocystoplasty can be performed on a male patient if a U-shaped segment (approximately 16 inches [41 cm]) of ileum reaches the urethra at the pelvic floor without tension. The ureters are anastomosed through small enterostomies to the distal ends of the mobilized and divided ileum.

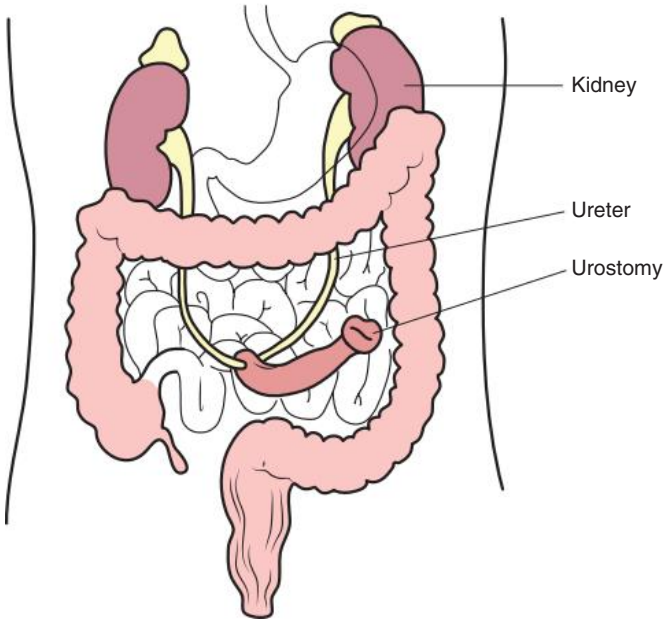
A urethroileal anastomosis in the midsection of the ileal reservoir allows the patient to void through the urethra. Continence is maintained by spontaneous contraction around the outflow valve at the site of anastomosis. Micturition occurs by relaxation of the perineal muscles and a Valsalva maneuver (i.e., a forced expiratory effort). Urine passes out the urethra.

Augmentation Bladder. Scientists in Germany have performed tests in pigs that demonstrate that bladder cells can be grown in a matrix of bovine collagen to create a new bladder. A segment of ileum is harvested and stripped of its mucosal layer. The epithelium-impregnated matrix acts as a scaffold for the growing cells, and blood vessels begin to form. The scientists believe that this is a step in augmenting a deficient bladder at this time but hope that this work will form the basis of total bladder replacement. Scaffolds can be used for the replacement of surgical mesh and can be adapted to repair other body parts.

Transcutaneous Urinary Diversion

Ileal Conduit. In the creation of an ileal conduit, a procedure popularized by Bricker in the 1950s, both ureters are anastomosed to an isolated segment of the terminal ileum near its proximal end. The distal end is everted and sutured to a predetermined stomal site on the skin, usually on the right side of the abdomen below the waist.

A urinary collection appliance is secured over the stoma before the patient leaves the OR. An ileal conduit with an incontinent



• **Fig. 35.24** Ileal conduit with stoma. Requires urostomy bag. Not continent.

external stoma (Fig. 35.24) creates the psychologic stress of an altered body image for the patient, but it may be the procedure of choice for the patient who will receive systemic chemotherapy after radical cystectomy. As a secondary procedure after chemotherapy, an incontinent ileal conduit may be converted to a continent ileal reservoir.

Cutaneous Ureterostomy. To create a cutaneous ureterostomy, the end of the ureter closest to the bladder is brought through the abdominal wall to the skin. This procedure can be performed unilaterally or bilaterally with a single cutaneous stoma or double-loop stoma. The patient must be fitted postoperatively with an appliance for collecting urine directly from the ureter to the exterior of the body.

This procedure may be performed as a temporary emergency measure after trauma to the bladder, such as a ruptured bladder.

Urinary Incontinence

Involuntary, uncontrollable voiding may accompany congenital or acquired physiologic conditions, such as a loss of bladder control after spinal cord injury or neurogenic disease. Urinary incontinence may develop in males because of loss of sphincter control after prostatectomy and in females after obstetric injury, radiation therapy, or severe pelvic fractures. Surgical intervention is often necessary for stress incontinence—the intermittent leakage of urine as a result of a sudden increase in intraabdominal pressure (e.g., during coughing or sneezing) on weakened urethral sphincter muscles at the bladder neck. Various surgical procedures are performed as determined by urodynamics.

Gynecologists perform some bladder suspension procedures (e.g., Marshall-Marchetti-Krantz suprapubic vesicourethral suspension), and urologists perform other procedures. Laparoscopic approaches have been developed for bladder neck suspension. Surgical procedures that suspend, support, or reposition the bladder can correct urinary incontinence or improve urinary continence.

Transvaginal Bladder Neck Suspension

Pereyra Procedure. In the Pereyra procedure, the bladder neck is elevated with sutures suspended from the anterior rectus fascia. The primary difference between this procedure and the Stamey procedure is that a Pereyra ligature carrier needle is passed blindly down through the retropubic space and out into the vagina.

Both procedures relocate the proximal urethra and bladder neck into the zone of intraabdominal pressure without necessitating open pelvic surgery. The Pereyra procedure is used for uncomplicated recurrent urinary stress incontinence and is 80% effective for long-term resolution of urinary leakage.

Stamey Procedure. In the Stamey procedure, sutures are placed on both sides of the urethrovesical junction from the anterior rectus fascia into the vagina. The patient is positioned in a modified lithotomy position so the legs extend laterally to flatten the lower abdomen. Short suprapubic incisions, right and left of midline, are extended to the anterior rectus fascia. The vagina is incised transversely and dissected from the urethra to expose the trigone of the bladder. The urethrovesical junction is located by palpating the balloon of the Foley catheter inserted into the bladder. A straight or angled Stamey needle is passed through the rectus fascia, along the internal vesicle neck, and out through the vaginal incision.

The cysto equipment should be set up on a separate sterile table, because contamination of the eyepiece is unavoidable. A cystoscope is inserted to ascertain correct needle placement without injury to the bladder. A heavy nylon suture threaded onto the needle is drawn from the vagina to the suprapubic incision; the needle is inserted again. The vaginal end of the suture is passed through a 1cm length of polyester tubular graft before it is threaded onto the needle. When the suture is drawn to the abdominal wall, it establishes a suspending loop on one side of the bladder neck. The suture is tied over the anterior rectus fascia with enough tension to elevate the bladder neck by traction on the adjacent vaginal fascia. This procedure is repeated on the contralateral side.

Artificial Urinary Sphincter

A prosthesis may be implanted to apply pressure to the urethra to maintain continence between periods of voiding. The pressure-regulating mechanism has a reservoir, urethral cuff, and a pump constructed of silicone rubber. A reservoir with a desired predetermined pressure is positioned intraabdominally beside the bladder.

Depending on the preferred surgical approach, the cuff encircles either the bladder neck or the bulbous urethra. The pump is placed in the subcutaneous tissue of the scrotum (in males) or labium (in females). A control assembly lies subcutaneously adjacent to the external inguinal ring; tubing connects the components. A sterile radiopaque isotonic solution is used to fill the prosthesis. When a patient squeezes the pump, solution is transferred from the cuff into the reservoir, thus releasing pressure on the urethra and permitting urine to flow.

Neurostimulation for Bladder Control

The detrusor muscle can be unstable and require electrostimulation. Electrostimulation simulates the signals from S2-S4 to mimic the autonomic activity necessary for bladder control. The patient is placed prone, and the leads are placed in the back through an incision. On completion of the lead placement, the patient is placed in a lateral position. A pocket is created in the flank for the small generator. Postoperatively the patient is taught to avoid metal detectors, theft devices in stores, and any large magnets. The patient is given a special magnet to turn the device on or off as needed.

Periurethral Injection of Bulking Agent

Collagen or Teflon may be injected into the tissues surrounding the urethra proximal to the external sphincter. The injection swells

the tissue, narrowing the urethra sufficiently for sphincteric control. This procedure is performed in select patients with moderate to severe urinary incontinence, such as in a male after a transurethral resection or a female in whom a suspension procedure has been unsuccessful. The injection is made transurethrally with a flexible syringe through a fiberoptic cystourethroscope. A suprapubic catheter is used for 3 to 5 days postoperatively to allow some voluntary passage of urine from the urethra. Postoperative complications include urinary retention, urethral fistulas, and infection.

Bladder Flap Urethroplasty

A bladder flap urethroplasty procedure is advisable when urodynamics show a resistance to urinary flow in a female with a neurogenic bladder. A lesion of the nervous system can cause bladder dysfunction.

Urethra

The urethra functions as the outlet for urine to pass from the bladder. Obstruction or dysfunction of the urethra may cause urinary retention or incontinence. Enlargement of the prostate may cause obstruction. Gonorrhea, other disease processes, or traumatic injury may cause a stricture.

Perineal Urethrostomy

When indwelling or intermittent urethral catheterization is contraindicated in a male patient with an obstructed or traumatized urethra, urinary drainage may be established through a perineal incision. An indwelling catheter is inserted into the bladder through an incision into the membranous urethra. Male patients may have a perineal urethrostomy after a total penectomy.

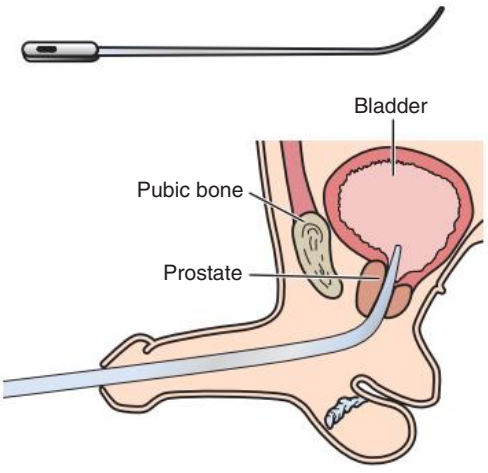
Urethral Dilation

Periodic dilation may be necessary for weeks to years after an infection or a trauma that has caused a urethral stricture. Balloon dilators, woven filiforms and followers, bougies, or metal sounds are used. If the latter are preferred, curved metal Van Buren sounds (Fig. 35.25) are used to dilate a male urethra; straight sounds are used for a female urethra. A short urethral stent may be inserted.

Urethral Stent

To prevent collapse of the lumen caused by stricture, a spring-loaded stainless steel mesh stent can be placed into the male urethra via a cystoscope at a level proximal to the bulbar urethra and distal to the external urinary sphincter. The stricture is measured and dilated or incised by internal urethrotomy. To be effective, the stent selected should measure 1 cm greater than the length of the stricture.

A special deployment applicator is used to place the stent in the urethra. The stent becomes a permanent urethral implant and is useful for males who have benign prostatic hypertrophy. It is contraindicated in bleeding disorders or for males who are receiving anticoagulation therapy. After the procedure, antibiotics are administered as a prophylactic measure.



• **Fig. 35.25** Van Buren sound is curved for safe use in male urethral dilation.

Urethrotomy

An Otis urethrotome may be used to cut into a urethral stricture. After the instrument is passed into the urethra, the blade is released to cut the stricture. If a specimen of the urethra is taken for biopsy, a rigid biopsy forceps is used through a cystourethroscope. This scope also is used with a laser to open a urethral stricture.

Urethroplasty

Reestablishment of continuity without stricture is the ultimate objective after a traumatic urethral injury and is usually associated with pelvic fractures in males. Scrotal-inlay urethroplasty or another method of urethral reconstruction is usually delayed until the extent of injury can be fully evaluated by urethrograms. A suprapubic cystostomy catheter inserted as an emergency measure can maintain urinary drainage for several weeks to months. Insertion of a urethral catheter into a ruptured urethra in the immediate posttraumatic period can produce periurethral infection, stricture, and other irreparable damage.

Perineum and Genital Surface Procedures

Ablation of Condylomata Acuminata

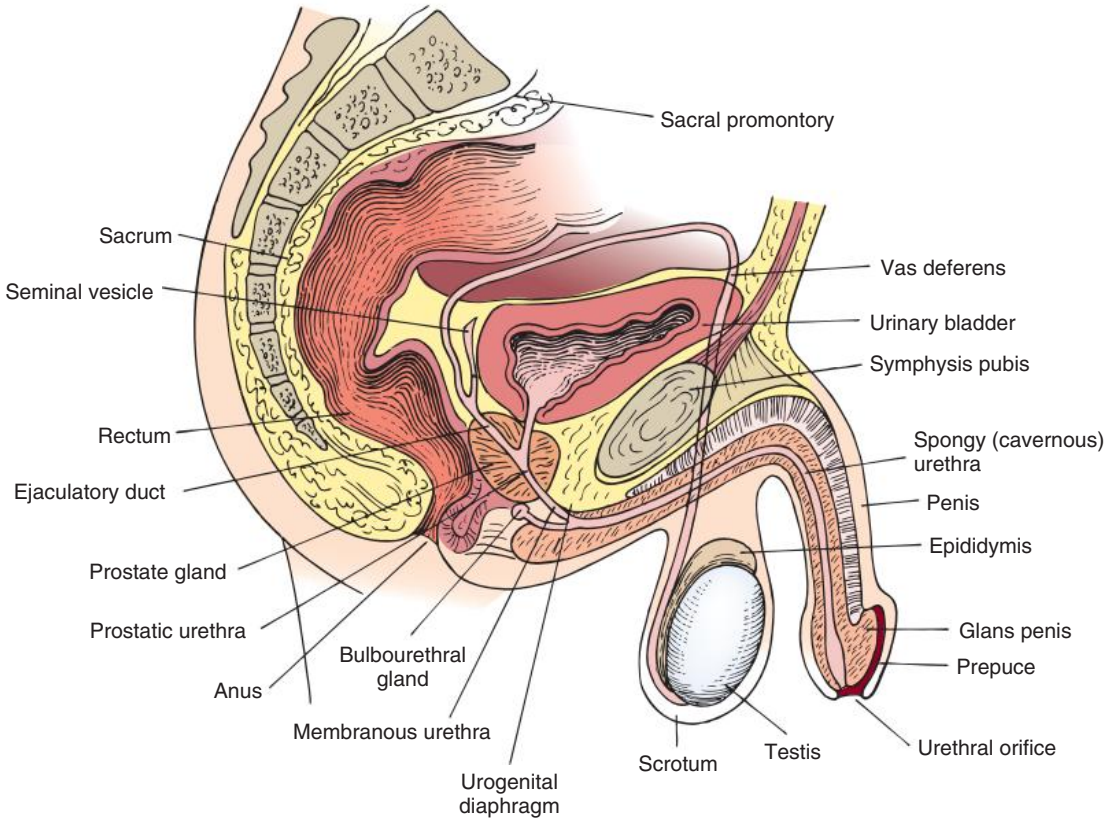
Condylomata are caused by a sexually transmitted human papillomavirus (HPV). Referred to as genital warts, this condition can affect the genitalia, perineum, perianal region, and mucous membranes of males and females. The incubation period is 1 to 2 months after exposure, but longer periods have been reported. HPV has been implicated in cervical cancer.

In an office setting or OR and with the patient under local anesthesia, condylomata are surgically ablated with a carbon dioxide (CO_2) laser. Before the procedure, 3% acetic acid is applied to the area to make the lesions visible by causing them to turn white and raised. As with all other laser procedures, laser precautions (e.g., appropriate eyewear for all persons in the room, proper instrumentation) are followed.

Viral mutation in laser plume has been documented, and personal protective equipment is required. Appropriate laser eyewear and masks should be worn by the staff and the patient to prevent contamination of respiratory and ocular mucosa with virus-laden plume. The eyewear also protects from laser light. Surgical plume is removed and filtered from the surgical field with an evacuation device

Male Reproductive Organs

The primary functions of the male reproductive organs are procreation, sexual gratification, and hormone secretion. These organs are both internal and external (Fig. 35.26).



• **Fig. 35.26** Male reproductive organs in sagittal section.

Testes

The testes, or testicles, are both endocrine glands and male reproductive organs and are bilaterally suspended in the scrotum, which is divided by a membranous septum referred to as the median raphe. The testes contain a series of tubules, where spermatozoa are formed. As the sperm mature they move to the epididymis, where they are stored until ejaculated. The epididymis secretes seminal fluid to carry the mature sperm through the vas deferens between the lobes of the prostate into the seminal vesicles. The ejaculatory ducts empty sperm and prostatic secretions into the posterior urethra.

The Leydig cells of the testes secrete hormones that influence growth and development, sexual activity, the production of spermatozoa, and the development of secondary sex characteristics. Disorders in or around one testis or both testes that inhibit sexual activity or reproductive capability or cause discomfort in the scrotum may necessitate a surgical procedure. If both testes are excised (a bilateral orchiectomy), the patient becomes sterile and deficient in male hormones.

Male patients should be instructed to conduct a monthly testicular self-examination (TSE), which should be completed when the scrotum is relaxed (after a warm bath or shower). When performing a TSE, each testis is gently rolled between the thumb and forefingers. The testis should feel smooth and oval, should be without lumps or hardened areas, and should move freely within the scrotal sac. Palpation should be pain free. Testicular cancer affects males in the 15 to 35 year age range. Studies have shown that 63% of the males studied did not practice TSE.

Orchiectomy

A bilateral orchiectomy may be performed in patients with prostatic cancer to alter the hormonal environment. After this relatively simple procedure, control of the disease is attempted before the urologist considers other endocrine surgery, such as an adrenalectomy. Psychologic preparation is important to help the patient accept the sterilization and the other body changes (e.g., breast enlargement) that may occur as a result of the alteration in the hormonal system.

In this procedure, bilateral oblique incisions in the inguinal canals extend into the upper anterior surface of the scrotum over the testes. The testes are removed from the scrotum after ligation of the spermatic cords at the external or internal inguinal rings. Silicone rubber prostheses may be implanted in the scrotal sac to improve aesthetic appearance, which helps with the psychologic rehabilitation of the patient.

The removal of one testis (unilateral orchiectomy) does not sterilize the patient. This procedure may be indicated after traumatic injury or infection, but it is more commonly performed to remove a tumor. Primary testicular tumors may be right or left-sided; germ cell tumors may develop bilaterally. Accurate histologic findings and clinical evaluations of the type of tumor and stage of disease are mandatory for determining the appropriate therapy. CT and lymphangiography or lymphoscintigraphy are valuable diagnostic tools.

Unilateral radical orchiectomy via an inguinal incision may be followed by radiation or chemotherapy and retroperitoneal lymph node dissection. The spermatic cord and vas deferens are ligated and divided separately at the internal ring so these structures can be identified if further dissection is needed for metastatic disease.

Retroperitoneal Lymphadenectomy

A transabdominal midline incision is made for exposure of the lymph nodes and sympathetic nerve fibers in the paraaortic plane, usually along the anterolateral aspect of the aorta in the retroperitoneal space. A unilateral lymphadenectomy usually is performed on the ipsilateral (same) side as the tumor unless regional metastases have spread via lymphatic invasion, in which case a bilateral dissection is indicated. If possible, the neurovascular bundles extending from the hypogastric plexus to the corporeal tissues of the penis are preserved. These nerve fibers are identified and placed in vessel loops before lymphadenectomy is carried out, thus preserving ejaculatory function.

Scrotal-Testicular Trauma

An injury may require exploration of the scrotum to ligate bleeding vessels or insert a Penrose drain. Infection is likely to develop after a penetrating wound; therefore extraperitoneal spaces in the scrotum must be drained thoroughly.

Testicular Torsion

The testicle can become twisted on the spermatic cord, causing extreme pain. Immediate correction is necessary or the testicle will become ischemic and tissue death will follow. Manual detorsion may be tried, but surgical intervention is indicated if reduction is not successful within 1 hour of onset.

Hydrocelectomy

A hydrocele is an accumulation of peritoneal fluid in the sac of the tunica vaginalis of the testis. Through an anterior incision into the scrotum, the hydrocele sac is dissected away from the testis and removed from the scrotum. There is a 5% incidence in newborns, most of which will resolve spontaneously. Hydrocele is more common in preterm babies, because they may have been born before 32 to 38 weeks' gestation (the average gestational age at which closure vaginalis occurs). Hydrocele is also more common in children who have increased fluid in the peritoneum (i.e., ventriculoperitoneal shunt to drain hydrocephalus or peritoneal dialysis).

Spermatocelectomy

A small mass attached to the epididymis may be palpated in the scrotum superior to the testis. This painless cyst is a collection of testicular fluid and sperm cells. These cysts are repaired if they become annoying to the patient.

Varicocele Ligation

Dilation of the spermatic veins in the pampiniform plexus of the spermatic cord can cause a soft, elastic, often uncomfortable swelling in the scrotum. This condition, known as a varicocele, occurs more often on the left side. It can cause a loss in testicular mass and a decrease of sperm density associated with male infertility caused by increased temperature. Ligation of the spermatic vein can improve sperm count if the testis has not atrophied.

The spermatic vein is ligated above the inguinal canal lateral to the inferior epigastric vessels or in the retroperitoneal space lateral to the iliac artery. In the latter approach, a transverse abdominal incision starts at the anterior superior iliac spine and extends toward the lateral aspect of the rectus abdominis muscle. The hemiscrotum must be manually emptied of all blood before the vein is ligated or the varicocele may persist postoperatively.

Laparoscopic approaches have been developed for spermatic vein ligation. In such a procedure, the internal inguinal ring is located laparoscopically and the spermatic cord and blood vessels are identified. The spermatic vein is dissected free, ligated with two endoscopic clips, and cut between the clips with endoscopic scissors. Most patients are able to return to work within 2 days of the procedure.

Vas Deferens

The vasa deferentia are the small fibromuscular excretory ducts that carry sperm upward through the spermatic cords from the epididymides (which lie along the upper portion of each testis) to the seminal vesicles, the pouch-like glands in front of the urinary bladder near the prostate gland. Interruption of or obstruction to a vas deferens inhibits normal spermatogenesis.

Vasectomy

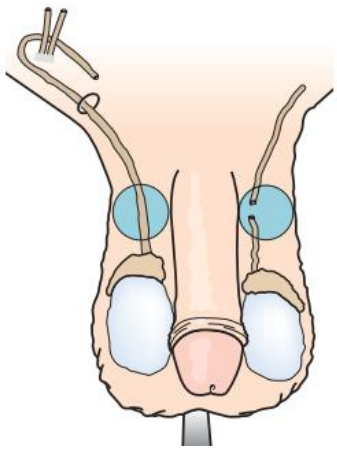
Elective bilateral vasectomy is an established method of male sterilization and is usually performed as an ambulatory surgical procedure. In a vasectomy, a segment of each vas deferens is removed and sent to the pathology department in individually labeled specimen cups (Fig. 35.27). Depending on the preference of the urologist, the cut ends are either ligated with suture or clips or the endothelium of the lumen is coagulated with the ESU.

Techniques vary, but all patients should be informed that spontaneous regeneration of a severed vas deferens does occur in a small percentage of patients and that sterility is not immediate. Follow-up care includes semen testing for sperm count; repeat testing should continue until no sperm is found in the seminal fluid. Patient teaching includes instructions to use alternative birth control methods until the seminal fluid contains no sperm.

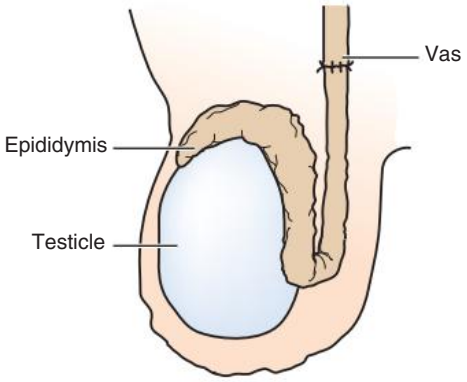
Vasovasostomy

Recannulization of the vas deferens for the restoration of fertility requires an unobstructed anastomosis. The vas deferens has a tough 2-mm outer diameter and an inner diameter of 1 mm or less at the distal end, as well as dilation at the proximal end. This makes precise anastomosis under the operating microscope preferable to nonmicrosurgical techniques, in which it is difficult to see the lumen of the vas deferens on the distal side. One-layer microscopic anastomosis and splinting techniques for a vasectomy reversal often result in a stricture caused by scarring within the lumen of the vas deferens, which inhibits the passage of sperm.

After a scrotal incision is made to expose the vas deferens above and below the site of previous ligation, the two ends are cut to



• **Fig. 35.27** Completed vasectomy.



• **Fig. 35.28** Vasovasostomy.

excise scar tissue and open the lumen. Under magnification of the operating microscope, interrupted sutures are placed in the mucosal lining of the lumen to create a fluid-tight anastomosis (Fig. 35.28). Muscularis is approximated separately. A CO_2 milliwatt laser may be used to weld tissue to overcome the scarring and stricture that may be associated with suturing. Sperm counts return to normal soon after the surgical procedure.

Male Infertility

Primary infertility is diagnosed after a failure to conceive during a period of 1 year of unprotected sexual intercourse. Causes of infertility include abnormality in the female and/or male reproductive systems. Male infertility can be the result of deficient sperm production, obstructed sperm passage, a mechanical inability to pass sperm, hormonal imbalance, testicular disease or injury, a low sperm count, and antibodies against sperm.

The history and physical examination should be concurrent with the female partner's gynecologic evaluation. Issues assessed should include sexual history, previous pregnancies, health history, the use of lubricants, drug use, radiation exposure, and timing and frequency of intercourse. Childhood illnesses such as high fevers and viral infections may be factors. A previous sexually transmitted disease can cause scarring that prevents the transport of sperm. Endocrine testing includes follicle-stimulating hormone, luteinizing hormone, testosterone, and prolactin levels. Urinalysis is performed to rule out infection and/or retrograde ejaculation.

The semen analysis includes determining ejaculate volume, sperm count and motility, morphology, and the presence or absence of white blood cells or red blood cells in the seminal fluid. The patient is advised to abstain from sexual intercourse for 2 to 3 days before the testing is performed.

Prostate Gland

The prostate gland, a musculoglandular organ in males, is encased in a fibrous capsule and surrounds the posterior urethra at the bladder neck. It is divided into five lobes. The arterial supply is derived from the pudendal, inferior vesicle, and hemorrhoidal arteries that terminate into two large groups of bilateral prostatic vessels. The venous drainage is through the dorsal vein divided into three bundles bilaterally. The innervation is from parasympathetic fibers arising at S2-S4 and from the sympathetic nerve fibers at the thoracolumbar nerve from the hypogastric nerve. This forms the pelvic plexus that innervates the bladder, ureters, seminal vesicles, prostate, and cavernous nerves of the corpus cavernosa of the penis. Lymphatics drain into the internal iliac and sacral nodes into the intestinal trunk to the cisterna chyli.

The normal function of the prostate gland is to provide alkaline secretions to the seminal fluid for sperm mobility during ejaculation. The standard of care includes an annual digital prostate examination and prostate-specific antigen (PSA) testing after 55 years of age.[5]

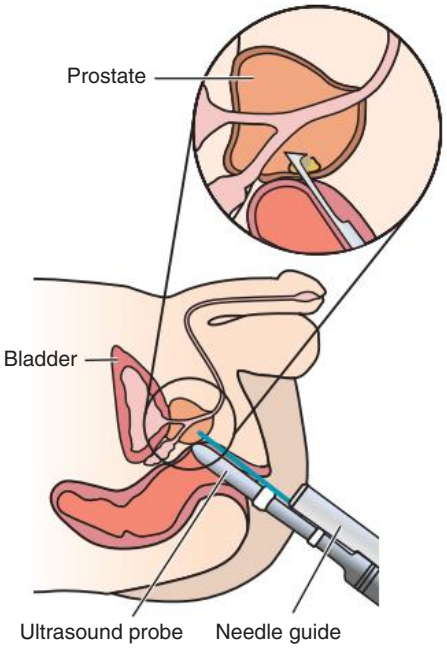
Although the prostate gland normally weighs 20 g, in most men it will enlarge to some degree by 50 years of age. Fifty percent of all men older than 80 years will have prostatic cancer. Enlargement of the prostate gland can obstruct the urethra and interfere with voiding; this difficulty in voiding is what most often brings men with prostatic disease to the urologist. The urologist will examine the prostate and order a PSA blood test. If the tests indicate benign prostatic hypertrophy/hyperplasia (BPH), surgery is not the first treatment method of choice.

Conservative treatment for benign enlargement of the prostate includes administration of oral tamsulosin (Flomax). If the prostate does not respond to drug therapy by shrinking, then balloon dilation, stenting, or other surgical procedure may be indicated.

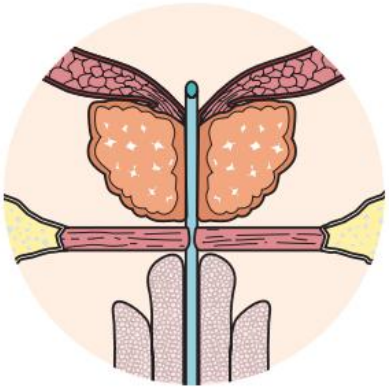
The entire prostate gland or one or more lobes can be resected from its capsule transurethrally (transurethral resection of the prostate [TURP]). Prostatectomy also can be performed robotically or through a suprapubic or retropubic abdominal approach or a perineal incision.

A radical prostatectomy, performed through a retropubic abdominal or perineal incision, includes extirpation of the prostate, periprostatic tissue, seminal vesicles, and vas ampullae en bloc. The approach and procedure depend on the urologist's preference for removing the type of pathologic condition.

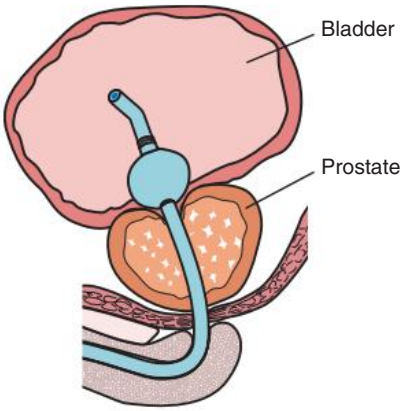
Transrectal aspiration, core biopsies, or ultrasonography helps establish the correct diagnosis (Fig. 35.29). Prostatic carcinoma may be treated by surgical removal, interstitial and external beam radiation, chemotherapy, and/or hormonal therapy. Management depends on the stage of the disease and the age and condition of the patient. Carcinoma of the prostate is the second most common cause of cancer-related deaths in men in the United States.



• **Fig. 35.29** Transrectal ultrasound-guided prostatic biopsy.



• **Fig. 35.30** Prostatic stent.



• **Fig. 35.31** Transurethral microwave thermotherapy (TUMT) probe delivers microwaves to the prostate tumor.

BPH is a common indication for prostate intervention in men older than 50 years if the prostate symptoms do not respond to drug therapy. Men younger than 50 years may not qualify for definitive treatment if prostate enlargement is caused by prostatitis. Conservative antibiotic therapy is the treatment of choice.

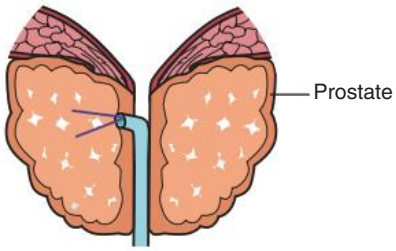
Balloon Dilation and Stenting of Prostatic Urethra

During a cystoscopy, a balloon dilation probe can be inserted into the urethra and expanded to relieve obstruction caused by prostatic hypertrophy. One or more titanium stents can be deployed to maintain patency of the lumen. The stent remains in the lumen and becomes overgrown with urothelium. This procedure permanently relieves urinary retention (Fig. 35.30).

Transurethral Microwave Thermotherapy

With transurethral microwave thermotherapy (TUMT), ultrasound guidance is used to insert a microwave probe into the urethra to the level of the prostate blockage (Fig. 35.31). Microwaves are generated by a console and transmitted to the distal aspect of the probe. Heat generated by the microwave probe is absorbed by the urethral portion of the prostate for 1 hour.

The probe is cooled with water circulation at 68° F (20° C) to protect nearby structures. A rectal probe is used to record rectal temperature. The heated tissue sloughs, which causes the urethral stricture to release. Most patients can void with ease, although a few patients require a Foley catheter for several days postoperatively.



• **Fig. 35.32** Transurethral needle ablation (TUNA) probe delivers selective radiofrequencies to prostate via directed needles.

Transurethral Needle Ablation

With transurethral needle ablation (TUNA), an ambulatory procedure, cystoscopic guidance is used to insert a probe into the urethra to the level of the prostate stricture. Two small needles are passed from the side of the telescopic probe into the hypertrophied prostatic tissue (Fig. 35.32). Radio waves are transmitted selectively into the tissue via the needles.

Prostatic tissue in contact with the needles is ablated; nearby structures, such as nerves and vessels, are spared. Up to six select areas of stricture can be precisely ablated in the same procedure. Each application creates a defect in the prostate. The tissue reabsorbs over a period of 3 months, causing the stricture to release. The patient may complain of urinary retention or burning on urination for 24 to 96 hours after the procedure. The main side effect is the potential for retrograde ejaculation.

Transurethral Prostatectomy

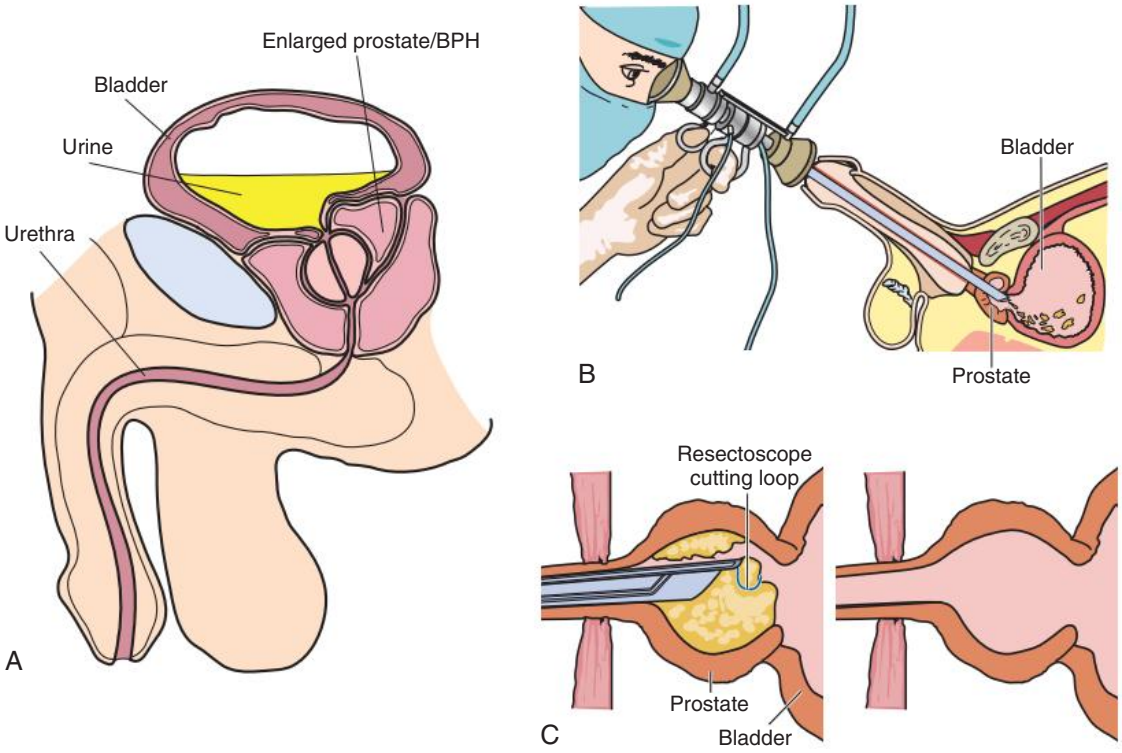
Transurethral resection, also referred to as *transurethral resection of the prostate* (TURP), involves the removal of all or part of the glandular tissue within the prostatic capsule by electroresection through the urethra (Fig. 35.33). A resectoscope, via cysto sheath, is introduced into the prostatic urethra. Using alternating currents from the ESU through the cutting loop electrode, the urologist resects tissue and coagulates bleeding vessels. The bladder is distended with solution to create a working space during resection. Irrigation solution (10 to 12 L) may be needed. Glycine was used with older equipment, but newer bipolar resectoscopes are designed to work with sterile normal saline.

Sterile water as an expansion medium can cause complications related to intravascular hemolysis. Care is taken not to permit the patient to absorb excessive amounts of solution through the prostatic venous sinuses or TUR syndrome may occur. This can cause dilutional hyponatremia less than 125 mEq/L. Glycine is a neurotransmitter inhibitor that is metabolized into glycolic acid and ammonium. Ammonia has been noted to be elevated during TUR syndrome. Risk factors include the following:

- Height of the solution bags (extremes of height increase the amount of pressure of the fluid as it enters the bladder)
- Deep resection (which allows for increased venous absorption of solution)
- Amount of tissue resected in excess of 45 g
- Duration of the procedure (risk increases when the procedure exceeds 90 minutes)

Signs of TUR syndrome include the following:

- Mental confusion
- Nausea and vomiting
- Hypertension followed by hypotension
- Symptoms of fluid overload and pulmonary edema



• **Fig. 35.33 A,** Enlarged prostate. **B,** Transurethral resection of enlarged prostate with resectoscope (TURP). **C,** Obstructive prostate is removed with cutting loop. *BPH,* Benign prostatic hyperplasia.

- Bradycardia and dysrhythmia
- Visual disturbances
- Seizures and twitching
- Coma

Treatment of TUR syndrome includes the following:

- Administration of IV hypertonic saline
- Monitoring of serum sodium levels
- Diuretics

Resected prostatic tissue is collected in an Ellik or other evacuator. After the surgical procedure, tissue fragments must be sent to the pathology department for analysis and weighing. The urologist may insert a three-way 30 or 50-mL Foley catheter for irrigation and hemostasis. The large inflated balloon compresses against the bladder neck fossa to form a tamponade to help control bleeding. Some urologists place the Foley catheter under direct tension by taping the catheter to the patient's leg or abdomen to increase the tamponade effect for hemostasis. The third lumen provides a means for continuous postoperative irrigation to prevent the formation of clots in the bladder.

Benign nodular hyperplasia of glands less than 50 g in size is the usual indication for TURP. This approach has the potential complications of **impotence** and urinary incontinence. The technique is one of the most difficult for a urologist to master. Although electroresection is used most commonly, transurethral incision of small prostate glands (less than 25 g), balloon dilation of the prostate, laser surgery, and cryosurgery are other invasive techniques for treating BPH. TURP may be performed for the diagnosis or treatment of localized cancer.

Suprapubic Prostatectomy

The suprapubic approach for prostatectomy is limited almost exclusively to the removal of a large, benign, hypertrophied gland weighing more than 50 g. Through a midline vertical incision above the symphysis pubis, the superior bladder wall is opened to expose the prostatic urethra (Fig. 35.34, *A*). The prostatic lobes are enucleated with a finger that is inserted through an incision into the mucosa of the urethra. This procedure may be termed transvesicocapsular prostatectomy, because the prostatic capsule is approached through the bladder.

Hemostatic agents are usually packed into the extremely vascular prostatic fossa to help control bleeding. Pressure from the Foley catheter balloon inserted after closure of the urethra also helps obtain hemostasis. A suprapubic cystostomy tube is inserted to facilitate urinary drainage from the bladder during the healing process.

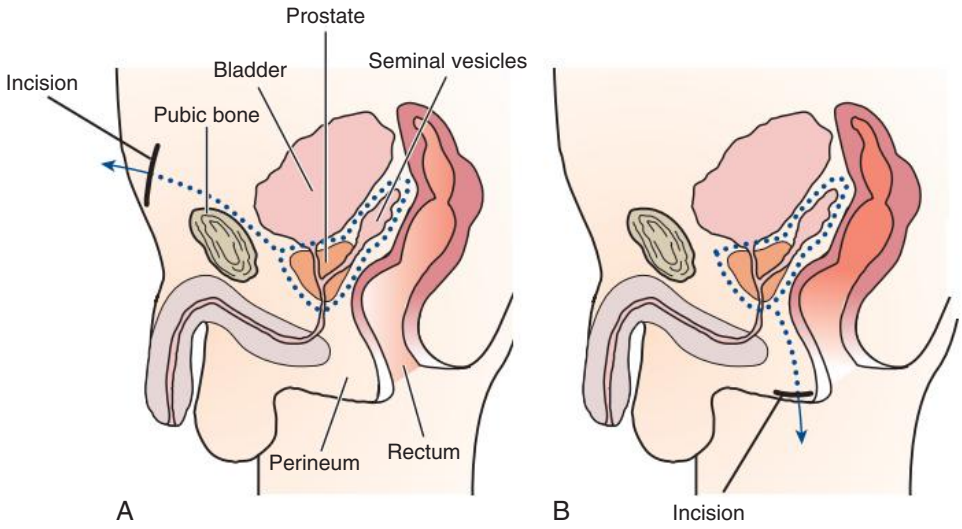
Retropubic Prostatectomy

In the retropubic approach, the prostate gland is exposed below the bladder neck through a vertical or transverse abdominal incision above the symphysis pubis. The bladder is not opened. The gland is removed through an incision in the prostatic capsule; this procedure is called a transcapsular prostatectomy. The periprostatic tissue, seminal vesicles, and vas ampullae also may be excised. This method is common for prostate glands larger than 50 g.

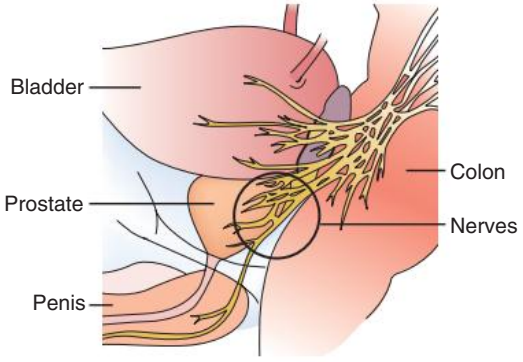
Radical Retropubic Prostatectomy

A limited pelvic lymph node dissection is performed for carcinoma with no evidence of spread beyond the prostatic capsule. This radical procedure may be carried out as initial curative therapy or after transurethral prostatectomy. After dissection of the lymph nodes, one of two approaches may be used to totally remove the prostate:

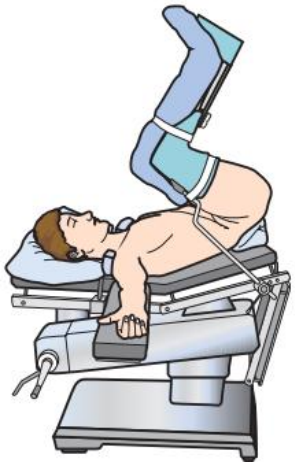
1. *Campbell technique:* An incision is made at the bladder neck, and the urethra is transected. The prostate and periprostatic tissue are widely dissected anterograde from the bladder. The



• **Fig. 35.34** **A,** Suprapubic prostatectomy. **B,** Perineal prostatectomy.



• **Fig. 35.35** Innervation of the male genitourinary organs and the relationship between prostatic and penile nerves.



• **Fig. 35.36** High lithotomy position.

bladder neck is reconstructed for the vesicourethral anastomosis. The patient will be impotent, because the nerves responsible for erection are transected. A penile prosthesis may be implanted.

2. *Walsh technique:* The prostate is resected retrograde beginning at the urethra, working back to the bladder neck. Dissection is carried out close to the prostatic capsule to preserve the neurovascular bundle and thus maintain potency. The vesicourethral anastomosis is completed.

Nerve-sparing procedures have been developed to preserve sexual potency. A device referred to as CaverMap can be used during the open prostatectomy procedure to locate nerves that control erection (Fig. 35.35). A sensor band is placed around the penis, and a handheld device with a nerve-stimulating probe is used to sense nerve impulses responsible for causing erection. Studies performed by the American Urological Association show that between 40% and 70% of radical prostatectomy patients experienced erectile dysfunction of varying degrees after the surgery. Some patients are unable to achieve erection until after 18 months postoperatively. The CaverMap helps locate the nerves but does not ensure the ability to achieve erection postoperatively.

Perineal Prostatectomy

The perineum affords the most direct open surgical approach to the prostate through a relatively avascular field (see Fig. 35.34, *B*). With the patient in an extreme lithotomy position, the perineum is incised between the scrotum and the anal sphincter (Fig. 35.36). The rectum is dissected from the posterior surface of the prostate, or dissection may be carried out between the external anal sphincter and the rectum.

The perineal approach may be used to enucleate the prostate gland from its capsule or for radical cystoprostatectomy. This latter procedure includes removal of the entire prostate gland, its capsule, the seminal vesicles, and a portion of the bladder. The classic radical perineal prostatectomy with pelvic lymph node dissection may be the surgical procedure of choice to reduce the morbidity of prostatic carcinoma. Urinary incontinence and impotence are common outcomes with this procedure. Laparoscopic methods can be used to sample intraabdominal lymph nodes.

Robotic-Assisted Prostatectomy

The robotic-assisted laparoscopic approach used is dependent on the method used to dissect the seminal vesicles and the vas deferens away from the rectum. Enucleation of the prostate is facilitated by traction on the Foley catheter.

Robotic-assisted prostatectomy has become the most commonly performed method of choice. When it was initially started

about 8% of urologists used robotic equipment for prostatectomy. Currently, the use of robots exceeds 67% of all prostatectomies and has been beneficial for the patients. Blood loss is minimal at 100 to 300 mL compared to open prostatectomy at 450 to 800 mL. Patients have demonstrated better urinary continence and preserved sexual function when robotics were used. Refined preservation of two key nerve bundles that innervate the prostate and urinary sphincters has been possible using robotics.[6] Surgeon experience and technique play a large part in the success of the procedure. Robotic surgery is discussed in Chapter 32.

Transperineal Prostatic Cryoablation

Transperineal prostatic cryoablation offers an alternative to radical prostatectomy in select patients with cancer of the prostate. This procedure is performed in the cysto room with the patient under general or spinal anesthesia. The entire prostate and periprostatic tissues are frozen. With the patient in the lithotomy position, an ultrasound probe is placed in the rectum for guidance in positioning five cryoprobes. Each cryoprobe is placed transperineally through a hollow sheath inserted in a small (18-gauge) needle puncture site. Liquid nitrogen is delivered to each probe from the cryosurgical device/console.

Care must be taken to avoid freezing the rectum. Warm water is run through a urethral catheter to keep the urethra warm to prevent tissue sloughing, a potential complication of transurethral cryosurgery. Both the prostate gland and the tumor cells are destroyed. The side effects of this procedure include a high risk for impotence (80% to 90%) and urinary incontinence (30%).

Pelvic Lymphadenectomy

A pelvic lymphadenectomy involves either a low abdominal incision into the extraperitoneal space or a laparoscopic approach. The lymph nodes are dissected bilaterally from the iliac vessels, obturator spaces, and hypogastric vessels. These nodes may be examined by frozen section to detect early and subtle metastases from prostatic carcinoma. If several nodes are positive for cancer, the patient is unlikely to benefit from a radical prostatectomy.

If the nodes are negative, the urologist may proceed with a radical retropubic prostatectomy. Pelvic lymphadenectomy also may be performed as a staged procedure before radical perineal prostatectomy. If feasible, at least one neurovascular bundle is preserved.

Penis

The penis is the cylindric erectile male organ of copulation. Because it contains the urethra, a deviation or malformation in structure may affect normal urinary flow from the bladder. Circumcision or surgical procedures to repair congenital anomalies of the penis are usually performed during infancy and childhood. Penile anatomy consists of the glans at the distal section, the corpus spongiosum circumferentially the length of the urethra, and the corpus cavernosa bilaterally the length of the shaft (see Fig. 35.26). The distal portion where the urethra exits is referred to as the glans. In its natural state, the glans is covered by redundant skin, which is referred to as foreskin. Some cultures electively remove this skin covering from males in infancy by circumcision. The CDC guidelines recommend circumcision as prevention for HIV. Studies have shown that the foreskin is vulnerable to the virus because of its cellular structure.[7]

The arterial supply of the penis arises from the inferior pudendal arteries. Venous drainage is from the venules in the periphery of the corpora and the superior and deep dorsal veins into the cavernosal and pudendal plexae. Innervation is from both sympathetic and parasympathetic origin combined with autonomic reflexes.
