The erection and ejaculatory responses are neurologically mediated by afferent and efferent pathways. Sacral efferent parasympathetic innervation causes both psychogenic and reflex erections. Destruction of these nerves during abdominal-perineal resection and radical prostatectomy result in impotence in 70% to 100% of patients. At the level of the penis, innervation is from adrenergic nerves in the arteriolar smooth muscle.

Complete transection of the spinal cord can result in impotence. Reflex erections may be found in patients with lesions of the upper cord. An exact locus of impulses in the brain has not been identified.

Adult Male Circumcision

Difficulty in the retraction of the foreskin is referred to as phimosis. Paraphimosis occurs when the foreskin retracts to expose the glans and cannot be repositioned back. These conditions may necessitate circumcision or removal of the foreskin to prevent necrosis and gangrene. In some patients, a small cut in the foreskin, a dorsal slit, is sufficient to release the constriction. An erection that cannot be released because of tight foreskin is a medical and possibly a surgical emergency. Attempts to drain the penis are made by injecting vasodilators. Once the penis is flaccid, a determination is made as to surgical intervention.

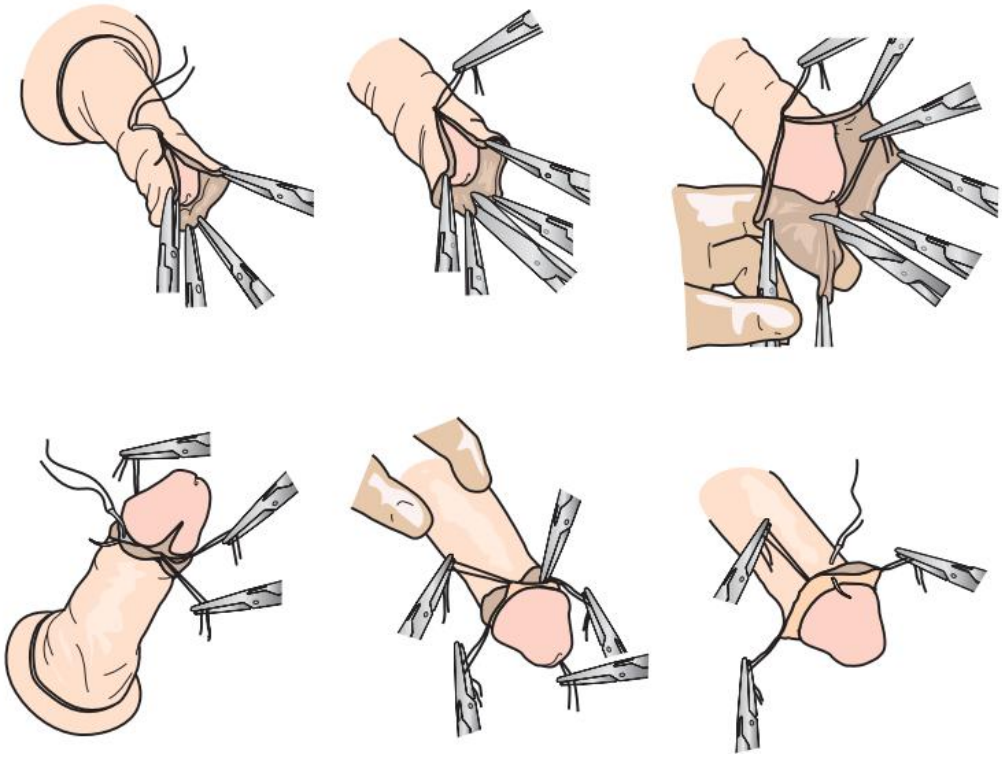
Adult male circumcision requires more dissection and ligation than does a pediatric procedure (Fig. 35.37). The patient is placed in the supine position. The foreskin is retracted to prep the glans penis. ESU should be available; however, a small battery-operated cautery is usually sufficient to provide hemostasis for pinpoint bleeders. Some surgeons prefer fine absorbable free-ties. The tissue around the foreskin is dissected, incised, and trimmed away. The remaining edges are circumferentially sutured with fine interrupted absorbable sutures. Vaseline gauze is used as a dressing. A scrotal suspension strap may be used to hold the dressings in place and provide support.

Impotence

The cause of erectile dysfunction (ED), or impotence, can be classified as organic or psychogenic. Patients are thoroughly evaluated by a urologist and properly selected for surgical therapy. Organic causes are confirmed by angiography, neurologic testing, and papaverine injection–induced erection studies. A test dose of sildenafil (Viagra) delineates vasculogenic causes from psychogenic causes. Viagra is ineffective if neurologic damage has occurred. Other ED drugs include tadalafil (Cialis). Tadalafil is also used to treat BPH. Side effects of ED drugs include hypotension and decreased circulation to the blood supply to the eye. Some patients may experience priapism (prolonged erection over 4 hours) and may need emergency treatment to prevent permanent damage to the penile vascular system in the corpus cavernosa.

Studies of penile activities include the measurement of erections during the rapid eye movement (REM) phases of sleep. A small band attached to a pressure-sensitive machine is placed around the penis. Erections, referred to as nocturnal penile tumescence, are recorded during sleep. This helps rule out organic causes of impotence.

Psychogenic causes are suspected after organic causes have been ruled out. Some psychogenic causes may be attributed to a fear of sexual relations after a heart attack or surgical procedure. Antidepressants and psychologic counseling may be helpful.



• **Fig. 35.37** Adult male circumcision.

Most procedures for the diagnosis and treatment of organic impotence are performed with the patient under regional anesthesia.[8] Consideration for the patient's privacy should be included in the plan of care.

Dorsal Vein Ligation

A failed erection can be caused by inadequate filling or inadequate storage of blood in the erectile tissue of the corpus cavernosa of the penis. Some patients can achieve erection but cannot maintain it for more than a few minutes because of a cavernosal leak. The diagnosis is made by the dynamic infusion cavernosometry and cavernosography (DICC) procedure. In select patients with this condition, the urologist may elect to ligate the dorsal vein and several collateral vessels of the penis to delay the venous return from the erectile tissue and help sustain erection. This procedure is not always successful.

Penile Prosthesis

Implantation of a penile prosthesis as treatment for organic impotence can enable some men to achieve a satisfactory return of sexual activity within 4 to 6 weeks postoperatively. Complications include scar tissue formation and erosion of the implant through the penile tissue. Penile prosthetic implants are of three types: semirigid silicone, semiflexible silicone–braided silver, and an inflatable hydraulic device:

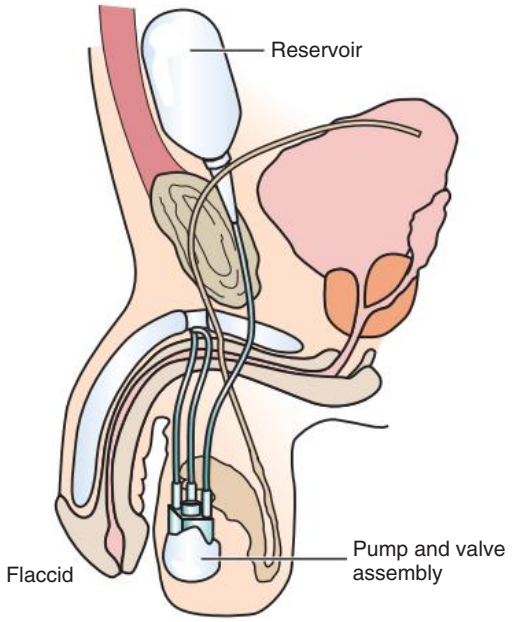
- The Small-Carrion semirigid prosthesis consists of two foam-filled silicone rods that are inserted into the corpus cavernosum on each side of the penis, usually through a vertical incision in the perineum underneath the scrotum. The suitable-size prosthesis is selected from available lengths. This prosthesis maintains a permanent semierection.
- The Finney Flexirod is similar to the Small-Carrion prosthesis except that it is hinged at the penoscrotal junction when implanted. This allows the penis to hang in a dependent position when an erection is not desired.
- The Jonas prosthesis is constructed of malleable braided silver and silicone. It is semiflexible.
- The Scott-Bradley inflatable hydraulic device is inserted through a midline incision that extends from the base of the penis to a point midway between the symphysis pubis and the umbilicus. Silicone cylinders are implanted into each corpus cavernosum (Fig. 35.38). Tubing connected to these cylinders at the base of the penis is brought into the left inguinal canal, the prevesical space, and the right inguinal canal, where it is connected to tubing from the pump-release mechanism placed in the scrotum.

A reservoir filled with a radiopaque solution is sutured into the abdominal fascia of the prevesical space; the tubing from this reservoir is also connected to the pump-release mechanism. To achieve an erection, the patient squeezes the pump in the scrotum (Fig. 35.39).

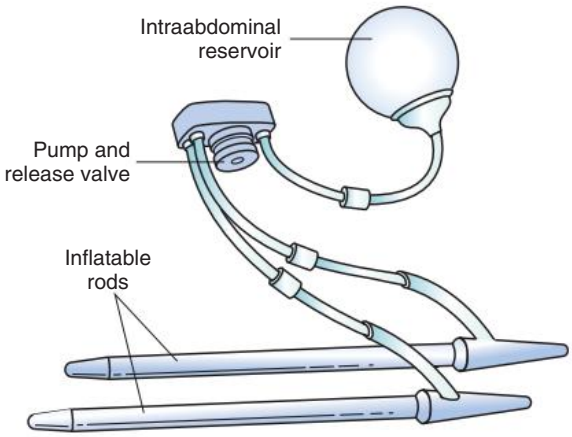
Penectomy

Cancer of the penis is uncommon in the developed world.[9] It accounts for 1.3% of all cancers occurring in men.[3,10] Penile cancer is more commonly found in men between 50 and 70 years of age, although 22% are younger than 40 years.[9,11] The common factor in the majority of penile cancer cases is an intact foreskin, which has a cancer rate of 3:1. Jewish males, who are circumcised at birth, rarely develop penile cancer. Any treated lesion of the glans that does not clear in 2 to 3 weeks should be investigated as a cancerous or precancerous lesion, especially in an uncircumcised man.[9,11] Another common factor is HPV infection in the presence of an intact foreskin.[11] The incidence increases with the number of sexual partners.

Approximately 78% of all penile cancers are located between the coronal sulcus and the distal aspect of the glans.[11] Fewer than



• **Fig. 35.38** Inflatable penile prosthesis in position.



• **Fig. 35.39** Inflatable penile prosthesis components.

2% are located on the shaft. Nearly 58% of males presenting with penile cancer have positive palpable inguinal lymphadenopathy on examination. Sentinel node biopsy can be used to guide inguinal node dissection. Diagnosis of superficial lesions can be done with Mohs microscopic mapping. A clear margin of 2 cm is desired. Treatment of penile cancer with chemotherapy has not been very successful.

The penis may be partially or completely resected because of neoplasm or trauma. A partial penectomy may allow the patient enough length for upright voiding. Cosmetic reconstruction may be possible in some patients. Invasive disease may necessitate a complete penectomy, including removal of the scrotum and testes (orchiectomy). Reconstruction after a complete penectomy includes urethral diversion to the perineum. The plan of care should include consideration for psychologic counseling.

Endocrine Glands

Two pairs of glands in the endocrine system are of primary interest to the urologist: the adrenal glands in both sexes and the testes in the male.

Adrenal Glands

The adrenal glands are located in the retroperitoneum on the superior margin of each kidney. The adrenal cortex is the outer covering and produces hormones, including glucocorticoids (cortisol) and mineralocorticoids (aldosterone), which control the body's metabolic processes and help regulate fluid and electrolyte balance. With low levels of cortisol or aldosterone, the body is not able to respond adequately under minimal physical or emotional stress, including change in temperature, exercise, or excitement. The adrenal medulla is the inner portion of the gland and secretes the stimulants epinephrine and norepinephrine and assists the body in coping with stress. The adrenal glands secrete hormones that stimulate the sexual organs.

An adrenalectomy may be indicated to remove a benign, malignant, or metastatic tumor within the adrenal medulla or eliminate adrenal hormonal secretions. Pheochromocytoma, a tumor of the adrenal medulla, causes excessive amounts of these stimulants to be released, resulting in hypertension. Pheochromocytoma is most commonly found in younger patients. Only a small percentage of the lesions are malignant.

The adrenal glands are a rich source of estrogens, and estrogens may stimulate a recurrence or metastasis from prostatic or breast cancer. A bilateral adrenalectomy may be performed as a supplemental treatment of advanced prostatic or breast cancer to reduce the hormonal environment within the body.

For an open unilateral adrenalectomy, the adrenal gland is usually approached posteriorly through a lateral incision into the retroperitoneal space. The twelfth rib is usually resected on the right side because the adrenal gland lies above the kidney, behind the liver. The surgeon may also prefer a posterior approach for a bilateral adrenalectomy with the patient placed in a modified prone position for the bilateral incisions. Other surgeons prefer an anterior thoracoabdominal or transabdominal incision into the retroperitoneal space with the patient in the supine position.

The circulating nurse must verify with the surgeon the preferred position before the patient is positioned, prepped, and draped. Depending on the preoperative diagnosis, the thoracoabdominal incision may be preferred to extend the incision across the costal margin into the eighth or ninth intercostal space for exposure and exploration of the extraadrenal paraganglion system. Laparoscopic methods are commonly employed by many surgeons with good results.

Transsexual Surgery (Sex Reassignment)

Transsexual surgery may be the only acceptable alternative for a patient who psychologically desires to become a member of the opposite sex—both physically and emotionally.[10] Before having surgery, the patient is usually required to live in the desired sex role for a period of 1 year. This type of surgery presents challenges to both the urologic and the gynecologic teams.

Sex transformation requires a stable personality, psychiatric counseling for feasibility, and careful preparation and support.[10] The patient changes legal identity and social status. Adolescents who have gender dysphoria may choose to live as the sexual identity in which they feel comfortable, but may experience resistance from parents and friends. They are not necessarily candidates for transsexual surgery, but in some circumstances may be permitted to dress and live in the gender role they choose. Hormonal changes at puberty can be altered by hormone therapy under the guidance of a physician.[10]

The Harry Benjamin International Gender Dysphoria Association Standards of Care safeguards both transsexual people and the men and women who provide professional services for them. This set of standards divides the transition process into a series of discrete steps that enable the patient to progress at a livable pace during transition.[10] These steps maximize the chance that the sex change process will be successful. The first step a transsexual should make is to locate a therapist who is familiar with the standards of care. It is also important to find a good support group.

Male to Female

Surgical techniques have been developed to eliminate the external genitalia of a male by dissecting the penile structures, shortening the urethra, and removing the testes. Preservation of the sensitive erogenous tissues was pioneered and perfected by Dr. Georges Borou in Morocco in the early 1960s. The patient undergoes counseling and feminization with female hormones (estrogen) preoperatively.

The patient is placed in the lithotomy position for the procedure. The process is performed in several steps:

1. The perineum is dissected, and the penile shaft and scrotal skin are preserved for construction of a neovagina and labia.
2. A tissue tube is created from portions of the scrotal skin and sutured to the inverted penile skin for length.
3. A tunnel is created in the perineum between the urethra and the rectum at the space of Douglas and packed with lap tapes.
4. The corpus spongiosum is dissected, and the urethra is cut to length. A Foley catheter is used to stent the urethral placement.
5. The dorsal vessels and nerves are spared as the glans is separated from the corpus cavernosa. The glans and a pedicle stalk are all that remain of the penile shaft. A clitoris is fashioned from the remaining glans and sutured into position. The lower abdomen is tunneled transversely and retracted superiorly so the pedicle of nerves and vessels can be nested into the retropubic space. Some procedures retain a thinly trimmed glans as a neocervix in an inverted penis-to-vagina transition.
6. The vaginal skin tube is placed inside the vaginal tunnel like a graft and sutured into place after removing the lap tapes. The neovagina is packed with vaginal packing to create equal pressure on the walls circumferentially.
7. The edges of the abdominal skin and dorsal penile tissue are pulled up and over the edge of the pubic bone and sutured into place as the anterior perineum. The remaining scrotal skin and perineal tissue are fashioned into the new posterior perineum and labia majora. The urethra is exteriorized and positioned by sutures. The apex at the superior margin is joined to form a clitoral hood and labia minora at a later procedure.
8. Drains are placed in the groins bilaterally, and the neovagina is packed.
9. The lateral edges of the left and right labia majora are approximated with temporary stay sutures to provide compression to the perineum to prevent dependent hematoma and loss of the vulvar flap. These sutures are removed several days postoperatively when the danger of hematoma is passed.

Breast implants are placed at a later date after enlargement with tissue expanders. Some patients prefer to have breast implants before the feminization procedure to make the transition preoperatively. Most patients have lived as a woman for several years before undergoing genitalia surgery. Suppression of beard and body hair, redistribution of adipose tissue, voice change, and removal of pronounced thyroid cartilage (Adam's apple) are gradual processes that are managed surgically or chemically over a period of time.

The prostate and seminal vesicles are retained so that clitoral orgasm with emission from the urethra is possible, although sperm are not produced. The actual success rate for orgasm potential is estimated at 25%. The resultant newly created vulva is realistic in form and function.

Female to Male

Female-to-male transsexual surgery is also possible in satisfactory candidates. Management of this change is complex. A treatment schedule of hormonal substitution (i.e., androgens [male hormones] in the female patient) is begun well in advance of the procedure.

In a one-stage procedure, a bilateral subcutaneous mastectomy or reduction, total abdominal hysterectomy, and bilateral salpingo-oophorectomy are performed. Three to five additional stages are necessary to complete the transformation, as follows:

1. Urethral elongation and reconstruction, to the tip of the enlarged clitoris. Some patients do not opt for urethral lengthening and maintain its natural position in the perineum. Urethral reconstruction can be performed using buccal tissue from inside the mouth.[12]
2. Revision of the labia for penile lengthening and scrotal construction.
3. Flaps or grafts to create a penile shaft.
4. Placement of penile erection implants. Rigid implants are commonly used.
5. Prosthetic testicular implantation.

An understanding, nonjudgmental, unembarrassed attitude on the part of health care personnel can help the patient adjust psychologically, as well as recover physically, after the radical change. Consideration should be given to the patient's family and significant others, because they, too, must adjust. The patient may have married and produced children while in the role of his or her birth sex. In addition to confusion about parental roles, the patient may experience rejection or revulsion from offspring and other family members. Referral for family and individual counseling should be included in the plan of care.

Postoperative Complications of Urologic Surgery

Oliguria, the diminished capacity to form urine, is often seen after urologic surgery. Water and sodium are conserved by antidiuretic hormone, aldosterone, epinephrine, and norepinephrine secreted during stress; this decreases urinary output. Dehydration, shock, cardiac failure, renal failure, or third-space loss (e.g., edema, ascites) may contribute to oliguria. Because prolonged oliguria may result in renal failure, a urinary output of less than 30 mL/hr should be reported to the surgeon. Treatment depends on the cause.

Because of the introduction of the catheter and instruments, the patient should be watched for infection after all urinary tract procedures. Cloudy urine, dysuria, frequency, urgency, and pain or burning on urination are symptoms of urinary tract infections. Damage to bladder sphincters from instrumentation or urethral infection may lead to incontinence. Sharp abdominal pain after cysto or the manipulation of a ureter to remove calculi may suggest peritonitis from bladder or ureteral perforation. Susceptibility to infection accompanies urinary diversion.

Orthopedic Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Identify the pertinent anatomy and physiology of the musculoskeletal system.
- Discuss several types of fractures and the stabilization of each.
- Describe several common specialty orthopedic instruments.
- Discuss bone healing.
- Discuss the process for applying a cast.
- Describe the care of a patient undergoing orthopedic surgery.

KEY TERMS AND DEFINITIONS

Arthrodesis Fusion of a joint.
Avascular necrosis Disruption of the blood supply to a bone, resulting in death and irreversible decay of the osseous tissue.
Bi-valved cast Cast cut into two parts—front and back—for removal and reapplication.
Bone cement implantation syndrome (BCIS) Adverse physiologic response of the patient to placement of bone cement in the medullary canal.
Cast material Used to encase and stabilize a structure. Casts are made of plaster or fiberglass.
Closed reduction Closed reduction (CR) of a fracture without opening the skin.
Compartment syndrome Swelling between layers of fascia that causes damage to tissue. Toxins cause death of tissue.
Exothermic Generating heat.
Exsanguinate Evacuation of blood from a limb before inflating a tourniquet to create a bloodless field.
Fasciotomy Emergency procedure to release pressure on region of compartment syndrome.
Laminar airflow Specialized clean air delivery to the orthopedic operating room. The direction of airflow is carefully calculated to enter and exit the room without generating airborne particulate.
Open reduction and internal fixation (ORIF) of a fracture The fractured limb is opened surgically, and the bone is repaired with plates and screws.
Osteoblasts Basophilic cells that synthesize collagen and glycoprotein to form bone matrix.
Osteoclasts Cells in the bone that influence growth and regeneration by breakdown and resorption of existing cellular material.
Osteomyelitis Bone infection.
Union Healing process of bone. Nonunion is the failure of the bone to align and heal.

The Art and Science of Orthopedic Surgery

The word *orthopedics* is derived from two Greek words: *orthos,* meaning "straight," and *paithee,* meaning "child." As the name implies, orthopedics began with the treatment of crippled children by means of rest, braces, and exercise. Degenerative diseases and disabilities affecting the musculoskeletal system cause loss of function and impair activity of the aged. Consequently, orthopedic surgeons treat a large number of geriatric and pediatric patients in comparison to other surgical populations.

Orthopedic patient care is individualized. As a branch of medicine and a contemporary surgical specialty, orthopedics is concerned with the diagnosis, care, and treatment of musculoskeletal disorders—that is, injury to or disease of the body's system of bones, joints, ligaments, muscles, and tendons. Conservative, noninvasive medical and physical methods are used, if possible, to restore form and function.

Orthopedics depends on many disciplines to help evaluate and treat patients. Diagnostic imaging, bioengineering, electrobiology, genetics, microbiology, oncology, and transplantation are only a few of these. Professional registered perioperative nurses who specialize in orthopedic patient care are eligible for certification by examination through the Orthopaedic Nurses Certification Board (ONCB).

Eligibility for the certification includes current licensure in the United States or Canada and a minimum of 2 years' experience as a registered nurse with a minimum of 1000 hours of nursing practice in orthopedic patient care in the preceding 3 years. The certification period is 5 years and can be renewed through 75 contact hours of continuing education or by successful passage of the certification examination. (More information about certification and the National Association of Orthopaedic Nurses [NAON] is available at www.oncb.org/exam-eligibility.

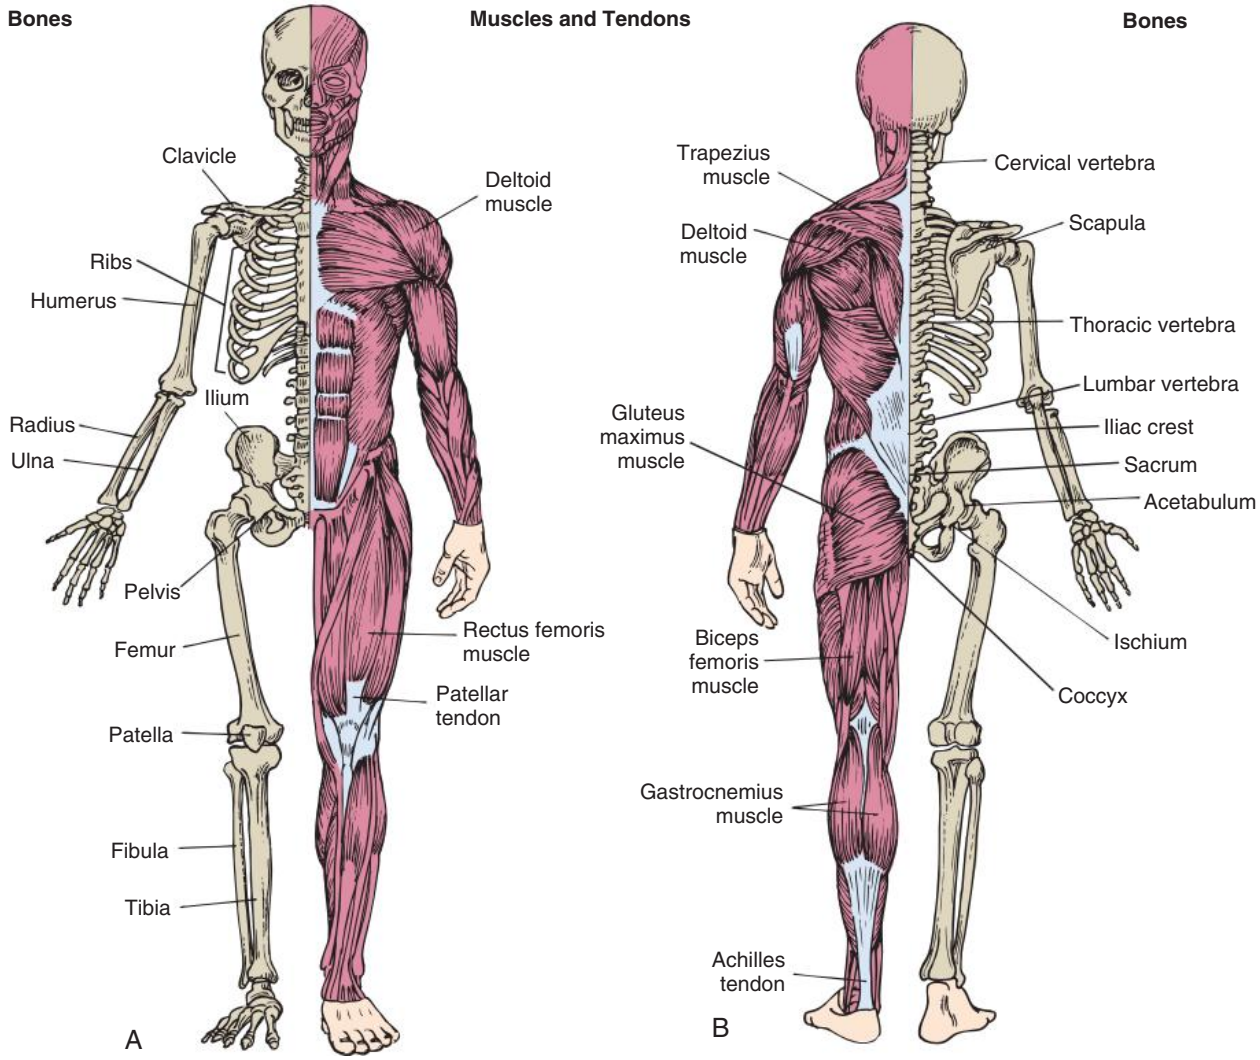
Anatomy and Physiology of the Musculoskeletal System

Structures that make up the musculoskeletal system provide bone shape, support, and stability; protect vital organs; and enable parts and the body as a whole to move. The musculoskeletal system includes bones, cartilage, joints, ligaments, muscles, and tendons. Orthopedic surgery is concerned primarily with these structures in the upper and lower extremities, including the shoulder and hip joints, and the vertebral column. Neurosurgeons also specialize in vertebral column surgery.

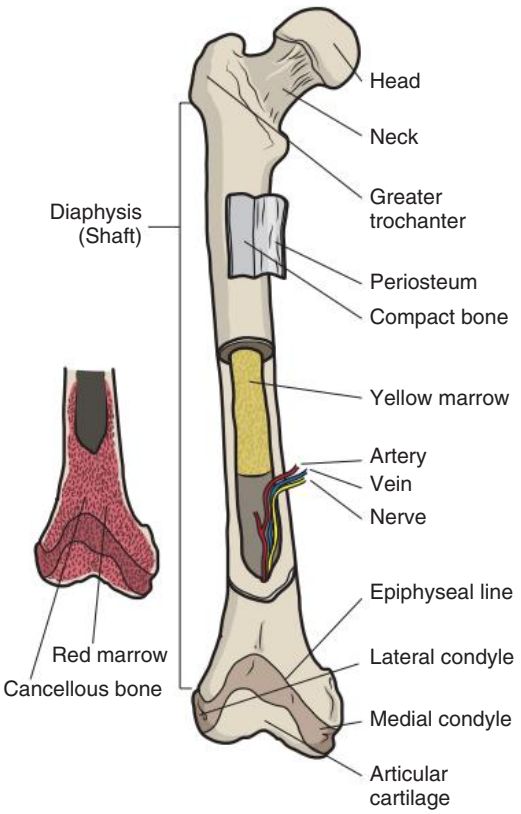
Bones

The human skeleton (Fig. 36.1) has 206 separate bones. The bony framework of the human body is divided into the axial skeleton, which consists of 80 bones that comprise the skull, vertebrae, and ribcage, and the appendicular skeleton, which consists of 126 bones that make up the limbs. Each upper extremity is composed of 32 bones, and each lower extremity is composed of 31 bones. Bones are classified according to shape: long, short, flat, and irregular. The humerus in the upper arm, radius and ulna in the forearm, femur in the thigh, and tibia and fibula in the lower leg are long bones.

The end of a long bone is referred to as the *epiphysis,* and the shaft is referred to as the *diaphysis*. Thin plates of cartilage are found in the ends of long bones. In immature bone this is the area of growth and elongation and accounts for 18% of pediatric fractures.[1] A child's x-ray may appear normal even when the epiphysis



• **Fig. 36.1** Musculoskeletal system. **A,** Anterior view. **B,** Posterior view.



• **Fig. 36.2** Long bone anatomy.

is fractured.[1] In mature bone these plates are ossified and do not grow (Fig. 36.2). The bones in the hand and foot are short bones. The scapula and patella are examples of flat bones. The vertebrae are irregular bones.

The cortex (outer layer) of bone is compact, hard connective tissue. This cortical osseous tissue surrounds porous, spongy, cancellous tissue. The innermost substance is bone marrow and is classified as either red or yellow according to its location and function (see Fig. 36.2).

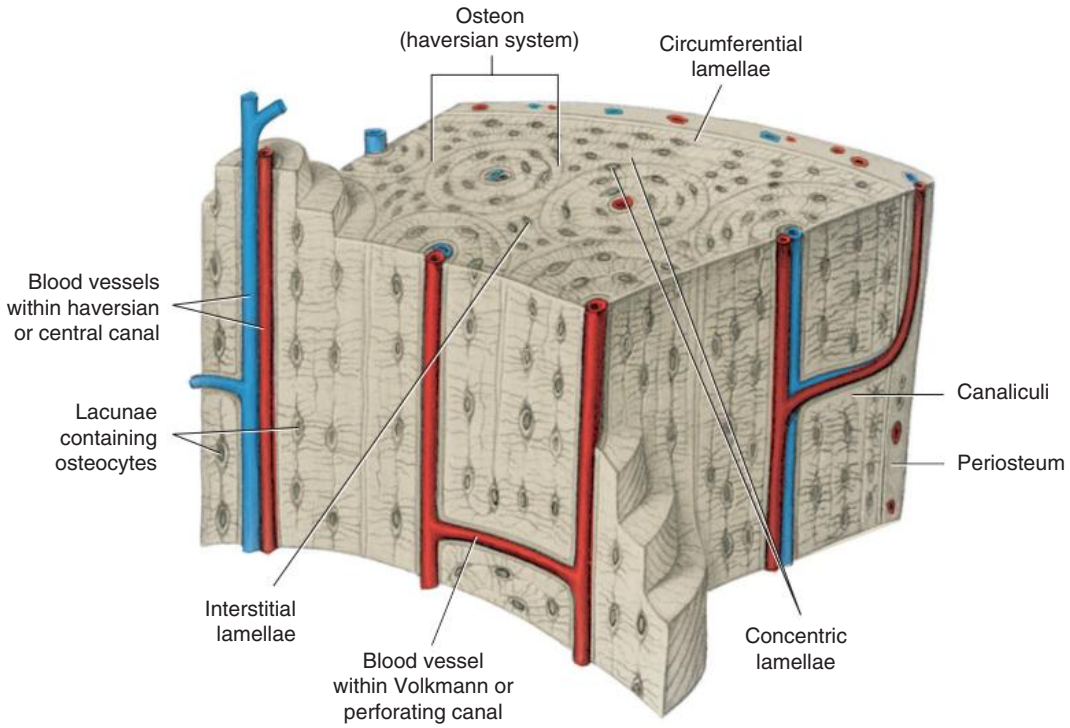
The red marrow is found in the ends of long bones, porosities of cancellous bone, and flatter bones, such as the skull, sternum, and pelvic bones. This type of marrow is responsible for erythropoiesis, which is the formation of red blood cells and certain white blood cells. Yellow marrow is found in the medullary canals, or shafts of long bones, and has a higher adipose content.

Periosteum, a strong fibrous membrane, covers bone, except at joints. Pediatric periosteum is thicker and more pliable, allowing for less fracture displacement.[1] The blood supply and innervation penetrate periosteum and enter the bone through structures known as Volkmann canals. Lengthwise, lamellar structures, referred to as haversian canals, provide weight-bearing strength and passage for additional blood supply (Fig. 36.3). The inner aspect of bone is lined with endosteum, which is tissue similar to periosteum. In small children this layer contains **osteoclasts** that destroy bone to enlarge the marrow cavity for circumferential growth.

Bone Healing

Broken bones heal by a process referred to as **union**. Union of bones takes place in a series of steps (Fig. 36.4):

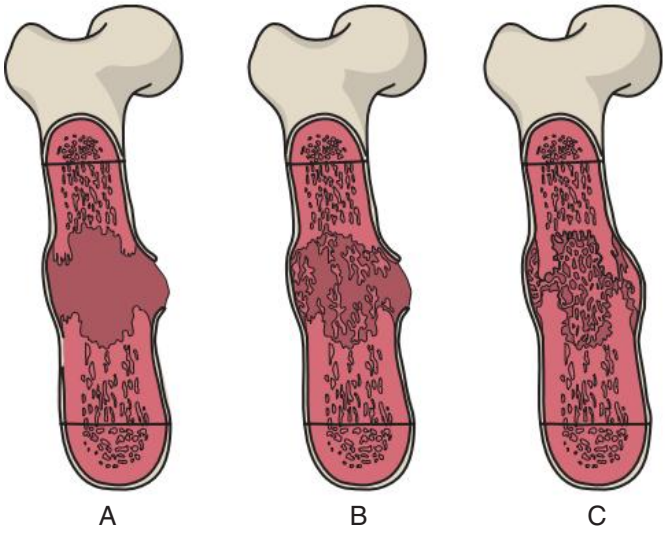
1. *Hematoma formation:* Blood accumulates in the area of break or injury. The inflammatory process ensues, and extravascular blood converts from liquid to a semisolid clot. Active phagocytosis removes necrotic tissue and debris.
2. *Callus formation:* Fibrin cells form a network around the injured area. The damaged periosteum is stimulated to generate



• **Fig. 36.3** Vascular structure of bone. (From Mourad LA: *Orthopedic disorders,* St. Louis, 1991, Mosby.)

osteoblasts, forming new bony substance referred to as *osteoid.* Minerals begin to accumulate in the network, forming a collagen callus. A callus is visible on radiograph within 1 to 2 weeks of injury.

3. *Calcification process:* Calcification begins and establishes support of the injury. Connective tissue proliferates across the site and is usually completely calcified within 6 weeks.
4. *Remodeling phase:* Excess cellular material is resorbed, and the bone resumes its preinjury strength and configuration. This remodeling phase is enhanced by stress and exercise. Depending on the site and severity of the injury, complete remodeling can take 6 months to 1 year to complete.



• **Fig. 36.4** Bone healing stages.

Cartilage

Cartilage, a smooth, relatively firm, compressible connective tissue, cushions most articular surfaces at the ends of bones. It does not have a direct blood supply and is devoid of lymphatics and nerves. Cartilage derives its nutrition from synovial fluid and maintains a high water content except in pathologic states.

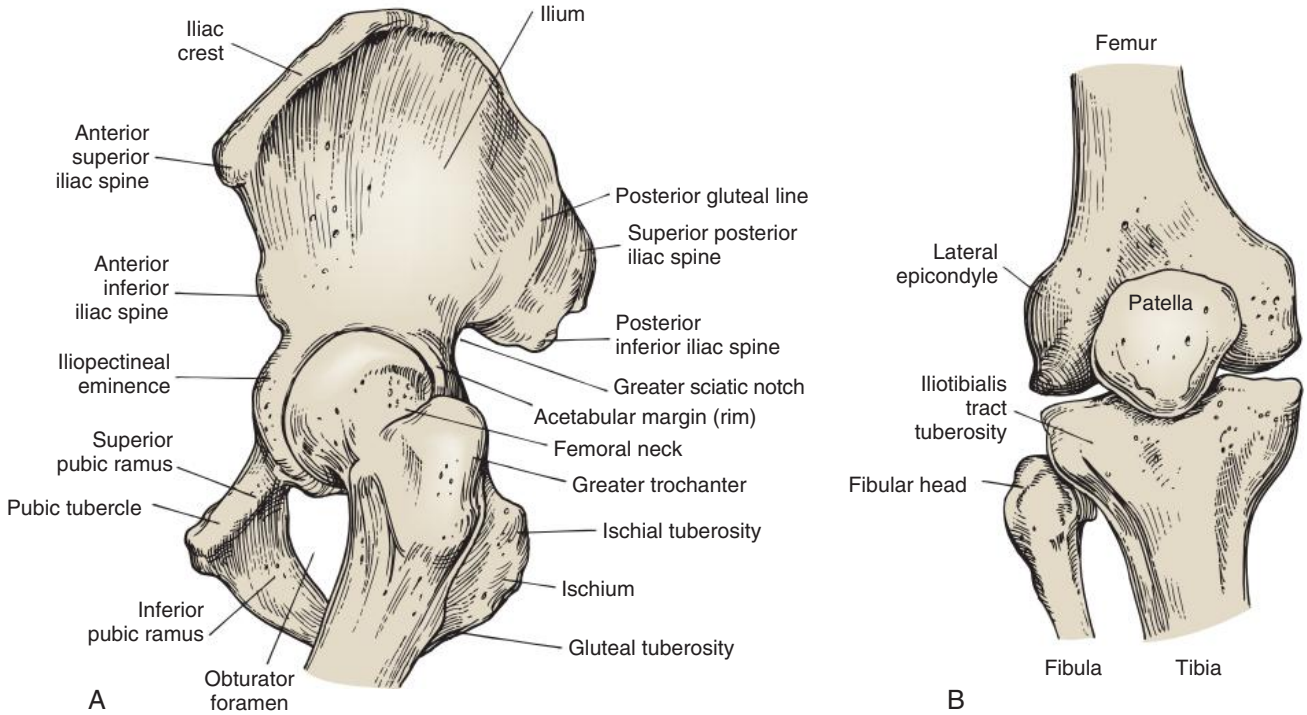
Joints

Bones give stability, but the body must bend and flex for locomotion. The ends of bones come together at joints. The articular cartilage and construction of the joint prevent bones from scraping against each other. Tough, fibrous connective tissue forms the outside capsule of the joint, and a finer membranous lining secretes synovium, which is similar to egg albumin. The synovial fluid contains macrophages and white blood cells that keep the joint free of debris and bacteria that could interfere with mobility.

Joints are classified by variations in structure that permit movement (Fig. 36.5). The hip and shoulder are ball-and-socket joints; the knee, ankle, elbow, and phalangeal joints of the fingers are hinged; the wrist is a condyloid joint; and the thumb is a saddle joint. The proximal and distal bone ends are held securely in place by the joint capsule attached to both bone shafts and by ligaments.

Ligaments

Ligaments are bands of flexible, tough fibrous tissue that join the articular surfaces of bones and cartilage. They become strong when the parallel configuration of their collagen fiber is oriented against the forces applied to them (e.g., the cruciate ligaments stabilize the knee joint). Ligaments are avascular and heal slowly. They do not readily reattach to bone when torn and are prone to subsequent reinjury.



• **Fig. 36.5** Joints. **A,** Ball-and-socket hip joint. **B,** Hinged knee joint.

Muscles

The human body has hundreds of muscles. Muscles are all the contractile tissues of the body and are classified as smooth (involuntary), branching (cardiac), or striated skeletal (voluntary). Muscles have a rich arterial supply because they require oxygen to perform many functions, and they have a multilevel venous drainage system because they perform as the venous pumps for resaturation by the lungs. They contract when an electrochemical impulse from the brain crosses the myoneural junction, causing fibers to shorten. Groups of muscles work together (i.e., contract simultaneously to bring about body movement).

Skeletal muscle is the largest category of muscle tissue. There are more than 600 skeletal muscles in the human body. Skeletal muscle constitutes approximately 23% of small female body weight and 40% of larger male body weight. Each muscle fiber is a single cell that ranges in length from 0.04 to 3 inches (1 to 80 mm). The fibers are bound together into fascia-covered bundles referred to as fasciculi. Several fascia-bound fasciculi constitute a skeletal muscle and contract in response to signals mediated by the nervous system and neurotransmitters, such as acetylcholine.

The peripheral attachment is referred to as the origin. The distal attachment is referred to as the insertion.

Tendons

Tendons are bands of extremely strong, flexible fibrous tissue that attach muscle bundles to the periosteum of bones (see Fig. 36.1 and Fig. 36.31, later in this chapter). They are encased in the synovial membrane sheath of movable joints.

Special Features of Orthopedic Surgery

The orthopedic surgeon, also referred to as an orthopedist or orthopod, attempts to restore function of the musculoskeletal system lost as a result of injury or disease. Surgical procedures may be performed to repair traumatic injuries, such as fractures, dislocations, torn ligaments, or severed tendons. Other procedures reconstruct joints, eradicate a benign or malignant disease process, or correct postural disabilities.

In addition to conventional x-rays, computed tomography (CT), magnetic resonance imaging (MRI), and bone densitometers allow evaluation of conditions amenable to surgical correction. Arthroscopy enhances diagnosis and treatment of joint disorders, especially those caused by sports injuries. Highly sophisticated implants and instrumentation make many orthopedic procedures possible. A large percentage of orthopedic surgical procedures involve contaminated traumatic wounds or tissues highly susceptible to infection.

The occurrence of **osteomyelitis** (infection in bone) typically is after bone is injured in an accident or is involved in a surgical repair.[2] Acute osteomyelitis may cause nonunion of fractures. Microorganisms may harbor in a hematoma or in soft tissues and spread directly to bone via the circulatory system. The most common microorganisms that cause osteomyelitis are *Staphylococcus aureus, Staphylococcus epidermis,* and *Streptococcus* species.[2] Osteomyelitis spreads via hematogenous seeding from soft tissue or direct contamination during surgical treatment. Soft tissue spread is common in the lower legs, feet, and toes of persons with diabetes. One osteomyelitis study covered 40 years and found that 60% of diabetic persons with the infection had amputations as a result.[2]

The incidence of osteomyelitis is highest among males of all age-groups. The risk increases by 50% with each decade of life.[2] The most prevalent microorganism is *S. aureus,* (44%) which has been further complicated by antibiotic resistance. Chronic osteomyelitis is often associated with peripheral vascular disease.

Meticulous attention to sterile technique is critical in all orthopedic procedures to prevent or at least minimize the devastating effects of infection.[3] Sterility of implants and fixation devices is absolutely essential.[3] Medical management of the patient receiving an implant should include a minimum of 6 months between any active infection and the placement of a prosthetic.

Precautions also must ensure protection for the orthopedic surgeon and team, especially when caring for a trauma victim. Manipulation of sharp bony fragments and instrumentation can be hazardous. Transmission of bloodborne pathogens is readily possible because of aerosolization of bone and debris during drilling and sawing, using powered irrigation units, and using heavy instrumentation. In addition to standard precautions recommended by the Centers for Disease Control and Prevention (CDC), the American Academy of Orthopaedic Surgeons (AAOS) recommends:

1. Wearing protective attire.
   a. Wear knee-high, waterproof shoe covers or boots. Blood and body fluids frequently splash to the floor and lower legs. Shoe covers should be removed and changed if they become contaminated.
   b. Wear a fluid-impervious gown and/or a waterproof apron under the gown. Copious irrigation frequently is used.
   c. Double-glove at all times, and/or have additional protection for fingers. Cloth gloves or glove liners of woven Kevlar may be worn between latex gloves in cases of trauma and major reconstructive procedures, when sharp instruments and mechanical devices are used.
   d. Wear protective eyewear at all times. A full-face shield should be considered when splatter is anticipated. Powered bone instruments can produce a fine mist. A space suit–type helmet should be considered when powered bone instruments are used. See Fig. 16.7 for orthopedic helmeted attire.
2. Avoiding inadvertent penetration of the skin of personnel during the surgical procedure.
   a. Use instrument ties and other no-touch suturing and sharp instrument techniques whenever possible.
   b. Pass sharp instruments on a tray or magnetic mat, not hand to hand.
   c. Announce when instruments are being passed.
   d. Cover exposed internal wires and pins that extend through the skin with appropriate tubing, cork stoppers, or plastic caps.
3. Wearing clean gowning and gloving (i.e., the scrub person should change contaminated gloves before gowning and gloving another team member during the surgical procedure).

Instrumentation

Each orthopedic procedure must have the correct instrumentation for that particular bone, joint, tendon, or other structures the surgeon will encounter. An instrument used on a hip procedure is not appropriate for a hand procedure. Orthopedic instruments are heavy—often large and bulky, resembling carpentry tools—but also delicate. Each instrument has a specific purpose and requires special care and handling. Orthopedic instruments can be divided into categories by functional design.

Exposing Instruments

To expose a bone or joint, special retractors and elevators are used (Fig. 36.6). Retractors are contoured to fit around the bone or joint without cutting or tearing muscles. Periosteal elevators are semi-sharp instruments used to strip periosteum from bone without destroying its ability to regenerate new bone. They are used for blunt dissection.

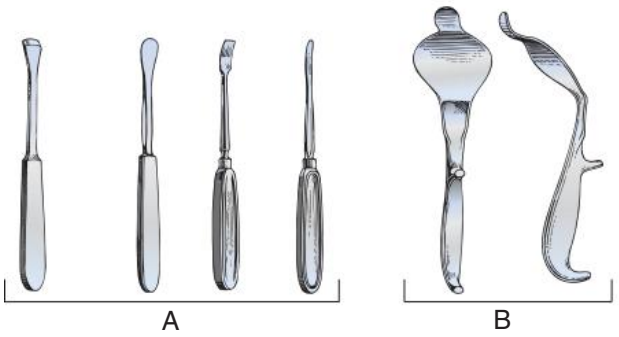
Grasping Instruments

Grasping instruments are required to hold, manipulate, or retract bone. Bone-holding forceps should be selected appropriately for the size of the bone in the surgical field. Bone hooks are used for retraction and leverage (Fig. 36.7). Heavy clamps are needed to hold smaller bones or grasp a joint capsule, such as a meniscus clamp for fibrocartilage in the knee.

Dissecting and Debulking Instruments

Cutting instruments are used to remove soft tissue around bone; to cut into, cut apart, or cut out portions of bone; and to smooth jagged edges of bone. The surgeon's armamentarium includes osteotomes, gouges, chisels, curettes, rongeurs, reamers, bone-cutting forceps, meniscotomes, rasps, files, drills, and saws (Fig. 36.8). These have sharp edges. Extra care should be taken not to nick or damage cutting edges; they should always be protected on the instrument table and during cleaning, sterilizing, and storing. Fitted sterilizable cases (see Fig. 36.8, *E*), trays, foam towels, metal, or canvas cases are used to keep sets together by sizes (e.g., osteotomes, gouges, chisels, curettes), as well as to protect cutting edges.

Cutting instruments must be sharp. Osteotomes, chisels, gouges, and meniscotomes can be sharpened with handheld hones or a honing machine designed for this purpose. Most manufacturers provide a service for sharpening and repairing instruments. Curettes, rongeurs, and reamers should be returned for sharpening. Small drill bits and saw blades usually are disposable (Fig. 36.9).



• **Fig. 36.6** Exposing instruments. **A,** Periosteal elevators. **B,** Bennett retractor.

Power-Driven Cutting Instruments

Instruments powered by electricity or compressed air or nitrogen offer precision in drilling, cutting, shaping, and beveling bone. The instrument may have rotary, reciprocating, or oscillating action. Rotary movement is used to drill holes or insert screws, wires, or pins. Reciprocating movement, a cutting action from front to back, and oscillating cutting action from side to side are used to cut or remove bone.

Some instruments have a combination of movements and can be changed from one to another with hand controls. In some the change may be made by adjusting the chuck forward or backward and locking it into the desired position. Powered instruments increase speed and decrease the fatigue caused by the use of manually driven drills, saws, and reamers. They also reduce blood loss from bone by packing tiny particles into cut surfaces.

Measuring Devices

Rulers, calipers, depth gauges, and flexible devices for measuring angles are important for the appropriate sizing of implants and selective bone cutting. Measurements of bone diameter are performed when selecting a joint prosthesis (Fig. 36.10).

Implant-Related Instruments

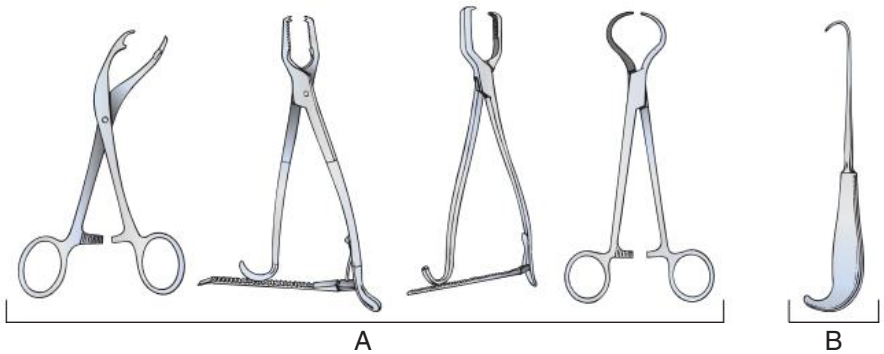
Drivers, clamps, and retractors are used for inserting, securing, or removing fixation and prosthetic implants. Each type of implant requires its own instrumentation. Instruments used for insertion or extraction of metallic implants must be of the same metal as the implant to prevent galvanic reaction.

Materials and Equipment Used Frequently

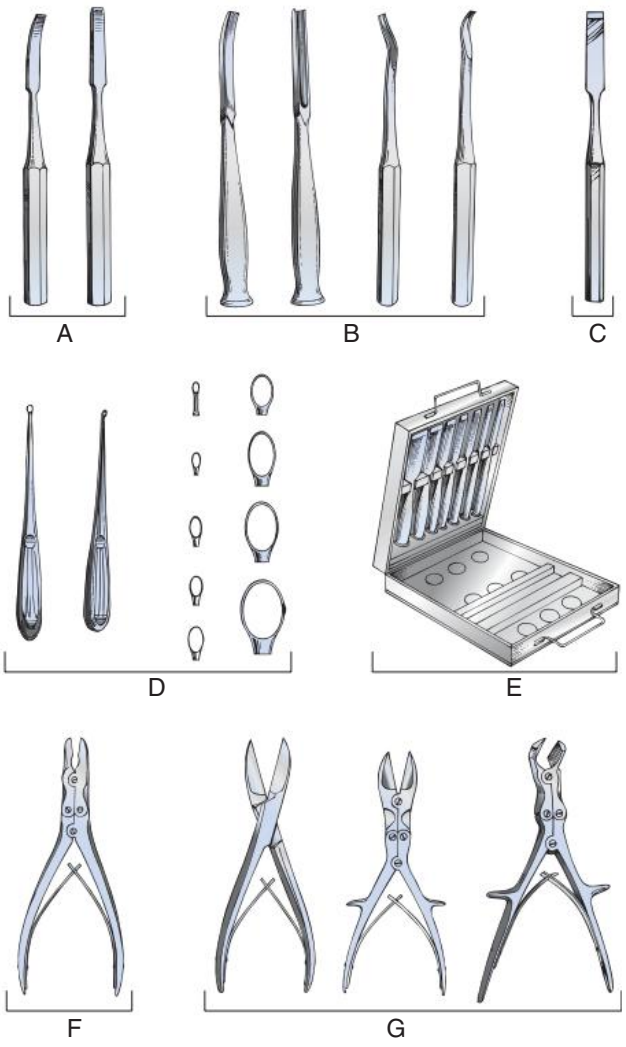
The items discussed in this section are used frequently in many orthopedic procedures.

Bone Grafts

When necessary to provide structural support, a piece of bone from one part of the skeletal system may be obtained from the patient to reinforce another part of the skeletal system. Autologous cancellous and cortical bone is obtained from the crest of the ilium, and cortical bone is obtained from the fibula.



• **Fig. 36.7** Grasping instruments. **A,** Bone-holding forceps. **B,** Bone hook.



• **Fig. 36.8** Cutting instruments. **A,** Osteotome, curved or straight tapered blade. **B,** Gouge, curved, straight, or angled tip. **C,** Chisel, straight blade. **D,** Curette with assortment of sizes of cutting loops. **E,** Sterilizing case for set of osteotomes, gouges, chisels, or curettes. **F,** Rongeur. **G,** Bone cutter, straight or angled blade.

Free vascularized fibular grafts may be preferred to replace avascular (dead) bone or large segments of long bones after trauma or tumor resection. Autologous bone may not have adequate shape or strength, it may not be available in sufficient quantity, or the surgeon may deem it undesirable to subject the patient to a secondary incision or added operating time.

Allograft bone, coralline hydroxyapatite, or a bone graft substitute of tricalcium may be used. Donors, both living and cadaver, should be tested for human immunodeficiency virus (HIV) antibody before a graft is transplanted. Living donors should be retested 90 days after procurement if possible. People who are HIV positive, have any immune disorder or active infection, or have a history of hepatitis are excluded as donors. The probability of transmission of HIV in frozen or freeze-dried bone is remote. Secondary sterilization by ethylene oxide or ionizing radiation may increase the margin of safety but will reduce the biologic effectiveness of the graft.

Soft Tissue Allografts

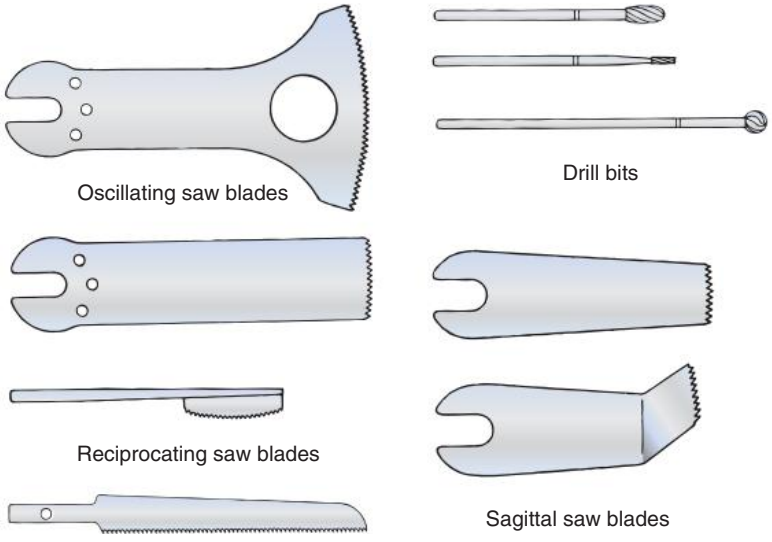
Cartilage, ligaments, and tendons obtained from cadavers may be frozen or freeze-dried for use to augment soft tissue repairs.

Fixation Devices

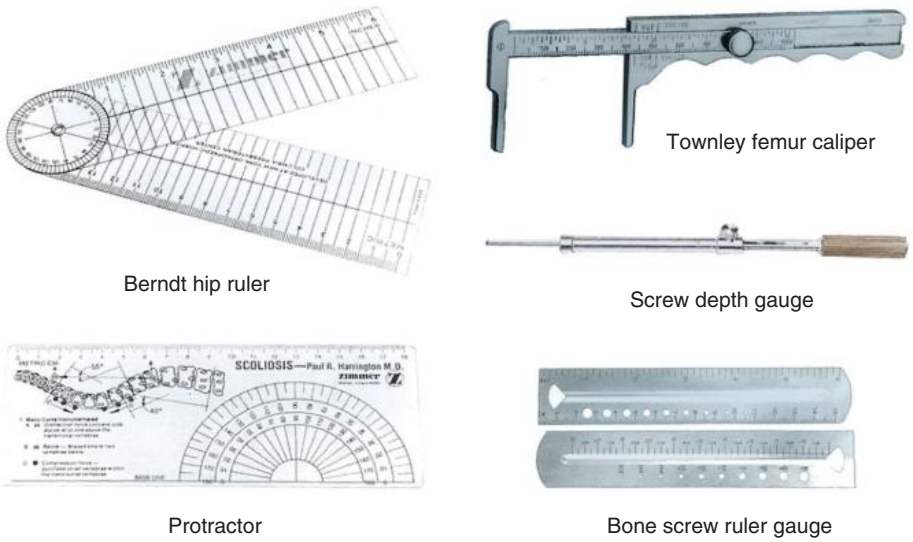
External and internal fixation devices are used to stabilize or immobilize bone, usually after skeletal injury. External devices provide temporary support during healing. Many types of screws, plates, and nails are used for temporary or permanent internal fixation of fractures or bone segments after a reconstructive procedure. Devices are also used to stabilize the vertebral column.

Prosthetic Implants

Prosthetic implants are used to permanently replace bone, joints, or tendons. They are made of nonmagnetic and electrolytically inert metals such as stainless steel, cobalt, and titanium alloys or of polymers such as silicone and polyethylene. Some modular implants are made of several materials. All metals have some corrosion factors and can create a sensitivity reaction that results in a rash or dermatitis over the metallic implant.[4] Others have a polymeric or porous coating for tissue ingrowth over a portion of the implant. The design of the prosthesis is balanced and sized to fit



• **Fig. 36.9** Saw blades and drill bits. (From Gregory B: *Orthopaedic surgery,* St. Louis, 1994, Mosby.)



• **Fig. 36.10** Measuring devices used in orthopedics. (From Gregory B: *Orthopaedic surgery,* St. Louis, 1994, Mosby.)

according to body motion and measurements. The principles of biomechanics have revolutionized orthopedic surgery.

Polymethylmethacrylate (bone cement, PMMA) may be used to reinforce fixation or increase the strength of the implant. An orthopedic implant must withstand stresses within the internal environment. Fatigue strength, corrosion resistance, biocompatibility, and biomechanics are critical factors in selecting an implant.

Because of the high cost of prosthetic and fixation implants such as plates and screws, the inventory is kept as low as possible, yet large enough to ensure availability when needed.

Expensive implants are patient-charge items; they cannot be reused even if they are temporary. After measurements are taken, an implant of the correct size, shape, and design is selected from the sets available. Only the implant to be used is handled, without the others being touched. Sterilized sets of screws and plates are packaged in slotted trays according to size. Several graduated sizes are included in each set. Always check that the set includes the appropriate screwdriver for the type of screws in the set.

An infection around a fixation or prosthetic implant may require its removal, often resulting in permanent deformity or disability.[4] Sterility at the time of implantation is imperative. Joint implants are supplied sterile by the manufacturer. They can be stocked by consignment. Some facilities have the sales representative bring in the needed sizes the day before surgery. Implant sizes and availability should be checked before the patient is brought to the operating room (OR). Confirmation of the correct implants is part of the "time out" process.

Implants, such as plates and screws, should not be flash-sterilized for any reason. Only standard cycles with appropriate biologic monitoring should be used. Some implants cannot withstand the heat of steam sterilization; ethylene oxide or some other appropriate method is used. Aeration time is necessary after ethylene oxide sterilization. Each sterilization cycle containing an implant(s) should be biologically tested per load and internal biologic monitoring. The implant(s) are not considered safe for use until a negative biologic test result is known. The manufacturer's recommendations should be followed.

A metal implant should not be removed from a package with an instrument. The surface could be scratched. An implant with a scratched or dented surface cannot be used because an electrolytic reaction will occur in the body. Team members who handle prosthetic implants should have clean, sterile gloves.

Specifics about the device or prosthesis and fixation method must be recorded in the patient's intraoperative record. This includes the type, size, and other identifying information, such as the manufacturer's lot number. Lot numbers are recorded in the departmental lot number log as appropriate in case of recall.

Lasers

Although not used as commonly as in other surgical specialties, lasers are used in some orthopedic procedures. They are useful in confined areas (e.g., through an arthroscope) to minimize bleeding.

Carbon Dioxide (CO_2) Laser

PMMA can be vaporized with a carbon dioxide (CO_2) laser to remove a cemented joint implant during a revision arthroplasty. Care is taken to use a smoke evacuator during the procedure. The CO_2 laser cannot penetrate a fluid environment; therefore the joint is insufflated with CO_2 gas to create a working space. The vaporization of cellular water destroys soft tissue. The CO_2 laser is useful in arthroscopic surgery for synovectomy and sculpturing articular cartilage. The joint is irrigated after the laser use to evacuate charred tissue.

Holmium:YAG Laser

Used primarily in the knee, ankle, shoulder, and elbow, the holmium:yttrium aluminum garnet (Ho:YAG) laser is approved for all joints except the spine. The 2.1 mm wavelength with low penetration depth combined with pulsed high energy is delivered through a fine fiberoptic fiber. The Ho:YAG laser acts on water in cells without charring or damaging tissue extensively. It can ablate dense cartilage, bone, and soft tissue. It is used through an arthroscope to cut, shape, smooth, and sculpt cartilage and tissues in joints.

Neodymium:YAG Laser

The neodymium:yttrium aluminum garnet (Nd:YAG) laser is used primarily in arthroscopy of the knee and shoulder joints on articular cartilage. It vaporizes protein and bonds collagen. It can be used for percutaneous disk procedures. Delivered fiberoptically, the Nd:YAG laser may have a reusable sapphire tip or a

disposable, single-use ceramic contact tip. The Nd:YAG laser may be passed through a potassium titanyl phosphate (KTP) crystal, which has good cutting properties, to vaporize protein.

Bone Wax

Bone wax is used for hemostasis on cut bone. The surgeon's preference card should be checked before the packet is opened to the sterile field. The inner sterile foil packet can be placed in warm saline irrigation to soften the wax for use. Alternative bone edge hemostasis can be attained with Gelfoam slurry or synthetic non–bee's wax copolymers. Bone wax and other bone edge hemostatics are discussed in Chapter 29.

Nerve Stimulator

A nerve stimulator is used occasionally to identify neural tissue during a partial nerve resection to control spastic muscles such as in cerebral palsy or muscular dystrophy. When the popliteal nerve, for example, is stimulated with the nerve stimulator, the foot jerks. Both direct electric current and sterile disposable battery-operated stimulators are available.

Sutures

Ligaments, tendons, periosteum, and joint capsules are fibrous tissues. They are primarily tough, stringy collagen and contain few cells or blood vessels. As a result, they heal more slowly than do vascular tissues. Nonabsorbable synthetic materials are used to suture ligaments, tendons, and muscles involved in movement of the bony skeleton. Absorbable suture is preferred to suture periosteum. The surgeon's preferences should be checked before the suture packets are opened to the sterile field.

Casts and Braces

A cast, brace, or other rigid support is a means of obtaining external fixation of a fracture or a part after tendon repair, arthrodesis, or other surgical procedures. It is the means of putting a part at rest for healing after surgery or attempting to correct an injury or structural abnormality. (More information about casting is located at the end of this chapter.)

Cast Room

Casts may be applied in a cast room located outside of the OR suite, sometimes referred to as the plaster room. **Closed reduction (CR)** and other noninvasive structural support procedures are performed in the cast room. It keeps plaster dust from the perioperative environment—an important aspect of aseptic environmental control.

Laminar Air System

Special care must be used to carry out strict asepsis. Infection is the most serious, dreaded, and costly complication of orthopedic surgery. Some surgeons prefer to operate within an ultraclean air system, especially for total joint replacement procedures. Orthopedic surgeons use laminar airflow more frequently than do other surgical specialists.

A surgical patient isolation drape may be used to isolate the sterile field from personnel and equipment. Surgical helmets are available that isolate airborne contaminants shed from each team member. Hoses exhaust exhaled air. Masks are not worn under the helmet. Fig. 16.7 depicts the team wearing the helmet system. This system can be used independently or in conjunction with a laminar airflow system. **Laminar airflow** design is described and illustrated in detail in Chapter 10.

Isolation suits are fully contained gowns with acrylic plastic face shields and a battery-powered air filtration system. Because the suits retain heat, the OR may be kept at 70° F (21° C) for the comfort of team members. The patient should be maintained in a normothermic state with forced-air warming or protected by some other independent warming method.

Fracture Table

An orthopedic OR bed, often referred to as the fracture table, is used for many surgical procedures requiring traction, x-ray image intensification, and/or cast application. The patient is anesthetized on the transport cart before being positioned on the fracture table. The many available attachments make possible any desired position and traction on any part of the body. The table can be raised, tilted laterally, or put into Trendelenburg's or reverse Trendelenburg's position.

Attachments are designed not only for stabilizing the patient in the desired position but also for exerting traction to help reduce a fracture and for providing a means of evaluating the diagnosis or surgical site by real-time x-ray imaging. Bakelite or some other radiolucent material that does not interfere with x-ray studies is used for attachments that might otherwise obscure the findings.

Essential standard component attachments on all models of orthopedic tables include narrow, three-section patient body supports, a lateral body brace, a sacral rest, perineal post, and traction apparatus.[5] Optional accessories are available to accommodate the types of procedures performed and the model of the OR bed. When the fracture table is used, the following preparations are considered:

1. Consult the surgeon's preferences and manufacturer's manual for attachments needed for each desired position. The fracture table is used for supine procedures and cannot accommodate lateral positioning.
2. Check the patient's height and weight in kilograms. Each style of OR bed has specific weight limits. The weight limit is printed on the base of the table.
3. Assemble the necessary attachments. Pad all parts of the OR bed and attachments to prevent pressure on joints, the sacrum, and the perineum.
4. Attach the standard components and accessories to the OR bed frame so all is in readiness for positioning the patient after the administration of anesthesia. The patient may have a spinal or general anesthesia. Patients with several comorbidities usually have spinal anesthesia to avoid any complications associated with general anesthesia.[6]
5. Arrange appropriate staff to move the patient from one surface to another. The patient will be a full lift whether general or regional anesthesia is used. Placement on the fracture table is somewhat precarious because the body section is very narrow. It is easy for the patient to fall if not carefully positioned and secured.

X-Ray Equipment

Conventional x-ray equipment and fluoroscopy frequently are used during orthopedic procedures. Considerations for patient safety and personnel protection described in Chapter 13 apply to the use of x-ray for all invasive or noninvasive orthopedic procedures performed in the OR suite. Special positioning and draping techniques may be necessary, especially when C-arm fluoroscopy is used.

Often both anteroposterior (AP) and lateral views are necessary to assess the alignment of a bone or determine the position of a fixation device or prosthetic implant. X-rays or C-arm fluoroscopic images document the work of the surgeon for the permanent record.

Special Considerations in Orthopedic Surgery

1. Unit beds are used to transport patients in traction apparatus. Beds, frames, and transport carts can be decontaminated in the vestibule/exchange area.
2. A cast should be removed preoperatively in the cast room. If the OR suite does not have a cast room, a cast may be **bi-valved** (cut) in the patient's room and then removed in the OR to minimize the dispersal of particulates in the air.
3. Positioning the patient intraoperatively and postoperatively should be directed by the surgeon. Immobilization and good body alignment contribute to patient comfort and prevention of neurovascular injury. Pillows or other supports should not cause pain, impair function of unaffected muscles and joints, or compromise circulation.
4. Transcutaneous electrical nerve stimulation (TENS) may be used for postoperative analgesia. The electrode pads are affixed to the skin along the sides of the incision when a dressing is applied. Before application, the skin should be cleansed with water. (Saline is a conductor, so it cannot be used for cleansing.) The wires are connected to the stimulator in the postanesthesia care unit (PACU) or after recovery from anesthesia. The patient can be taught preoperatively how to use TENS for relief of pain postoperatively.
5. Electrostimulation promotes cellular responses in bone and ligaments. Mechanically stressed bone generates electrical potentials related to patterns of bone regeneration. If stimulated, healing may accelerate.

Both internal direct-current stimulators and external pulsating electromagnetic field or electrical capacitor devices are used to stimulate bone and neural regeneration, revascularization, epiphyseal growth, and ligament maturation.

Extremity Procedures

Although instrumentation varies by procedure and the size of structures involved, basic techniques apply to handling both upper and lower extremities.

General Considerations

1. A sterile irrigating basin or pan is placed under an extremity to catch solution if an open wound is to be cleansed, irrigated, and debrided, as for a compound fracture. If an irrigating basin is not used, the runoff is collected by an absorbent pad under the prepped limb. A staff aide wearing gloves can elevate the limb during the prep procedure.
2. A pneumatic tourniquet is commonly used for a surgical procedure on or below the elbow or knee to provide a blood-free field. The tourniquet cuff is applied before the extremity is prepped. Prevent prep solution from running under the tourniquet cuff by covering the cuffed area with a sticky drape or towel. The tourniquet is not inflated until the limb is elevated and **exsanguinated** with a sterile Esmarch. It is important to exsanguinate the limb to assure a bloodless field and prevent blood clots. Do not discard the Esmarch in case it is needed again. Re-roll it and place on back table.

   Always check the pressure setting with the surgeon before inflating a tourniquet. Ischemia time is a critical factor in patient safety. Notify the surgeon of the time lapse after the first hour and every 15 minutes thereafter throughout tourniquet inflation. Document the tourniquet location, time, pressure, and unit identifying number.
3. The extremity is elevated for the skin prep. A dry, sterile drape is positioned under the limb by the scrub person before it is lowered to the sterile field.[3]
4. A self-adhering incise drape may be used as the first drape applied over the incision site. If the extremity must be manipulated during the surgical procedure, the entire circumference must be draped free with sterile stockinette.
5. Stockinette may be used over a self-adhering plastic drape or to cover skin and wrapped with Coban or ACE bandage to keep the circumferential drape in place. This wrap is cut with bandage scissors over the line of the incision. An extremity sheet or split sheet may be used over the wrapped stockinette as a body drape. A large sterile glove can be placed over the foot to protect the sterile field during lower limb surgery.
6. A fluid-control drape collects blood and irrigating fluids in a pouch to prevent strike-through of and runoff from drapes. Fluids can be drained or suctioned for disposal. Blood may be suctioned directly from the surgical site for autotransfusion if blood loss is more than 400 mL, as in some hip procedures.
7. After a surgical procedure on a knee joint, a pressure dressing is usually applied to prevent serum accumulation. This may be a Robert Jones dressing, which includes a soft cotton batting roll, sheet wadding, and cotton elastic bandage. A cotton roll or other bulky material may be placed on each side of the knee and held in place with sheet wadding. A four-ply, crinkled-gauze bandage or cotton elastic bandage over this provides even, gentle pressure. Depending on the surgical procedure, a plaster splint or some other type of knee immobilizer may be preferred.
8. After a surgical procedure on a shoulder, the arm may be bound against the side of the chest for immobilization. An absorbent pad or a large piece of cotton or sheet wadding is placed under the arm to keep skin surfaces from touching, because they may macerate. The arm is held in a shoulder immobilizer that supports the humerus and wrist, or it may be bound firmly to the side of the chest with a cotton elastic bandage.
9. Postoperatively the extremity is elevated on a pillow placed lengthwise. This facilitates venous return, decreases swelling, and minimizes pressure on nerves. The hand should be elevated above the level of the heart; the toes must be higher than the nose.

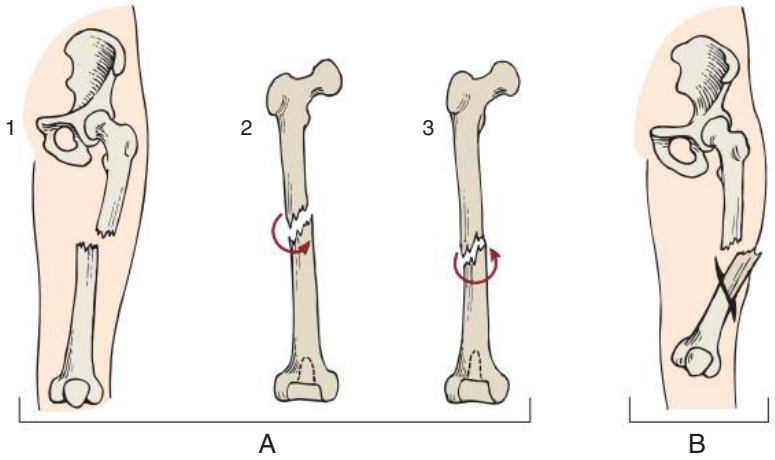
Indications for Orthopedic Surgery

Preoperative assessment of an acute or chronic disability affecting the musculoskeletal system of an extremity includes evaluation of the extent of bony or soft tissue involvement with or without concomitant neurovascular compromise.

Assessment for signs and symptoms of neurovascular impairment in an extremity includes the six Ps: *p*allor, *p*ulses, *p*ain, *p*aresthesia, *p*uffiness, and *p*aralysis. The six Ps are assessed postoperatively and monitored until support devices, such as casts or splints, are removed from the surgical site.

Adult orthopedic surgery is usually necessitated by trauma or by a degenerative disease process. Surgical procedures on the following major anatomic classifications of structures are discussed in this chapter:

- Fracture of bones
- Reconstruction of joints
- Repair of tendons and ligaments



• **Fig. 36.11** Fractures of a long bone. **A,** Simple closed fractures. *1,* Transverse break runs across bone; *2,* oblique break runs in slanting direction across bone; *3,* spiral break coils around bone. **B,** Compound open fracture protrudes through skin.

Fractures

Intact bones are essential to the stability and mobility of upper and lower extremities. A comminuted (splintered) or fractured (broken) bone can cause malfunction and pain. Fractures vary by cause, location, type of fracture line, and extent of injury. Typical long bone fracture lines are depicted in Fig. 36.11. They are either traumatic or pathologic.

1. *Traumatic fracture:* The impact, forced twisting, or bending of an accidental injury can break one or more bones in the body. Traumatic fractures can occur when bone has become fatigued from overwork or has inadequate muscle support during exertion; a stress fracture may result (e.g., in the tibia or fibula of an athlete). Traumatic fractures are either closed or open.
   a. *Closed fracture:* Sometimes referred to as *simple fractures*, broken fragments do not protrude through adjacent tissue to puncture the skin. The fracture is named for the direction of the line of breakage (e.g., spiral, transverse, oblique).
   b. *Open fracture:* Also referred to as a compound fracture, the proximal or distal end of bone, or both, protrude from the fracture site through adjacent tissues and skin. Because of the risk for infection developing in the exposed bone, an open fracture is a surgical emergency.
2. *Pathologic fracture:* Demineralization of bone (e.g., from osteoporosis or the aging process) and primary or metastatic malignant bone disease can spontaneously fracture a bone without undue stress. Although they are technically simple fractures, pathologic fractures may require more than simple fixation of bone fragments.

Bone allografts or autografts may be needed. Methylmethacrylate bone cement may be used to increase the strength of a fixation implant or as an adjunct to fill a bone defect (e.g., after removal of a tumor around a pathologic fracture). Bone grafts can be biologic, synthetic, or a combination (bioengineered) of substitutes. The patient's own bone can be ground in a bone mill to autograft the fixation. A compound made from collagen protein mixed with ceramic material may serve to stimulate creation of cartilage and osteoblasts (bone-forming cells).

Mechanical means are used to reduce a fracture and immobilize the parts, maintaining the fragments in proper alignment. Fractures must be handled gently with support above and below the site to prevent further trauma. The surgeon should assume responsibility for supporting the fracture site during transfer of the patient from one bed surface to another. Other personnel must be instructed regarding the special care needed to move a patient. The surgeon removes or directs removal of temporary splints or traction. An adequate number of personnel must be available so the patient can be lifted gently. More lifters should be on the affected side, because this helps support the fracture during transfer.

In treating a fracture the surgeon seeks to accomplish a solid union of bone in perfect alignment, return joints and muscles to normal position, prevent or repair vascular trauma, and rehabilitate the patient as early as possible. Treatment of fractures usually includes three distinct phases: reduction, immobilization, and rehabilitation. The methods of treating fractures include the following:

- Closed reduction (CR) with immobilization
- Skeletal traction
- External fixation
- **Open reduction and internal fixation (ORIF)**
- Electrostimulation

Closed Reduction

A fracture may be manipulated (set) to replace the bone in its proper alignment without opening the skin. This technique is referred to as a **closed reduction (CR)**. Many fractures of the lower leg or arm can be treated by CR.

Often performed in the emergency department, CR with the patient under anesthesia and application of a device for immobilization may be done in the cast room of the OR suite.

A plaster, fiberglass, or other lightweight synthetic cast, castbrace, or molded plastic fracture-brace may be used to hold the reduced fracture site in alignment during union.

Skeletal Traction

Traction is the pulling force exerted to maintain proper alignment or position. In skeletal traction the force is applied directly on the bone after insertion of pins, wires, or tongs placed through or into the bone. A small sterile setup is required. Traction is applied by

means of pulleys and weights. Weights provide a constant force; pulleys help establish and maintain constant direction until the fractured bone reunites.

Forearm or Lower Leg

A Kirschner wire (K-wire), either plain or threaded, or a Steinmann pin is drilled through the bone (preferably cortical) distal to the fracture site. For forearm fractures the wire or pin must be strong enough to prevent side-to-side, angular, and rotary motion while the fracture is healing. A traction bow is attached to the protruding ends of the wire or pin. The pulleys are fastened to this bow. The ends of the wire or pin are covered with corks or plastic tips to protect the patient and personnel from the sharp ends.

Finger

A fine K-wire may be drilled through the distal phalanx. The ends may be attached to a banjo splint. Or a cast may be applied to the forearm with a loop of heavy wire incorporated in it that fans out beyond the fingers. The K-wire is fastened to this loop by a rubber band.

External Fixation

External fixation devices are used for the treatment of selected types of skeletal injuries, especially to the pelvis and extremities, with marked soft tissue loss and instability. Skeletal pins and connecting bars permit rigid fixation but with access to devitalized skin and soft tissue for wound management, especially for open injuries of the tibia. Fixation devices used for unstable pelvic fractures allow early ambulation.

Femur and Tibia

External fixation applies tension and compression forces to bone. Tension stimulates bone growth. Compression helps control infection and promotes union in fractures without bone loss. External fixators also can be used for correcting bone deformities and for lengthening the femur and tibia after osteotomy for limb length discrepancy. Several types of devices used on the lower extremities allow the patient to ambulate.

Stabilization Bar

Two or more pins or screws aligned parallel to each other are inserted into the cortex of each fragmented section of bone. These may be connected to a metal bar, such as the dynamic axial fixator, that runs parallel to the bone on one side of the leg, or the pins may protrude through the leg and be clamped onto bars on both sides, such as with the Hoffman external fixation system.

Ilizarov Technique

Particularly useful for salvaging infected and nonunion fractures, the Ilizarov external fixator frame consists of a series of stainless steel rings connected by rods, nuts, and bolts. It can be assembled in various configurations and lengths. Wires are inserted percutaneously through the bone and connected under tension on both sides of the rings. Usually two wires are attached to each ring, at the proximal and distal levels, to stabilize bone fragments. The placement of wires is checked under C-arm fluoroscopy. Threaded rods are placed parallel to each other and in line with the longitudinal axis of the bone to connect and stabilize rings.

The system has more than 120 interchangeable components, including wrenches, pliers, and wire cutters. Wire insertion is a sterile procedure. The frame is assembled on the sterile field. It weighs approximately 8 lbs (3.6 kg) when fully assembled.

Open Reduction and Internal Fixation (ORIF)

Internal fixation is necessary for fractures that are not amenable to CR and stabilization with cast or brace immobilization, skeletal traction, or external fixation methods. Open reduction exposes the fracture site for realignment under direct visualization; CR sometimes precedes the insertion of an internal fixation device. The fracture is reduced to align fragments. If vascular structures have been traumatized, internal fixation followed by vascular repair may be necessary to restore arterial tissue perfusion and adequate venous drainage.

The procedure may be performed with the patient under regional block anesthesia, especially in patients in poor physical condition, such as a geriatric patient or one who has suffered multiple trauma. Intravenous (IV) moderate sedation may be given to dull the patient's awareness of the sound of drills and mallets.

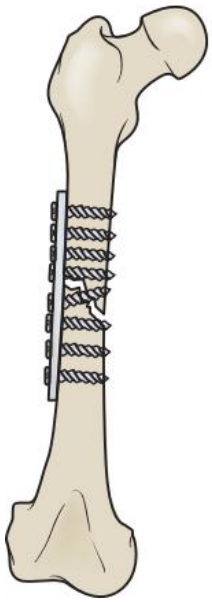
Excellent results can be obtained with internal fixation of a fracture soon after it occurs. This method provides firm immobilization and close approximation of the fragments so that the gap between the ends is not too great for the callus to bridge. It reduces to a minimum the space between fragments and movement at the fracture site (Fig. 36.12). Healing seems to take place faster. The patient starts non–weight-bearing exercises and progresses to ambulation early, which reduces joint stiffness and muscle atrophy and prevents a long period of rehabilitation.

Colles fracture of the radial bone in the wrist is sometimes surgically stabilized with plates and screws (Fig. 36.13, *A*) or CR under finger trap distraction (see Fig. 36.13, *B*).

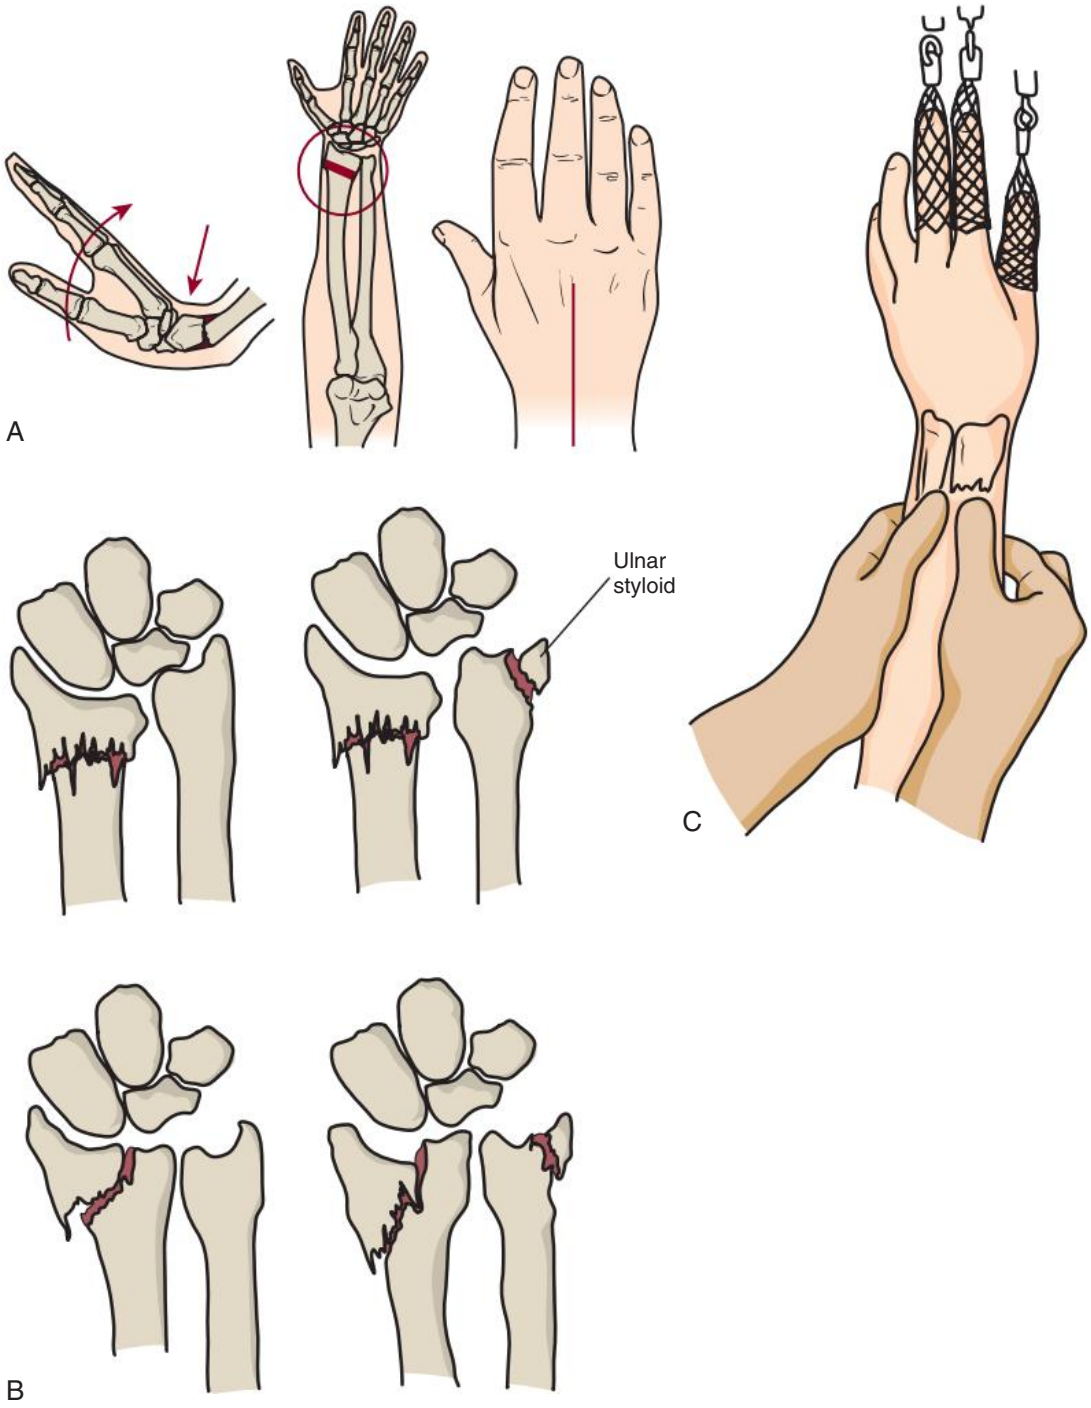
Screws, Plates, and Nails

Many types of rigid fixation implants are available. The surgeon chooses the type best suited to serve its purpose. The implant may remain permanently, or it may be removed after the fracture has healed, especially in a young person. For example, a plate can cause a stress fracture from the shielding forces exerted over time along its rigid edges on the less rigid underlying bone. If osteomyelitis develops, an implant must be removed.

Screws, plates, nails, rods, and pins are made of stainless steel 316 L, titanium, or cobalt alloys. These metals are nonmagnetic



• **Fig. 36.12** Open reduction and internal fixation of femur with plates and screws. Note that one screw has been transfixed across the fracture line for stability.



• **Fig. 36.13** **A,** Mechanism of Colles fracture of wrist with incision for open reduction. **B,** Common Colles fractures. **C,** Closed reduction of Colles fracture on wrist positioning frame.

and electrolytically inert. Only one kind of metal is used in a patient. The instrumentation used to implant it must be of the same metal. Semirigid carbon fiber–reinforced plastic plates also are used in some situations.

Biodegradable screws, plates, and rods provide stability during osteogenesis. A plate may be affixed to cortex of the bone, or an intramedullary rod can be inserted into the bone. The type and size of implant(s) must be documented in the patient's record and logged according to institution policy and procedure.

Screws

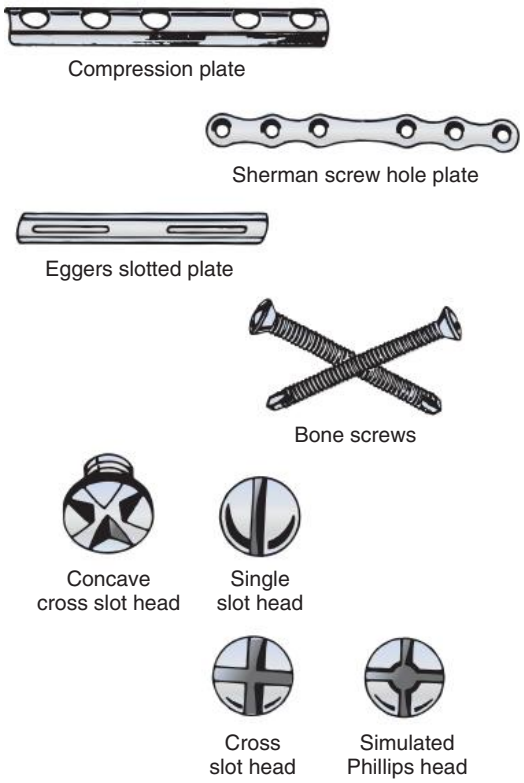
Screws alone may be used for fixation of an oblique or spiral fracture of a long bone. Screws must be long enough to penetrate both cortices. Hard cortical bone gives the best fixation, and two cortices generally hold better than one. Screws are available in various lengths and diameters. Not all screws have the same type of head (e.g., heads may be single slot, cross slot, concave cross slot, hexagon, or Phillips) (Fig. 36.14). The correct screwdriver must be used with each type of screw.

Compression Plates and Screws

Many fractures requiring open reduction are rigidly fixed through the compression method. Compression plates are heavy and strong. They are held in place by specially designed cortical lag screws. The threads of these screws are deeper than those on other types of screws and are farther apart, which allows a larger amount of bone between the threads. This construction gives maximum holding power and rigid fixation. Locking compression plates (LCP) are available, which gives the surgeon two options: placement of a conventional screw in one side or use the threaded hole to place a threaded screw to prevent movement or loosening.

A compression instrument may be used. It is connected to the end of the plate and then fastened to the bone with a short screw. When the nut on the compression instrument is tightened, the bone fragments are brought tightly together. The remaining screws are put into the plate, and the fracture is fixed. Screws alone are used only in selected situations. A cast may or may not be applied.

After ORIF of an acetabular fracture, a compression plate may be bent to conform to the contour of the acetabulum and secured with long cortical and cancellous lag screws.



• **Fig. 36.14** Fixation plates and screws.

Eggers Plate and Screws

The plate is slotted, which permits the muscle tone of the extremity to keep the ends of the fragments pressed closely together. The pressure stimulates osteogenesis.

Sherman Plate and Screws

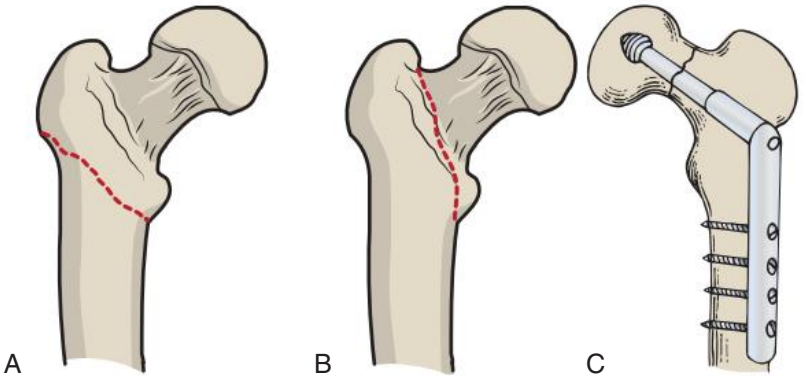
The appropriate-size plate is fitted to the contour of the bone, by bending it slightly if necessary, before the screws are applied. With a drill guide, holes for the screws are drilled with an electric or air-powered drill in the center of the screw hole and perpendicularly to the plate. The drill bit should be slightly smaller than the screws. The screws should pass through both cortices of the bone.

Nails

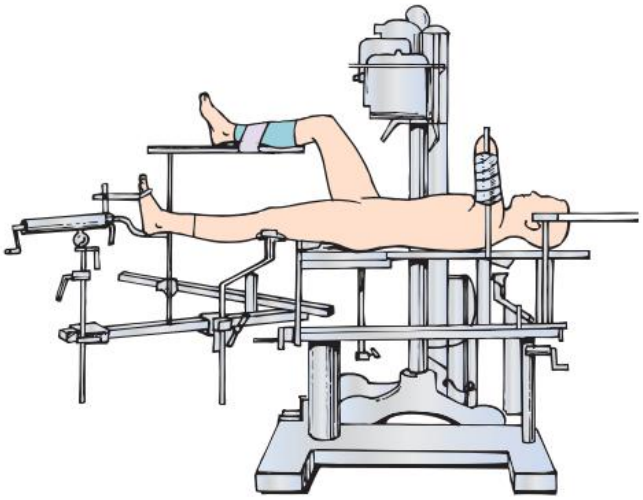
An intertrochanteric or subtrochanteric fracture of the neck of the femur may be treated by inserting a nail, compression screw, or multiple pins through the neck into the head of the femur (Fig. 36.15). Many different types of nails are used. They are usually inserted over or alongside a guidewire. The nail may form a continuous angulated unit with a plate that fits on the outer lateral cortex of the femur, or the plate may be attached and the nail, screws, or pins inserted separately. Screws secure the plate to the shaft of the femur before or after the nail is inserted, depending on the design of the implant.

The patient is positioned supine on the fracture table. The surgeon and assistants assume responsibility for moving and positioning the patient. Fig. 36.16 shows the position for nailing the left hip. The procedure may be performed with C-arm fluoroscopic image intensification, rather than conventional x-ray machines. All sterile tables are positioned on the affected side.

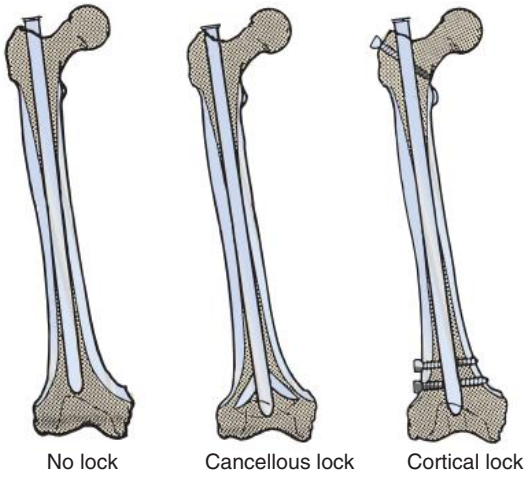
Intramedullary Nailing. An intramedullary nail, rod, or pin is driven into the medullary canal through the site of the fracture (Fig. 36.17). This brings the ends together for union, splints the fracture, and eases pain. It permits early return of function so the patient can be ambulatory. Intramedullary implants also provide a method of holding fragments in alignment in comminuted fractures. Rigid implants generally are used for pathologic fractures or impending fracture of diseased bone. Flexible



• **Fig. 36.15** Fractured hip. **A,** Type I fracture. **B,** Type II fracture. **C,** Compression hip screw for fixation of fracture of femoral neck.



• **Fig. 36.16** Position on orthopedic table for nailing left hip. Note arm on affected side suspended from screen to remove it from surgical field. Note traction on affected leg and support under knee. Elevated right leg permits C-arm x-ray to be adjusted below for lateral view.



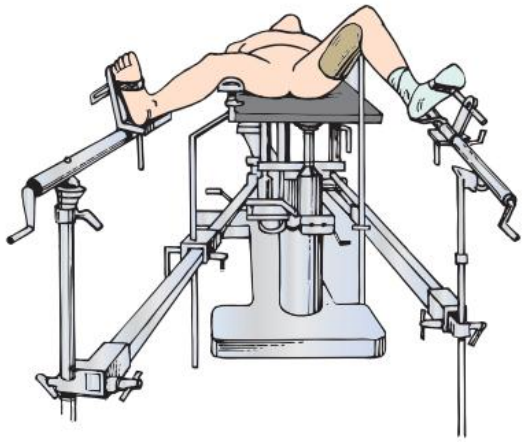
• **Fig. 36.17** Examples of intramedullary nail and rod devices. (From Gustilo RB, Kyle RF, Templeman DC, editors: *Fractures and dislocations,* St. Louis, 1993, Mosby.)

intramedullary rods may be preferred for some traumatic fractures, particularly femoral fractures. The length, size, and shape of the nail or pin depend on the bone to be splinted.

The patient with a femoral or tibial fracture is positioned on the fracture table. This permits traction as needed to maintain reduction. Fig. 36.18 shows the position of the patient for intramedullary nailing of the left tibia. C-arm fluoroscopy is used.

The fracture may be repaired by either ORIF or CR procedures. In some situations the medullary canal must be reshaped or enlarged before an implant is inserted. The implant may be removed after union at the fracture site has taken place, especially if it causes pain. If nonunion occurs, the implant may need to be removed.

Interlocking Nail Fixation. After CR of the fracture, an intramedullary rod or nail is inserted down the length of the shaft of a long bone without exposing the fracture site. This technique is called closed intramedullary nailing and may be used



• **Fig. 36.18** Position on orthopedic table for intramedullary nailing of left tibia. Note left foot anchored to foot holder and knee resting on elevated curved knee rest. Right foot is anchored, and knee rest is adjusted for support of leg.

for transverse or short oblique fractures of the midshaft of the femur or tibia. An incision is made to expose the femoral trochanter or tibial tuberosity.

To stabilize more oblique, comminuted fractures and those beyond the midshaft region, transfixion screws are also used with locking nails. These screws pass through the cortices of the bone and holes in the intramedullary nail. This method of closed interlocking nail fixation may be static or dynamic, depending on the location and configuration of the fracture. In the static method, screws are inserted in both the proximal and distal fragments; in the dynamic method they are proximal or distal. Several types of interlocking nail systems are available, such as the Grosse-Kempf, Brooker-Wills, and Russell-Taylor systems. All systems prevent gliding and rotation of fragments, as well as shortening of the limb from bone loss.

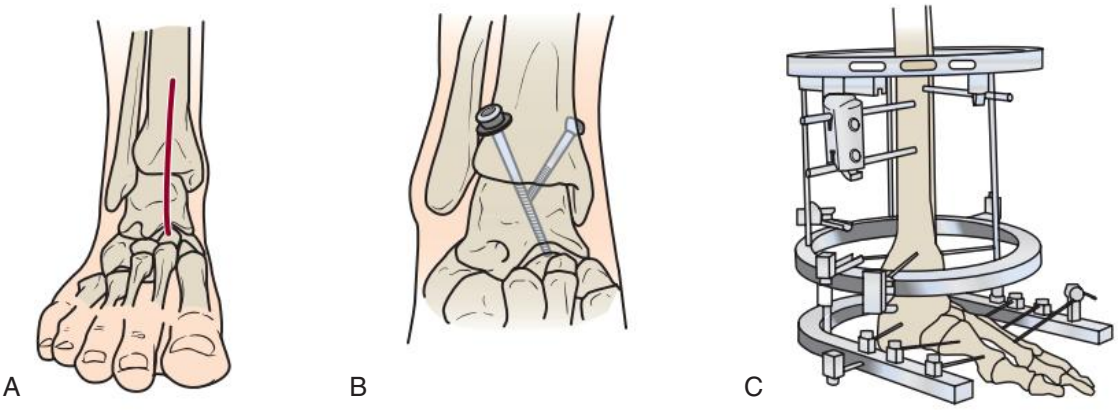
Joint Procedures

Joint function depends on the quality of its structures. Articular cartilage covers the two ends of bone where they meet to form the joint. Bones are held securely in place at their articulation by ligaments and the joint capsule attached to both bone shafts. The synovial membrane lining the joint capsule secretes synovial fluid to lubricate the joint. When the joint is injured or altered by arthritis or some other degenerative disease, normal joint motion is impaired and/or painful.

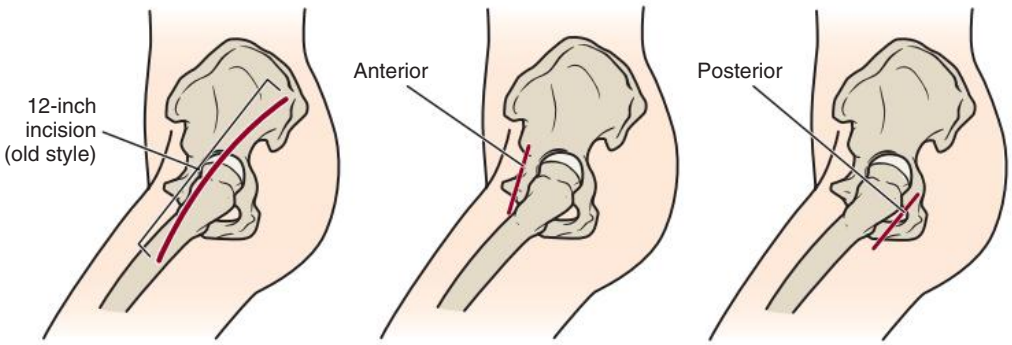
Dislocations

Dislocation of one or more bones at a joint may occur with or without an associated fracture. Tendons, ligaments, and muscles are deranged. The articular surface of the bone is displaced from the joint capsule. The force of displacement damages the capsule and tears ligaments and surrounding tissues. Blood vessel and nerve damage can occur, impeding circulation and causing changes in sensation and muscle strength.

CR, with or without skeletal traction, may be necessary at the time of an acute injury. If CR fails to stabilize the joint and prevent recurrence, ORIF may be necessary. Surgical procedures to stabilize chronic recurrent dislocations are most frequently performed on the shoulder.



• **Fig. 36.19** Ankle arthrodesis. **A,** Incision for internal ankle fusion (arthrodesis). **B,** Fusion. **C,** External fixator during fusion.



• **Fig. 36.20** Hip arthroplasty incisions compared.

Arthrodesis

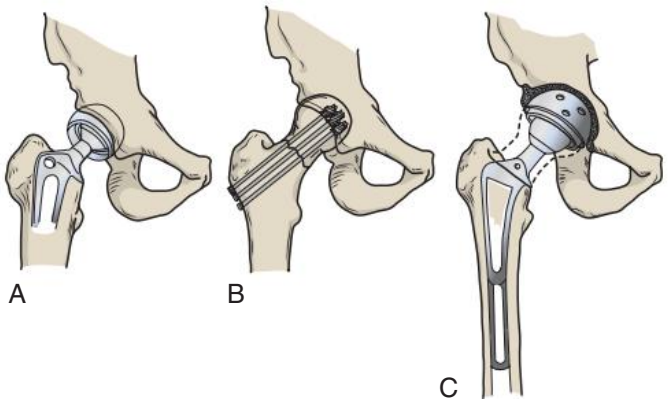
Fusion of a joint may be achieved by removing the articular surfaces and securing bony union or by inserting a fixation implant that inhibits motion. **Arthrodesis** may be performed after resection of a recurrent benign, potentially malignant, or malignant lesion that involves the ends of the bones and joint. After resection of the diseased portion of the bones the joint may be stabilized with a bone graft or an intramedullary fixation implant.

Arthrodesis is performed most frequently for lesions in the distal femur and proximal tibia around or including the knee joint. It also may be performed to relieve osteoarthritic pain or stabilize a joint that does not respond to other methods of treatment after injury, such as instability of the thumb. Because arthrodesis limits motion, other joint reconstructive procedures are usually attempted first.

Triple arthrodesis of the ankle is performed to correct deformity or muscle imbalance of the foot. The subtalar, calcaneocuboid, and talonavicular tarsal joints are fused. Staples are sometimes used to hold bones together (Fig. 36.19).

Arthroplasty

Arthroplasty (reconstruction of a joint) may be necessary to restore or improve range of motion and stability or relieve pain.[7] This may be done by resurfacing, reshaping, or replacing the articular surfaces of the bones. The incisional approach to the hip joint can vary according to the technique used. Traditional incisions were longer than newer methods used (Fig. 36.20). Hip arthroplasty is performed using several methods (Fig. 36.21).



• **Fig. 36.21** Hip arthroplasty methods.

Femoral and Humeral Head Replacement

A metal Austin-Moore prosthetic implant can replace the femoral or humeral head and neck to articulate with the existing acetabulum (Fig. 36.22). Austin-Moore prostheses have a shaft that is driven into the medullary canal of the bone. The head of the natural femur is removed. In some cases the femoral head is ground into bone graft matrix for reimplantation around the prosthesis. The neck is shaped or removed as necessary for accurate placement of the prosthesis. A reamer may be used to enlarge the canal for insertion of the prosthesis. These prostheses are used for the following purposes:

- To mobilize the joint in arthritic patients
- To replace a comminuted fractured head when soft tissue attachments are destroyed

• **Fig. 36.22** Austin-Moore prosthesis to replace femoral head and neck in hemiarthroplasty. Shaft is driven into medullary canal of femur.

- To replace the head if **avascular necrosis** or nonunion occurs after reduction of fractures

A free vascularized fibular graft may be preferred to decompress the femoral head, provide structural stability, and vascularize bone in an area of avascular necrosis. This procedure preserves the femoral head rather than replacing it with a prosthesis after removal of dead bone. The peroneal artery and vein are preserved with the graft. Under the operating microscope the vessels are anastomosed to branches of the femoral circumflex vessels. Restoration of vascularization prevents progression of necrosis and stimulates osteogenesis (new bone formation).

Femoral Head Surface Replacement

As an alternative to femoral head replacement a concentric metal shell is cemented over the femoral head. A high-density polyethylene shell is cemented into the acetabulum. Surface replacement to relieve severe hip pain and disability is reserved for young adults with good femoral and acetabular bone stock.

Patients with sclerotic, well-vascularized subchondral bone of hypertrophic osteoarthritis, for example, may be candidates for this procedure. Resurfacing induces healing and reduces stress on the hip joint.

Total Joint Replacement

The surgeon's goal in total joint arthroplasty is to alleviate pain and create functional mobility and stability.[7] The prosthesis must maintain normal anatomic relationships and biologic fixation to bone. Correct alignment and fit of component parts are crucial aspects of their function.

Although prosthetic implants for some joints have not been as well developed as those for others, total joint replacement is an accepted therapeutic modality, especially for the hip, knee, ankle, and elbow joints. Usually performed to improve mobility and relieve the pain of severe arthritic joints, total joint replacement may be indicated when other therapeutic measures have failed to correct a congenital defect, traumatic injury, or degenerative disease.

A functional design for the prosthesis must consider a combination of load bearing, strain-stress, and kinetics in association with the pathologic condition. Positioning of the prosthesis influences the distribution of stress and rate of wear.

The bones on both sides of the joints are replaced or resurfaced. Both component parts must be solidly anchored to avoid movement of the prosthesis and wear on surrounding tissue. All movement must be between the smooth articulating surfaces of the prosthesis. Various alloys, ceramics, and high-density polyethylene or silicone are used; component parts of many prostheses are made of more than one material.

Metal-to-plastic joints are self-lubricating. Natural synovial fluids help lubricate other types. The rate of wear on parts must be low so the prosthesis will remain functional over many years (the exact number is undetermined). The major complication of total joint arthroplasty is loosening of the prosthetic components over time, particularly in weight-bearing joints of obese and/or active patients. Configuration, surface features, and the method of fixation of component parts influence the mechanical stability of an "artificial" joint. The orthopedic surgeon must consider the following factors:

1. *Biomechanics*: Ideally a prosthesis provides full range of motion. The support provided by cartilage, ligaments, and the articular capsule surrounding the prosthesis influences its stability. Prostheses may be constrained or nonconstrained.
   a. A constrained prosthesis provides a stable joint but restricts motion to a single plane or limits motion in all planes.
   b. A nonconstrained prosthesis allows gliding and shifting motions resembling normal range of motion, but it is inherently unstable.
2. *Biophysical components:* A total joint prosthesis has at least two components—one for each side of the articulation. To determine the size and shape of components to fit the patient, measurements of bones that form the joint may be obtained preoperatively by developing templates (i.e., patterns on grids) from the patient's x-rays. If templates have not been obtained, x-rays and measurements are taken at the surgical field. The surgeon also takes trial measurements at the site to verify the correct selection of the implant.
   a. Solid components have a predetermined configuration. The surgeon must select the most appropriate size from those available. Bone may need to be reshaped to accommodate the prosthesis.
   b. Modular systems have interchangeable components so the surgeon can customize the prosthesis at the OR bed. For example, the width, depth, or length can be adjusted to the patient's anatomy. A quick-setting Silastic mold may be formed for precise matching in three dimensions. The mold is sent to a laboratory, where the prosthesis is customized with the use of a laser scanner and a computer-guided milling machine.
   c. Computer-assisted arms and robotic surgical techniques use CT technology to preplan the surgical procedure.[8] Exact models of the patient's anatomy are created in three-dimensional format for precise measurements and implant size. The surgeon guides the robot or arm to drill or make precision cuts for improved implant position and better outcomes. This technology can be used for most joint replacements.
3. *Fixation:* The bone into which the component part is implanted and the surface of the prosthesis will determine the method of fixation.
   a. Press-fit fixation relies on direct bone-to-prosthesis contact. This can be achieved by a variety of methods, including reshaping the bone to the size and/or configuration of the implant and/or securing threads, pegs, or screws on the prosthesis into bone.
   b. Biofixation refers to a surface on the implant that allows tissue ingrowth for stability. Ingrowth is defined as the development of bony tissue in an empty hole. A portion of

the implant has a porous or rough surface. Bone grows into pores or interstices. Many types of coatings are used, such as tricalcium phosphate or coralline hydroxyapatite sprayed on the surface.

Others have a porous material, such as polysulfone bonded to metal. Surfaces that are porous enough for bone ingrowth without greatly expanding the surface area or weakening the implant are most desirable. Cementless prostheses require a precise fit in bones. They are particularly suited for young, active patients.

c. PMMA fixation uses self-curing thermoplastic acrylic cement to provide long-term fixation. It is not a type of glue but, rather, a space-filling fixation material. Several different preparations of PMMA, commonly referred to as bone cement, are available. Several types contain antibiotics such as gentamicin or tobramycin. Although antibiotics may be a component, it is not recommended for use in a joint with active infection.

The powder and liquid components are mixed at the instrument table in a vacuum container immediately before insertion into the intramedullary canal of a long bone or socket of a joint. It becomes like dough when mixed. PMMA cures, or hardens, in response to an **exothermic** reaction that reaches 114° F (46° C) and destroys surrounding cells.

Cement is produced in low, medium, and high viscosity. Low-viscosity cement has a 3-minute sticky phase and cures in 1 to 2 minutes. Medium-viscosity cement has a 3-minute working phase and a 1.5 to 2.5-minute curing time. High-viscosity cement has a short, sticky phase and cures in 1 to 2 minutes. Low environmental temperature can prolong the curing time.

Bone cement is injected under pressure to fill the interstices of bone. When the implant is placed, the cement fills the cancellous spaces around it for a secure fit. This is the method of choice for most patients older than 65 years because it allows early ambulation. Cement can crack or break and cause loosening of the prosthesis over time.

The liquid portion is highly flammable and should not be placed in proximity to the cautery. Use of appropriate venting devices during mixing provides an extra measure of safety for the team. Users should not wear gas-permeable contact lenses because fumes can penetrate and bind with the lens material. A second pair of gloves should be worn when handling bone cement and discarded when handling is complete.

Physiologic responses to bone cement are varied. Some patients experience hypotension and can suffer an embolus or cardiac arrest during the cementing process, a condition known as **bone cement implantation syndrome (BCIS)**. Rarely a tiny fragment of cement can enter the venous system and embolize to the lungs. Causes of BCIS are not exactly known but are attributed to several of the following situations:

- Exothermic effects of the cement
- Gas embolism by the polymerization of PMMA
- Emboli (clots, fat, or cement) from pressurized cementing process in the cancellous bone
- Fat emboli
- Enhancement of halogenated anesthetic gas by fumes of the cement. Increased cardiac depression and hypotension.

Close collaboration with the anesthesia provider during the use of bone cement affords the patient an additional measure of safety.

d. Hybrid fixation refers to a combination of fixation methods. Some components are cemented; some are press-fitted or held by screws or some other noncemented technique.

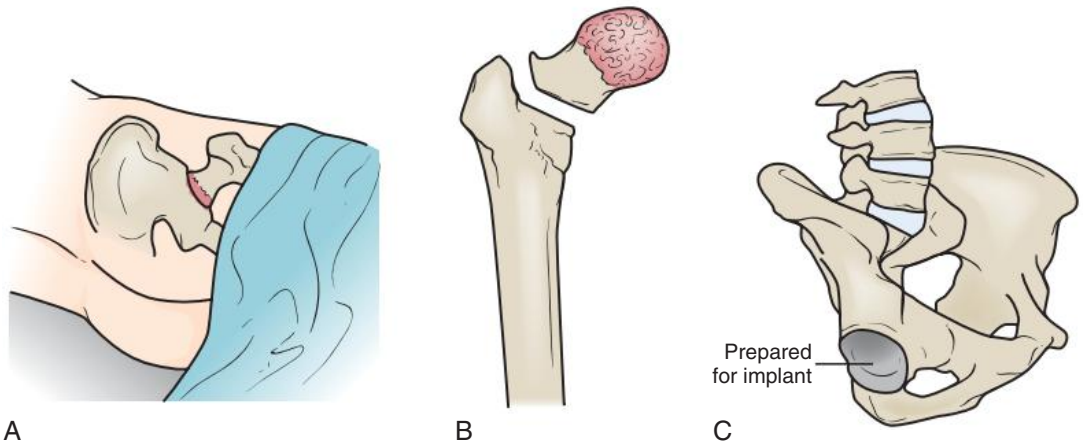
e. Bone grafts may be needed to replace bone loss around the joint. Either autologous or fresh-frozen allograft bone may be used.

Total Hip Replacement

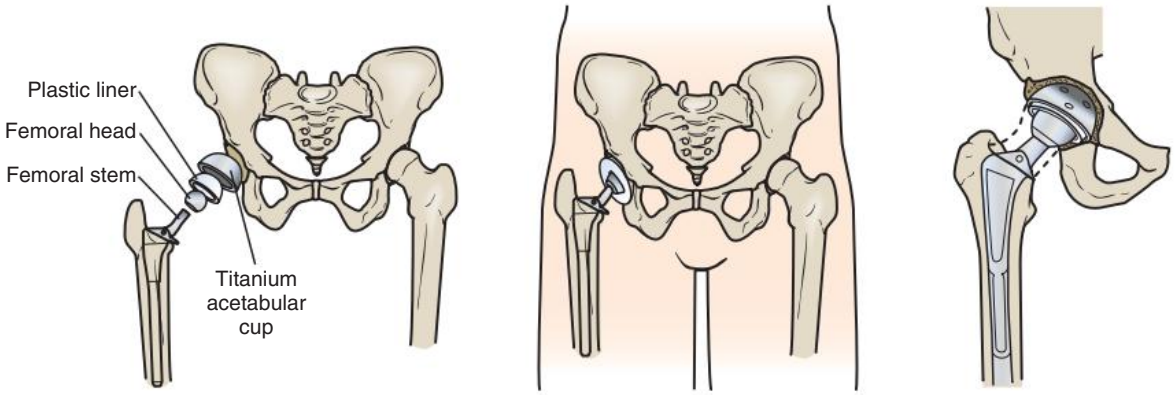
Total hip prostheses have greatly reduced the number of arthroplasty procedures previously described, especially in patients older than 50 years who have degenerative hip disease. Several types and sizes of prostheses are available. Each has its own advantages and disadvantages. The surgeon must select the appropriate one for each patient's particular condition.

With the patient supine on the OR bed, an incision approximately 10 inches (25 cm) long is made along the anterolateral aspect of the thigh to remove the greater trochanter. Removal of the greater trochanter facilitates exposure to prepare sites for insertion of the prosthesis. However, its removal can cause abductor muscle weakness, instability, and other complications. Therefore some surgeons prefer an anterior approach to the hip joint with the patient supine on a radiolucent table; others prefer a posterior approach with the patient in a lateral position (Fig. 36.23).

With all approaches the femur is disarticulated from the acetabulum. The femoral head is removed at the neck and replaced



• **Fig. 36.23** **A,** Lateral position of the patient for total hip arthroplasty. **B,** The diseased femoral head is removed. **C,** The diseased acetabulum is reamed to receive the acetabular cup implant.



• **Fig. 36.24** Components of a total hip joint replacement.

• **Fig. 36.25** Components of total knee joint replacement.

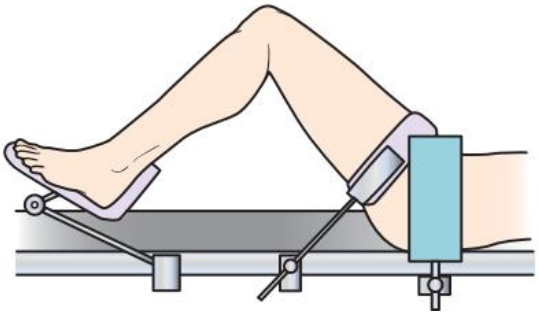
with a prosthesis. The prosthesis is a metal head, usually titanium, on a metallic stem that is seated into the medullary canal of the femur. Before the femoral prosthesis is inserted, the acetabulum is reamed to the configuration of the cup-shaped acetabular component (Fig. 36.24). This may be high-density polyethylene or metal with a smooth, rough, or porous outer surface. The inner surface is smooth polyethylene to articulate with the smooth finish on the head of the femoral prosthesis. The acetabular component is fixed in the socket. Then the femoral prosthesis is positioned. This sequence is reversed if a Silastic mold is made for a customized femoral component.

Computer-assisted surgical modeling or robotics may be used to help the surgeon plan the surgical procedure, select the most appropriate type and size of hip prosthesis, and prepare the surface of the bone.[9] A drill in the end of the robotic arm precisely drills the cavity in the femur to hold the implant stem.

Total Knee Replacement

Insertion of a total knee prosthesis may be indicated to provide for mechanical deficiencies in the function of the knee. The patient, usually older than 60 years, may have significant chronic pain and joint destruction as a result of arthritis, an inflammatory condition, or an autoimmune disorder. One or both knees may be affected. Bilateral total knee replacement can be performed safely in a patient who has the ability to actively participate in postoperative rehabilitation.

Selection of the appropriate prosthesis from among the types available depends on the deformity of the femorotibial articulation, patellofemoral articulation, and structure of the cruciate and collateral ligaments. The prosthesis consists of a multiradius femoral component, a modular tibial component, and a patellar component (Fig. 36.25). The tibial and patellar components of high-density polyethylene articulate with the polished metallic surface of the femoral component.



• **Fig. 36.26** Positioning device for knee surgery.

With the patient supine on the OR bed, the knee is maintained in a flexed position (Fig. 36.26). Numerous commercial devices are available for this purpose. The pneumatic tourniquet cuff is placed on the thigh before prepping. The knee will be draped free.

A vertical midline incision is made over the anterior knee. After the distal femur and the proximal tibia are measured and cut, a trial prosthesis is inserted. The knee is taken through a range of motion to assess alignment, ligament balance, and patellar positioning before the components are fixed in place.

To achieve stability, permanent bone ingrowth into a porous coated or rough-surface implant is desirable. Prostheses of this construction may not require bone cement for fixation. Hybrid fixation is used for others.

Total Ankle Replacement

Rheumatoid arthritis and posttraumatic osteoarthritis are the most common causes of ankle degeneration. Ankle joint replacement may be indicated as an alternative to arthrodesis in selected

patients, usually older than 60 years, to relieve pain and secondarily to increase motion and provide stability in the tibiotalar joint.

With the patient positioned supine, an anterior incision may be made from the base of the second metatarsal to the crest of the tibia. A posterior approach, with the patient positioned prone, may be preferred for wider exposure of anatomic structures. Procedures vary depending on the type of prosthesis to be implanted.

The nonconstrained type allows normal dorsiflexion, plantar flexion, and rotation of the foot but is inherently unstable; the constrained type restricts motion to a single plane but is inherently more stable. The tibial components of both types are high-density polyethylene, and the talar components are metal. They are cemented in place.

Total Metatarsophalangeal Joint Replacement

Hallux rigidus and hallux abductus valgus deformities can lead to pain and altered gait. Through joint replacement the deformity can be realigned with stability and motion. Several types of implants are available. The Silastic hinge toe, a double-stemmed silicone prosthesis with a hinge, is a popular choice to restore motion of the great toe and lesser metatarsophalangeal joints.

Total Shoulder Replacement

Shoulder replacement may be indicated for severe destruction by disease or posttraumatic degeneration of the humeral articular surface with resultant loss of motion, instability, and pain. The prosthesis replaces the humeral head and resurfaces the glenoid cavity, the articular surface of the scapula (Fig. 36.27). Preferred if ligamentous or capsular support is sufficient, a nonconstrained prosthesis has a plastic component for the glenoid socket and a metal humeral head. Only the articular surfaces are replaced with these gliding metal-to-plastic components.

A stable fixed-fulcrum, constrained prosthesis with interlocking components may be required to prevent dislocation. The patient is placed in a semi-Fowler position with the affected shoulder slightly off the edge of the OR bed for these surgical procedures.

Total Elbow Replacement

Prosthetic replacement may be indicated to correct intraarticular problems within the elbow joint, especially one with severe surface damage. Surface replacement with a nonarticulating, constrained prosthesis provides internal stability. A hinged or articulated, nonconstrained capitellocondylar prosthesis improves the functional range of motion in the humeroulnar articulation. Both the metallic humerus and ulnar components are cemented in place after shaping the bones. High-density polyethylene bushings facilitate articulation of the hinge assembly connecting the humoral and ulnar components.

Total Wrist Replacement

Silicone rubber implants are used to replace the radiocarpal joint in the wrist, primarily to improve function. A resection arthroplasty is done, usually from an anterior approach. The proximal row of carpal bones (i.e., scaphoid, lunate) and the trapezium are resected. Stems of the flexible, hinged implant are inserted into the intramedullary canals of the radius proximally and capitate carpal bone distally. A silicone cap is placed over the distal end of the ulna. Flexion and extension of the wrist are possible through free sliding of stems within the medullary canals. Some other types of prostheses have fixed stems.

Trapeziometacarpal Joint Replacement

A metal ball–to-plastic socket prosthesis restores function of the thumb. This prosthesis is cemented in place.

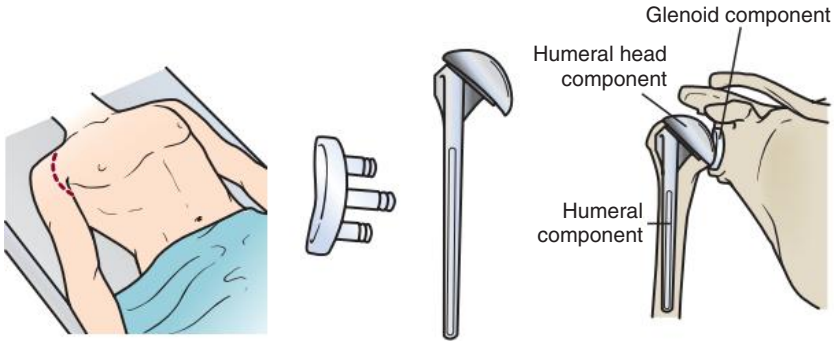
Metacarpophalangeal Joint Replacement

Known as implant replacement arthroplasty for small joints in the hands, the head of the affected metacarpal or proximal phalanx is removed in a metacarpophalangeal joint replacement. The silicone rubber implant bridges the excised joint. One stem fits into the medullary canal of the proximal metacarpal, and the other fits into the distal phalanx. The hinged body of the implant keeps the bones separated and mobile.

Patient Care Considerations in Arthroplasty

Patients of all ages may have debilitating and painful arthritis; many are older than 65 years. Attention must be paid to support all joints during moving and positioning of these patients. Other unique aspects of joint replacement should be kept in mind:

1. The prosthesis must be handled carefully.
   a. Use only instruments specifically designed for implantation of the prosthesis.
   b. Avoid causing dents and scratches.
   c. Avoid glove powder and lint. Silicone implants should not be placed on fabrics; place the implant in a metal basin or transfer it directly to the surgeon.
   d. Open sterile packages just before use, after the surgeon determines the size and style.
2. Bone cement, if needed, must be mixed by the scrub person immediately before use.
   a. Follow the manufacturer's instructions for handling this material. The scrub person should know by feel and appearance when the cement is of the correct consistency. A



• **Fig. 36.27** Components of total shoulder joint replacement.

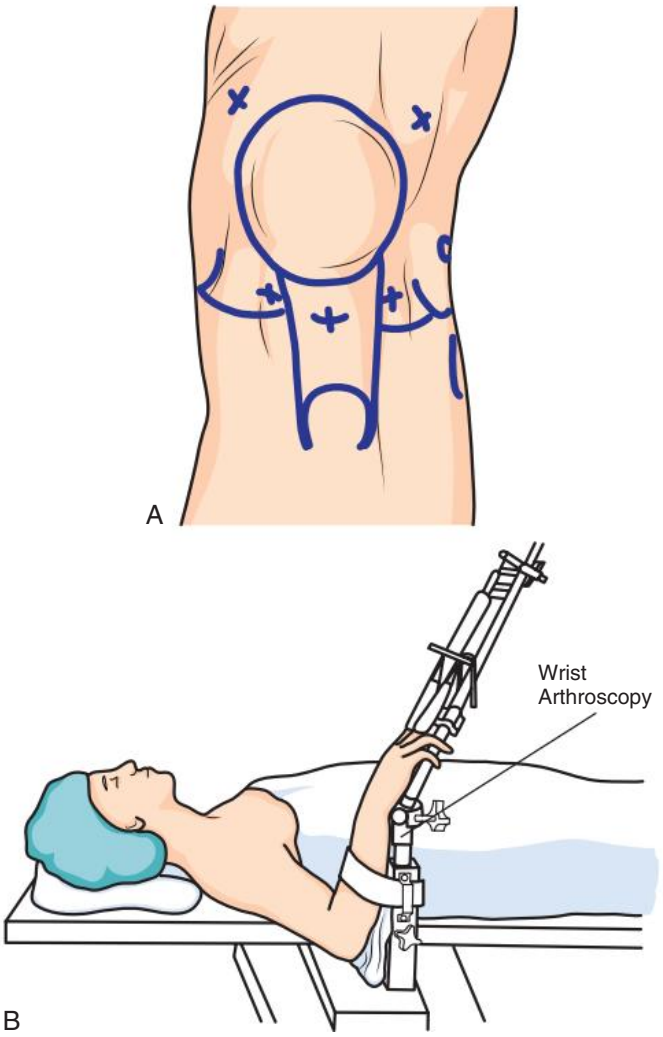
practice session is helpful before mixing for the first time during an actual surgical procedure.

b. Avoid excessive exposure to vapors. In addition to causing irritation to the eyes, vapors may damage gas-permeable contact lenses if worn. A scavenging system should be used.
c. Avoid getting lipid solvent on gloves. It can diffuse through the latex to cause allergic dermatitis. Wear a second pair of gloves during the process and then discard them when the task is complete.
d. Cement is poured into a syringe for injection into the intramedullary canal for joints such as hip or shoulder joints. Cement may be shaped manually for hinged joints.
e. The temperature of the room can affect the time necessary for cement to set or "cure."
f. Be aware that some patients have an alteration in vital signs (i.e., hypotension, cardiac dysrhythmias) during placement of the cement in the medullary canal.

3. A Silastic mold, if used to customize the prosthesis, must be prepared at the sterile field. The scrub person mixes the catalyst and silicone quickly and thoroughly and then pours the mixture into the injector tube immediately before it is inserted into the bone. The customized prosthesis must be steam sterilized when it arrives from the laboratory. A standard sterilization cycle with internal and external biologic monitoring, not flash-sterilization, is used.
4. Air-powered drills, saws, and reamers must be properly connected with adequate pressure. Check the pressure in tanks of compressed air or nitrogen before the surgical procedure begins. It must be more than 500 lbs. Turn on the tank by turning the knob to the left. Turn off the tank by turning the knob to the right.
5. Suction tubing must be kept open and collection containers changed as necessary to maintain suction for irrigation during the surgical procedure.
6. Blood loss should be appropriately monitored. It can be extensive during total hip arthroplasty. Blood may be salvaged from the sterile field with a separate suction tube and processed (e.g., through a cell saver) for autotransfusion.
7. Closed-wound suction drainage generally is used, especially after hip, knee, and shoulder arthroplasty.
8. The exhaust system for personnel wearing helmets must be functioning properly if the surgical procedure is performed within a laminar airflow system. Air circulation is affected by ambient airflow, causing misdirection of the clean air.
9. Traffic through the OR should be restricted to minimize air turbulence. Infection is a major potential hazard of all bone and joint surgery. It can be both disabling and expensive.
10. The type of prosthesis used must be documented, including the manufacturer's identifying information. The label of a sterile implant can be affixed to the patient's record.

Arthroscopy

Arthroscopy, the visualization of the interior of a joint through an arthroscope, allows diagnosis and conservative treatment of some cartilaginous, ligamentous, synovial, and bony surface defects. Arthroscopy is used for definitive treatment of meniscal, articular cartilage, and ligamentous defects in the knee. An arthroscope also may be used in the shoulder, ankle, elbow, wrist, and hip. Examples of arthroscopic port placement for the knee and wrist are shown in Fig. 36.28. Fiberoptic arthroscopes have diameters ranging from 1.7 to 6 mm to accommodate the size of the joint. Angles of the viewing lenses also vary from 0 to 90 degrees.



• **Fig. 36.28** Examples of arthroscopic access port placement. **A,** Knee. **B,** Wrist on frame.

Sterile irrigating solution, either lactated Ringer's or normal saline solution, at room temperature is necessary to create a working space in the joint. The solution is injected initially via a needle and syringe. Then through a small stab wound, a cannula is inserted into the medial aspect of the knee, for example, for inflow of irrigation. Outflow tubing is connected to the metal sheath of the arthroscope. It can be attached to suction or placed in a drainage bucket and allowed to drain by gravity.

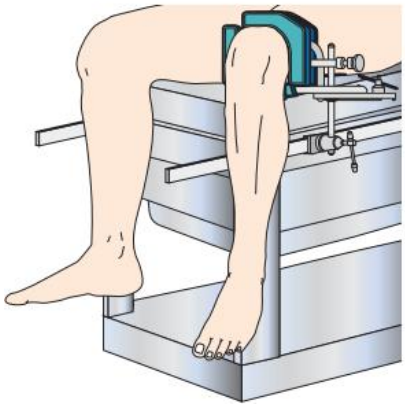
The sheath (sleeve) over a sharp trocar is inserted through a stab wound in the skin at the selected site of entry for the arthroscope. When the trocar penetrates the capsule, the capsule and synovium form a tight seal around the sheath. The sharp trocar is replaced with a blunt obturator to advance the sheath into the joint. The obturator is removed, and the arthroscope is inserted through the sheath. The inflow and outflow irrigating tubes are connected to the stopcocks on the sheath.

An operating arthroscope may have a channel for passage of long, thin, manually operated instruments such as probes, hooks, scissors, knives, punches, and grasping forceps. Or these instruments may be manipulated through separate access portals into the joint under visualization through the scope. Power-driven shavers are also used to smooth rough articular cartilage or bony surfaces.

A pulsed-energy Nd:YAG, Ho:YAG, or CO_2 laser may be adapted to some arthroscopes for use in a confined area and to minimize bleeding. A video camera attached to the eyepiece allows projection of the view to a closed-circuit television monitor so that the surgeon can manipulate instruments with precision. Some cameras attach to the side of a beam splitter on the scope. Discussion of endoscopy and the essential elements is found in Chapter 32 of this text.

Patient Care Considerations in Arthroscopy

1. All metal components of the arthroscope are steam sterilized. Some optical systems and fiberoptic cords can be steam sterilized; others require STERIS, STERRAD, or ethylene oxide (EO) gas sterilization. Protective sterilizing cases are recommended to protect the optics when the components are batch processed. Follow the manufacturer's recommendations for sterilization of the arthroscope and its component attachments.
2. The scrub person checks all sterile equipment and instruments while setting up.
   a. Check the arthroscope for clean lenses and unbroken optics.
   b. Check the patency of the inflow and outflow irrigation stopcocks and ports.
   c. All component parts must be the correct size; the optics, trocar, and obturator must fit securely into the sheath. Surgical instruments must pass through the channel. The fiberoptic cord must fit the arthroscope and projection lamp.
   d. Inspect the edges of cutting instruments, such as blades, burrs, knives, and scissors, under magnification. Blades must be sharp, set properly, and glide smoothly.
   e. Assemble power equipment. Rings must fit tightly. Forward and reverse rotating actions must function smoothly. Blades must be locked properly. The power source should be checked.
3. The circulating nurse checks all nonsterile equipment (i.e., fiberoptic light source, video equipment, fluid delivery elevation stand, laser).
4. The video camera and cable must be enclosed in a sterile cover unless the camera has been sterilized. The scrub person and circulating nurse coordinate draping.
5. The extremity must be firmly supported in a leg or arm holder that allows flexion of the joint (Fig. 36.29). A tourniquet is applied for arthroscopy of the knee, ankle, elbow, or wrist. Care is taken not to allow prep solution to run under the tourniquet cuff.



• **Fig. 36.29** Arthroscopy limb holder.

6. The patient is prepped and draped as for any sterile procedure on the extremity, with extra precautions to provide a waterproof barrier against contamination by irrigating solutions.
7. The circulating nurse hangs bags of sterile normal saline or lactated Ringer's solution on an IV pole at least 3 feet (1 m) above the joint. This ensures adequate hydrostatic pressure to keep the joint distended to create a working space and maintain the flow of the irrigating solution. Some facilities use irrigation pumps. Two to four 3000-mL bags may be needed.

   The solution is maintained at room temperature to avoid hyperemia from warm solution, which may appear as inflammation of synovium, or blanching, which produces an avascular appearance from cold solution. Used solution should be disposed of per biologic waste protocol.
8. Equipment must be appropriately attached after the patient is draped.
   a. The scrub person secures, for example, drainage tubes, fiberoptic cord, suction, and air-power cables to drapes in a location that will not impede movement of the extremity.
   b. The circulating nurse attaches, for example, tubing to irrigating and suction systems and cords to power sources.

Arthrotomy

Arthrotomy (i.e., incision into a joint) may be necessary to remove bone or cartilage fragments or to repair a defect in the synovium or joint capsule. Synovectomy may be the procedure of choice for relief of pain and control of inflammation in a rheumatoid arthritic joint. If a joint is ankylosed (fused), fibrosed, or deranged, open arthrotomy rather than arthroscopy may be necessary. Occasionally during arthroscopy, an injury or disease process that cannot be adequately treated requires arthrotomy while the patient is anesthetized or it may be performed at a later time. In the knee, for example, potential neurovascular complications may preclude arthroscopic repair.

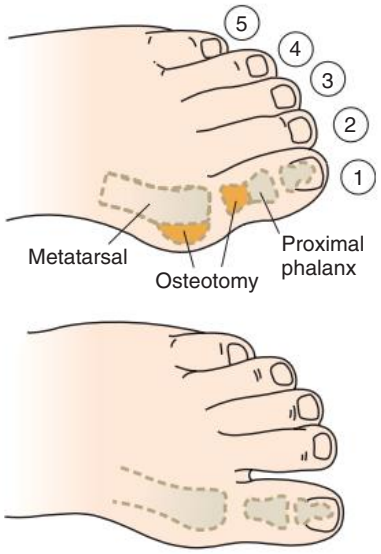
Bunionectomy

Hallux valgus, a lateral deviation in position of the great toe, increases the prominence of the adjoining metatarsal head. Pressure at the base of the first metatarsophalangeal joint causes inflammation that creates formation of an exostosis or bunion beneath the bursa and joint capsule. A bunionectomy is performed to remove a painful exostosis and functionally or cosmetically correct the deformity (Fig. 36.30).

A capsulotomy must be performed to enter the first metatarsophalangeal joint. The procedure may be done with the patient under local infiltration anesthesia and IV sedation. A pneumatic tourniquet around the ankle provides hemostasis, unless contraindicated in a patient with a circulatory problem in the foot. One of several procedures may be selected.

- *Keller arthroplasty:* The proximal third of the proximal phalanx of the great toe is resected. A silicone implant may be placed in the intramedullary canal to stabilize the metatarsophalangeal joint.
- *Metatarsal osteotomy:* The metatarsal alignment is corrected by moving the metatarsal head laterally.
- *McBride operation:* The abductor tendon is fixed to the lateral portion of the metatarsal neck, and the sesamoid bone is excised.
- *Silver bunionectomy:* The medial aspect of the exostosis is removed from the first metatarsal head.

Bunionectomies are only one of many procedures performed by podiatrists, as well as orthopedic surgeons, in the treatment of



• **Fig. 36.30** Bunionectomy.

foot-related disorders, including degenerative diseases and injuries of the foot and ankle.

Hammer Toes

A hammer toe is a deformity of the second, third, and/or fourth toes. The affected toe is bent at the middle joint and therefore resembles a hammer. Hammer toes are flexible at first and can be corrected conservatively, but if they persist, they can become fixed and require a surgical procedure, such as osteotomy, to shorten the angle of the toe.

Hammer toe can form in the presence of bunions that cause walking in an unbalanced gait. Improperly fitted shoes cause the toes to bend. The external surface of the affected toes develops painful calluses and makes wearing shoes very painful.

Neurolysis

Neuropathy caused by entrapment of a nerve produces tingling, numbness, and a burning sensation with radiating pain and compromise of function. Known as a tunnel syndrome, this most frequently occurs in the wrist from entrapment of the median nerve (i.e., carpal tunnel syndrome). It may originate from compression of the radial nerve in the lower arm (i.e., radial tunnel syndrome) or from the posterior tibial nerve in the foot (i.e., tarsal tunnel syndrome).

The cause of formation of scar tissue or adhesions around the nerve may be related to repetitive stress, trauma, or inflammatory disease. Neurolysis, freeing of the nerve from the surrounding structures, relieves pain and restores sensation and function. For example, in the wrist the transverse carpal ligament overriding the median nerve is incised. A segment may be excised and a synovectomy may be performed to relieve the symptoms of carpal tunnel syndrome. Release of the median nerve may also be accomplished endoscopically.

Repair of Tendons and Ligaments

Tendons and ligaments may be severed, torn, or ruptured. These injuries are frequently seen in athletes. Total or partial avulsion of the major ligaments and tendons torn from their attachments in or around an extremity joint requires repair to stabilize the joint.

Tendons can be lengthened, shortened, or transferred. When a surgical procedure is indicated, tendon repair is a meticulous but tedious procedure. Tenorrhaphy (close apposition of the cut ends of tendons, particularly extensor tendons) is imperative to successfully restore function. Tendons heal slowly.

Nonabsorbable or slow-absorbing suture is widely used in tendon repair because of its durability and lack of elasticity. A tendon may be wrapped in a silicone membrane to prevent adhesions after repair. Artificial tendons are made of a polyester center covered with silicone rubber. A double-velour polyester prosthesis is used for ligament repair of a shoulder separation.

Hand Surgery

Hand reconstruction has become a subspecialty of both orthopedics and plastic surgery. Tendon surgery is within the realm of orthopedic surgeons; however, many plastic surgeons also perform tendon repair and transfer for hand reconstruction. Restoration of function is the goal of the hand surgeon.

The surgeon often manages surgical correction of fractures and rotational deformities of the fingers. Tenosynovectomy (excision of the tendon sheath) may be performed to release arthritic contractures.

Sports Medicine

Sports medicine deals with the anatomic, biochemical, physiologic, and psychologic effects of motion, strength, and coordination on physical activity. Public awareness of and surgeons' concerns about athletic injuries have led to the development of sports medicine centers that emphasize physical conditioning, injury prevention, and rehabilitation of athletes.

Sports medicine is a rapidly growing area of orthopedics, primarily as a result of interest in exercise among the general population. The intensity of a sports activity places physical demands on the musculoskeletal system that can result in injury. Most injuries involve ligaments, tendons, and muscles rather than broken bones. Most injuries, such as a strained muscle or tendon, do not require surgical intervention. MRI is a reliable method of assessing intraarticular injuries, either acute or chronic.

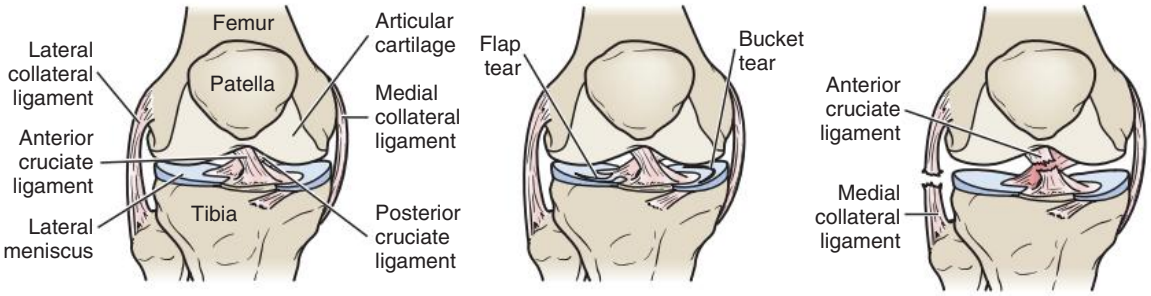
The knee, shoulder, and ankle are most prone to athletic injuries of ligaments and dislocations of joints. Arthroscopy is useful in the diagnosis and treatment of some injuries. Others require open surgical reconstruction to regain joint stability. For example, a complete ligament tear usually requires surgical repair. Some procedures combine arthroscopy and arthrotomy. Postoperative rehabilitation aims to restore range of motion, minimize muscle atrophy, and reestablish muscle endurance and joint position. The patient should commit to a long-term conditioning program to prevent reinjury.

Knee Injuries

The knee is the joint that is most vulnerable to both contact and noncontact sports injuries. For example, hyperextension can result from a noncontact activity. Contact sports can result in a combination of injuries to the cruciate and collateral ligaments, meniscus, and posterior capsule (Fig. 36.31).

Anterior Cruciate Ligament

Knee stability is influenced by the dynamics of the anterior and posterior cruciate ligaments. Injuries to these ligaments are the



• **Fig. 36.31** Normal internal knee anatomy and typical sports injuries treated with surgery.

most common and most serious types of knee injuries. The anterior cruciate ligament (ACL) can be partially or completely torn, ruptured, or avulsed. The extent of the injury determines the method of reconstruction. Arthroscopically, the ACL may be transferred into the posterior aspect of the lateral femoral condyle and secured with sutures, staples, or screws.

After an autograft is harvested through an open incision, the knee may be reconstructed through the arthroscope. One technique places a bone-patellar tendon-bone autograft and fixes it with cancellous or interference bone screws into tibial and femoral tunnels. In another method a composite of autogenous semitendinosus muscle with a polypropylene ligament augmentation device sutured to it extends from the tibial attachment across the joint and is stapled to the distal femur. In the open Insall procedure, a bone-block graft with an iliotibial band of fascia lata is secured to the tibial tubercle.

Artificial ligamentous substitutes may be preferred for ACL reconstruction. These materials also are used to stabilize torn or ruptured ligaments in the ankle. Expanded polytetrafluoroethylene (PTFE) can be secured with screws. Allograft ligaments also are used. Woven bovine collagen, bovine and carbon fiber material, or a partially absorbable matrix of polylactic acid polymer and filamentous carbon may be used as a scaffold for new collagenous tissue ingrowth for disrupted ligaments. Concomitant partial meniscectomy or meniscal repair may be performed with ACL reconstruction.

Meniscus

Partial meniscectomy or repair of a meniscal tear may be done by open arthrotomy or closed arthroscopy. Neurovascular injury is a potential complication of these procedures. Patients selected for arthroscopy usually have a single vertical longitudinal tear that can be debrided. Localized synovium can be abraded. Sutures must be placed to reduce displacement and stabilize the meniscus.

Ankle Injuries

Ankle sprains are commonly caused by inversion injury. Ankle fractures are usually eversion injuries. Fractures of the malleoli are referred to as Pott's fractures. Internal fixation of the inferior margins of the tibia and fibula to the superior surface of the talus may be required.

Rupture of the Achilles tendon can occur spontaneously during a physical activity, such as basketball or racquet sports, usually from indirect trauma. A gap is palpable at the back of the ankle. Severed ends of the tendon may be brought together through an open or percutaneous repair with heavy size #2 nonabsorbable suture.

Ankle arthroscopy may be the procedure of choice for placing internal fixation devices or removing osteophytes (bony outgrowths) in the joint after healing of an ankle fracture.

Shoulder Injuries

Many anterior glenoid labrum and minor rotator cuff tears, the most common acute injuries, can be repaired arthroscopically. Some recurrent dislocations also can be stabilized with sutures, staples, or screws. For a major rotator cuff tear, an open Bankart repair usually is necessary to suture the labrum and reattach the glenohumeral ligament. An open Putti-Platt correction for recurrent dislocation will limit external rotation of the shoulder.

Cast Application

For CR of fractures, traction, and postoperative applications, many orthopedic appliances must be available and at hand when needed. An orthopedic cart can provide the necessary items for these situations (Box 36.1). The items may vary somewhat at different hospitals, but many are universally used. The cart can be taken wherever needed in the OR suite. One higher shelf should be designated for sterile items.

Casting supplies are commonly found on the orthopedic cart. A cast is a rigid form of dressing used to encase and support a part of the body. It supports and immobilizes the part in optimum position until healing takes place. A cast usually includes the joints above and below the affected area. It may suffice as a conservative mode of treatment (e.g., for fractures). It can be fitted to

• BOX 36.1 Contents of an Orthopedic Cart

- Suture removal supplies
- Webril and soft roll
- Assorted gauze dressings and bandages
- Sterile and nonsterile gloves
- Skin antiseptic agents
- Clippers

Nonsterile Items on Another Shelf

- Pulleys and trapeze attachments for bed traction
- Ropes, weights, and carriers
- Felt padding and foam rubber
- Arm and shoulder immobilizers
- Pelvic slings and rods
- Assorted sizes of gauze bandages and stockinette
- Stapler
- Safety pins
- Disposable or reusable plaster bucket with plastic liner bag
- Plastic bag for trash
- Assorted sizes of plaster and/or fiberglass rolls and splints
- Cast cutters, knives, scissors, spreaders, and benders

any body contour or position and can be worn for months. The following are requirements of a cast:

- It must fulfill its intended function of maintaining position of the desired parts.
- It must not be too tight and must have no pressure areas. Post-application pain is an important symptom and must be promptly investigated to ensure that circulation is not impaired.
- It must not be too loose. It must be as light as possible, yet strong enough to withstand usage.
- It must be comfortable, with no binding or chafing.

Fiberglass Casts

A woven fiberglass tape impregnated with a water-activated polyurethane resin can be used for casting or bracing. Polypropylene stockinette is applied over the patient's skin. Polypropylene web wrap may be used for extra padding over bony prominences and pressure points. The person applying the cast must wear gloves to facilitate smoothing and blending the layers of the fiberglass tape and to prevent resin pickup on the hands. The resin is activated by lukewarm water. The tape is applied in the same manner as plaster.

The fiberglass cast is lighter and thinner, yet stronger, than a plaster cast and is more porous, providing better ventilation. The outside may get wet without deterioration. X-rays penetrate synthetic materials better than they do plaster to evaluate the healing process. A combination of plaster and synthetic resin on a gauze backing produces a thinner, more waterproof cast that weighs less and is as strong as a plaster cast. Because of these advantages, casting tapes are preferred by many orthopedic surgeons for extremity casts.

Plaster Casts

Plaster **cast material** is composed of gypsum or anhydrous calcium sulfate. It is finely ground to break up the crystals and is then heated to drive out the water. When water is added again, recrystallization takes place and the plaster sets. It was first used as a method of splinting fractures in the nineteenth century.

Plaster bandages and splints are made of crinoline or some other fabric, with the plaster powder entrapped in the mesh. These are available in rolls or strips 2 to 8 inches (5 to 20 cm) wide. Plaster splints are either supplied precut or made from rolls as the need arises. Usually six or eight thicknesses of the desired length are used. To provide added strength, splints are applied over areas that may weaken from extra strain. Plaster bandages and splints are available with the following three types of plaster:

- Slow-setting plaster requires up to 18 minutes to set. It is used in large casts requiring more time to apply and mold. It permits blending of the layers.
- Medium-setting plaster requires up to 8 minutes to set. This type is used in average-size casts.
- Fast-setting plaster requires 4 to 5 minutes to set. It is advantageous for small casts on children who are difficult to keep in position. Many surgeons prefer using the fast-setting type in all kinds of casts; it is the most universally used type of plaster.

Application of Plaster

1. Spread a disposable plastic or nonwoven fabric sheet on the floor around the OR bed to catch drips.
2. Protect the OR bed. If the fracture table is used, spread a sheet over table parts after the patient is suspended.
3. Protect the patient's hair with a cap.
4. Use a disposable plaster pail or a plastic liner bag in a plaster bucket.
5. Fill the bucket with water at room temperature. Water warmer than 70° F to 75° F (21° C to 24° C) will speed up the setting time and may cause excessive loss of plaster from the fabric. More important, plaster will get even hotter than its normal exothermic reaction if it is dipped in warm water. The patient could get burned.
6. Don nonsterile disposable gloves to protect the hands from irritation by lime content.
7. Remove the outer wrapping of the plaster roll. Start soaking the plaster only when the surgeon is ready to apply it. Keep just ahead in soaking it. Have the next roll ready when needed, but do not prepare several rolls ahead of time. They may harden and, if used, can produce an ineffective laminated cast. Avoid waste.
8. Hold the plaster roll under water in a vertical position to allow air bubbles to escape from the rolled ends. When air bubbles stop rising, the bandage is soaked through. Compress the ends between the fingers and palm of each hand to remove excess water. This procedure prevents telescoping during use.
9. Unroll the end approximately 1 inch (2.5 cm), and hand the roll to the surgeon.
10. Fan-fold a strip once toward the center, before soaking, leaving the ends free to grasp. When soaking, grasp an end in each hand, press the hands together, and submerge the strip in water for a few seconds; remove it, and pull the strip taut by the ends. It may seem drippy, but the layers blend together well when quite wet.
11. Ask the surgeon if another roll will be needed before soaking it when the cast appears near completion.
12. Handle the cast with flat, open hands—never fingers—and support the patient in such a way that he or she cannot attempt to bend an incorporated joint. Wet plaster has only one third to one half of its ultimate strength when dry. The person who supports an extremity while a cast is being applied takes care not to make finger-pressure areas in the plaster that will damage the tissue under it. Handle only with the palms of the hands.
13. Elevate an extremity on a longitudinal pillow until the cast hardens. If it is laid on a hard surface, flat pressure areas may be pressed onto it, causing pain and tissue damage. The surgeon may want to x-ray the casted extremity after CR to assure alignment of bones.
14. Clean up as much as possible while the cast is being applied. Wipe plaster off equipment, as well as off the patient, before it dries. Plaster is easy to remove when still damp; after it dries, it must be scraped off. A cast dryer, if used, hastens drying.
15. Avoid splashing plaster on the furniture, walls, and floor.
16. Clean the equipment and table thoroughly. If the sink has a plaster trap, all plaster drip can be washed down the sink and the contents of the bucket poured into the sink. If there is no plaster trap, leave the bucket until the plaster in the bottom hardens; then empty the water and throw the plaster pail or plastic liner bag into the trash. Clean a reusable bucket as soon as you are finished with it.

Padding under Casts

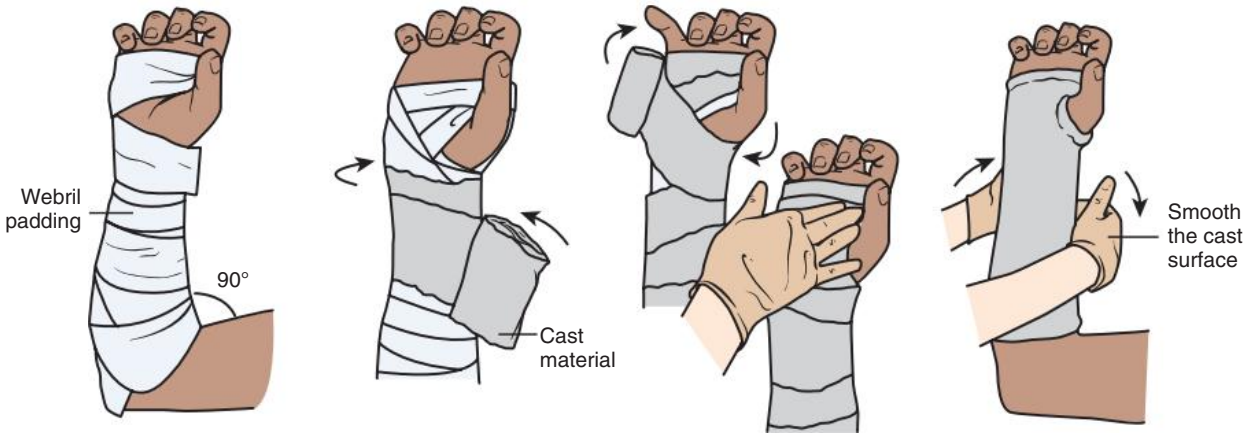
Padding is usually placed under casts and serves the following several functions:

- It absorbs inevitable ooze from the wound after an open surgical procedure. Sterile padding is put on over the dressing before applying the cast.

- It protects the wound and the patient's skin.
- It protects bony prominences.
- Materials used for padding include:
  - *Stockinette:* A seamless tubing of knitted cotton 1 to 12 inches (2.5 to 30.4 cm) wide, stockinette stretches to fit any contour snugly.
  - *Sheet wadding:* A glazed cotton bandage 2 to 8 inches (5 to 20 cm) wide is available as sheeting. It is used over stockinette or in place of it.
  - *Soft roll:* A soft roll of thin cotton batting that has some stretch for smooth contour.
  - *Felt:* Available in sheeting made of wool or blends of wool, cotton, or rayon in thicknesses ranging from ⅛ to ½ inch (3 to 13 mm), felt is cut into desired sizes to fit bony prominences. Felt pads are applied over sheet wadding. The plaster adheres to pads and prevents them from slipping.
  - *Foam rubber:* Available in sheets ¼ to 1 inch (6.4 to 25 mm) in thickness, foam rubber may be used in place of felt.
  - *Webril:* Webril is a soft, lint-free cotton bandage. The surface is smooth but not glazed, so that each layer clings to the preceding one and the padding lies smoothly in place.

Common Cast Configurations

- *Cylinder:* A circular cast, made by wrapping the plaster bandages around an extremity, is used after closed or open reductions of fractures, after some surgical procedures for immobilization, or for the purpose of resting a part of an extremity (Fig. 36.32).
- *Walking cast:* A rubber walking heel or polyurethane sole is applied to the sole of a cylinder cast for ambulation. Use of a lower extremity helps maintain strength and muscle tone and helps prevent atrophy.
- *Hanging cast:* A cylinder is applied to the arm with the elbow flexed. It extends from the shoulder to over the hand, leaving the thumb and fingers free. A wire loop is incorporated at the wrist. A strap through this loop and around the neck suspends the arm. The weight of the cast provides needed traction on the humerus.
- *Shoulder spica:* Applied to the trunk, arm, and hand, leaving the fingers and thumb free, a spica cast is used after some surgical procedures on the shoulder or humerus or for a fracture of the humerus. The OR bed may be used for its application, or the patient may sit on a stool with the surgeon supporting the arm in the desired position.
- *Hip spica:* A hip spica cast is applied to the trunk and one or both legs after some hip procedures and fractures of the femur. The orthopedic table is used. The sacrum rests on a sacral rest. The perineal post provides countertraction. Attachments may be used to support the legs of an adult.
- *Minerva jacket:* A Minerva jacket is applied from the hips to the head. If the head is to be completely immobilized, it is included in the jacket. The plaster is molded to fit around the face and lower jaw. A part of the plaster at the back of the head is cut out. It is used for fractures of the cervical or upper thoracic vertebrae. The orthopedic table is necessary.
- *Body jacket:* A body jacket extends from the axillae to the hips to immobilize vertebrae. Application of this cast usually requires the orthopedic or Risser table with the necessary attachments, although sometimes the patient may stand on the floor. Traction may be applied by an overhead sling. If an open surgical procedure is to be performed with the patient in a body cast, a cast cutter must be at hand in case of respiratory difficulty. However, a body cast is usually bi-valved before a patient is given an anesthetic.
- An opening is always made over the abdomen of a Minerva or body jacket to allow space for lung expansion and decompression of abdominal distention that normally occurs with ingestion of food. A folded towel may be placed over the abdomen before the stockinette is pulled over the body. This is removed when the opening is made in the cast to allow more space between the body and cast.
- *Plaster shell:* A body jacket is cut along each side, into anterior and posterior parts. The parts may be fastened together by heavy straps with buckles, or the patient may rest in one while the other is removed temporarily.
- *Wedge cast:* A wedge-shaped portion is cut from the cast. The edges are brought together and held with plaster reinforcement. This cast is used to overcome angulation in a fracture.
- *Plaster splint:* Six or more thicknesses of plaster of the desired width and length may be applied to the posterior part of an extremity and secured with gauze or a cotton elastic bandage. Excess water is pressed from the plaster splint after it is immersed in water. A splint may be used for immobilization of a fracture of the ulna or fibula. Inflatable air splints are commercially available. Splints are not circumferential; therefore tissue swelling does not create increased pressure around the limb.



• **Fig. 36.32** Application of a short arm cast. Webril is applied as padding followed by the rolled casting material.

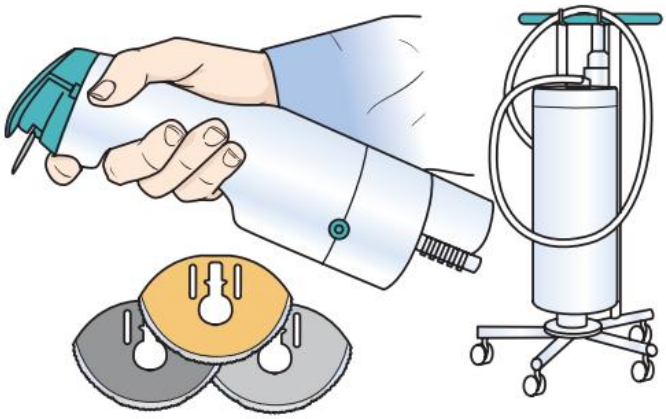
- *Hairpin or sugar tong splint:* A splint twice as long as the lower arm and hand is used for a fracture of the ulna or radius. After the plaster is soaked, it may be covered with stockinette. Starting with one end on the back of the hand, the splint is placed around the flexed elbow. The palm of the hand and fingers rest on the other end of it. It is secured with a bandage. It is commonly used to support distal radial and ulnar fractures, including Colles fractures.
- *Abduction hip splint:* An abduction hip splint keeps hips in constant abduction. If desired for postoperative management, it is applied immediately after a hip procedure.
- *Plaster rope:* Plaster rope may support the arm in a shoulder spica or join legs in a bilateral hip spica. It is made by twisting a wet roll of plaster bandage into a rope as it is unwound, fanfolding to the desired length and drawing it through a cupped hand to blend the strands. A wooden splint may be incorporated into the rope for reinforcement.
- *Molds:* Molds are made as plaster patterns for removable metal or leather braces for the body, neck, or extremities.
- *Waterproof cast:* A breathable synthetic liner made with expanded polytetrafluoroethylene (ePTFE) is used under fiberglass casting material instead of padding. The liner allows the skin to get wet and water to drain from the cast. The casting liner stays dry and body heat causes the cast to dry.[10] It is often used in children because it can be soaked while bathing or swimming and dries quickly without damage to the skin or shape of the cast. More information can be found at www.aquacastliner.com

Trimming, Removing, and Changing Casts

Rough edges of plaster are trimmed off, and the edges of a cast are covered with stockinette or adhesive tape to protect the patient's skin. Instruments specifically designed for cutting through plaster must be used for trimming or removing casts. These include the following:

- Plaster knives, which have short, slightly curved blades.
- Plaster scissors, which are heavy bandage scissors.
- Electric cast cutter, which is an oscillating saw. It cuts the cast but not the stockinette or other padding under it because the padding moves with the oscillations. The patient's skin also moves somewhat and is not injured if touched lightly, although care always should be taken not to touch the skin. One model has a vacuum attached to pick up the plaster dust created by the saw (Fig. 36.33). A carbide steel blade is recommended for cutting a fiberglass cast. (A regular blade dulls quickly and can result in an inadvertent burn to the patient.)
- Cast spreader, which is a long-handled instrument that has thin, serrated jaws that can be inserted in the cutting line to pry open the cast.
- Cast bender, which is a heavy forceps-type instrument used to bend a small portion of the edge of a cast away from an area, such as a portion of a jacket away from the mouth and chin, to give freer movement.

Sharp plaster knives or scissors generally are used to trim casts. For large casts the electric cast cutter may be used, for example, to cut an opening over the abdomen of a body jacket. In a hip spica, adequate space is provided for use of the bedpan without soiling. If it is necessary to cut a window (i.e., a small opening in a cast to remove sutures or inspect an area), it is put back in place and secured with a few turns of the plaster bandage. An opening in a cast encourages swelling of the tissues under it, known as *window edema*.



• **Fig. 36.33** Cast cutter and oscillating blades with vacuum attachment.

When the edema in a wound under a cast recedes, the cast does not furnish as much immobilization as may be desired. The cast is usually changed at this stage. A cast may be changed periodically during long-term immobilization because muscles atrophy with disuse. The cast becomes loose as muscle size decreases.

Skin sutures are removed at the time of a cast change if the cast was applied after a surgical procedure such as ORIF. A sterile suture removal tray should be ready for use when requested. Sterile sheet wadding may be needed to cover the wound after sutures are removed and before another cast is applied.

If the patient has been in a cast for some time, the skin is apt to be oily, somewhat soiled, and rough. If the surgeon wants the skin cleansed before applying another cast, only superficial dirt can be removed. Scrubbing off oily scales may cause irritation. Usually skin is not washed before applying sheet wadding and a new cast.

A large, plastic-lined trash container is used for disposal of the wrappings, trimmings, and removed cast during cast application and removal. The knives, scissors, cutter, spreader, and bender are washed and dried promptly after use. Before instruments are put away, lubrication is applied to all instrument joints to prevent rust and corrosion.

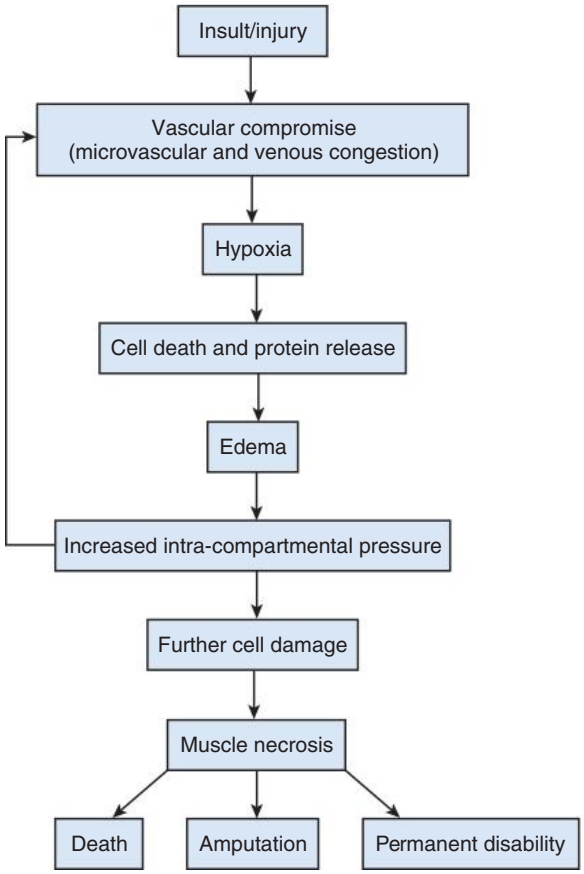
Complications after Orthopedic Surgery

Thromboembolism is the most common postoperative complication of orthopedic surgery, particularly if the patient must be immobilized for an extended period. Pneumonia can be fatal for older patients. Urinary tract infection and skin breakdown also are potential problems, particularly in geriatric patients. As previously emphasized, wound infection can be devastating.

Embolus

Fat embolism is possible after fracture of a long bone or crush injury. The yellow bone marrow at the point of the fracture of the long bone releases adipose cells into the circulation. The fat emboli enter the pulmonary circulation and cause the release of fatty acids. The alveoli are damaged, and the lung surfactant is rendered ineffective.

Thromboemboli can result from deep vein thrombosis, causing pulmonary emboli. Any vessel wall injury can cause this event. Air can enter the lung, but gas exchange cannot take place because of vascular obstruction at the level of the pulmonary artery. A vena cava filter may be indicated.



• **Fig. 36.34** Compartment syndrome.

Rarely a bolus of bone cement can enter the venous system and travel to the patient's lungs. Always be alert to signals from the anesthesia personnel that the patient may be having changes in vital signs during the surgical procedure, especially if bone cement is used.

Compartment Syndrome

Edema, hematoma, and seroma may form between tissue layers of the fascial plane, causing **compartment syndrome**. The pressure from prolonged swelling results in further tissue destruction and necrosis that can lead to toxicity and death (Fig. 36.34). The lymphatic system tries to compensate, but as swelling increases the load is more than the lymphatic vessels can transfer. The interstitium becomes engorged, causing increased arterial pressure. The increasing arterial pressure leads to loss of distal pulses. Critical aspects in the diagnosis of compartment syndrome is based on neurovascular status (pulses, sensation, and motor function).[11]

The pressure is relieved by a series of two to four longitudinal incisions in the fascia (**fasciotomy** incisions) that are left open to drain. Circulation can be tenuous, and the potential for nerve injury is great. Closure is not attempted for weeks or months. Meshed split-thickness or full-thickness skin grafts may be needed to cover the defect. Healing is slow, with significant scar formation over the incision sites.

Neurosurgery of the Brain and Peripheral Nerves

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify the pertinent anatomy of the brain and spinal cord.
- Describe the significance of neurologic monitoring.
- Discuss the risks associated with neurosurgery.

KEY TERMS AND DEFINITIONS

Arteriovenous malformation An abnormal collection of vessels that is not clearly defined as arterial or venous.
Benign tumor Neoplasm or abnormal growth that is not malignant and usually contained. The location in a vital area could potentially cause death or permanent injury.
Craniotomy Procedure in which the bones of the skull are opened by powered or manual instrumentation.
Glioma Tumor that arises between the neurons in the connective tissue.
Malignant tumor Primary tumor that begins in the brain and can spread to other central nervous system (CNS) tissue.
Secondary tumor Tumor that spreads to the brain from another area of the body. Metastatic cells from breast or lung form multiple brain tumors, for example.
Shunt Temporary or permanent bypass of a vascular or drainage system.
Stereotactic surgery Use of a computer imaging system to pinpoint the location of a tumor.
Subdural hematoma A collection of blood under the dural layer of meninges.
Trephine Creation of a circular hole into the skull (sometimes referred to as trepan) to relieve pressure on the brain. The procedure is referred to as trephination.
Tumor A collection of cells that exhibit uncontrolled growth. Brain tumors are named for the type of cell that mutates or for the location of origin.

Anatomy and Physiology of the Brain

An understanding of basic anatomy and physiology is essential for preparing for the approach used to reach intracranial and spinal cord structures.

Cranium

The brain is enclosed within the bony vault of the cranium (skull). Eight bones form the cranium: the single frontal, sphenoid, and ethmoid bones anteriorly; the paired temporal and parietal bones that form the middle fossa; and the occipital bone posteriorly. Although these bones are fused together by synarthroses (nonmobile joints) referred to as sutures, the cranium is described as being divided into three areas: the anterior, middle, and posterior fossae. Galea (tough, highly vascular fascia-like tissue over the cranium) connects muscles of the temples, forehead, and base of the skull. The scalp (skin) covers the muscles and extracranial vessels and nerves in subcutaneous tissue.

Meninges

The membranous covering of the central nervous system (CNS), referred to as meninges, lines the cranium and covers the brain

and spinal cord. The three distinct layers are the dura mater (in direct contact with the cranium), arachnoid (a weblike space), and pia mater (in direct contact with the surface of the brain).

Cranial dura mater, firmly attached to the inner aspect of the cranium, has two layers that separate in planes to form venous sinuses. The arachnoid, which lies under the dura mater, has weblike connections with the pia mater, which closely adheres to the gray matter of the brain.

Cerebrospinal fluid (CSF) circulates through the arachnoid layer to bathe the brain very slowly and absorbs at the same rate. At any given time, the CSF concentration is 75 mL in volume. The normal intracranial pressure (ICP) in adults is 8 to 14 mm Hg. Coughing or sneezing can cause a temporary ICP elevation between 30 and 50 mm Hg. Measurement of CSF and ICP values can help diagnose disease, response to treatments, or measure cerebral perfusion. Cardiac and respiratory activity creates pulsatile fluid movement and variation in cerebral perfusion. The pia mater is a meshlike vascular membrane that follows the convolutions of the surface of the brain. The pia derives its blood supply from the internal carotid and vertebral arteries.

The dura is arranged in three large folds: the falx cerebri, which covers the hemispheres; the falx cerebelli, which separates the lobes of the cerebellum; and the tentorium cerebelli, which supports the temporal and occipital lobes. The tentorium is a surgical landmark that denotes supratentorial structures and infratentorial structures, such as the brainstem and cerebellum.

Brain

The brain is divided into five main subdivisions composed of gray matter (neurons, cell bodies) and white matter (axons, dendrites, nerve fibers). The brain has three distinct anatomic units that consist of several subdivisions, as shown in Fig. 37.1. The cranial nerves (Table 37.1) originate from several locations in the brain and its subdivisions (Fig. 37.2). Cranial nerve V (trigeminal) innervates most of the face in correlation with cervical dermatomes (Fig. 37.3).

The blood supply to the brain is derived from the carotid and vertebral arteries. The arterial component collectively joins at the circle of Willis (Fig. 37.4).[1] The venous drainage is a series of valveless, bidirectional venous sinuses that communicate directly with the vertebral venous sinuses.[1] The patterns of infectious spread and metastasis can be easily noted via the venous system that ranges from the pelvis to the cranium.

Cerebrum

The right and left hemispheres of the cerebrum are connected centrally by the corpus callosum, a broad band of nerve fibers. The cerebrum, also known as the telencephalon, occupies most of the area within the cranium and is arranged into superficial folds (called gyri) and furrows (called sulci), which are surgical anatomic landmarks. The outer cerebral cortex is the gray matter; the

TABLE 37.1 Cranial Nerves

Number	Name	Origin	Action
I	Olfactory	Telencephalon	Smell
II	Optic	Diencephalon	Vision
III	Oculomotor	Mesencephalon	Somatic motor for eyeballs, iris, and ciliary body
IV	Trochlear	Mesencephalon	Somatic motor for eyeballs
V	Trigeminal	Metencephalon	Motor and sensory
VI	Abducens	Myelencephalon	Somatic motor
VII	Facial	Myelencephalon	Motor and sensory

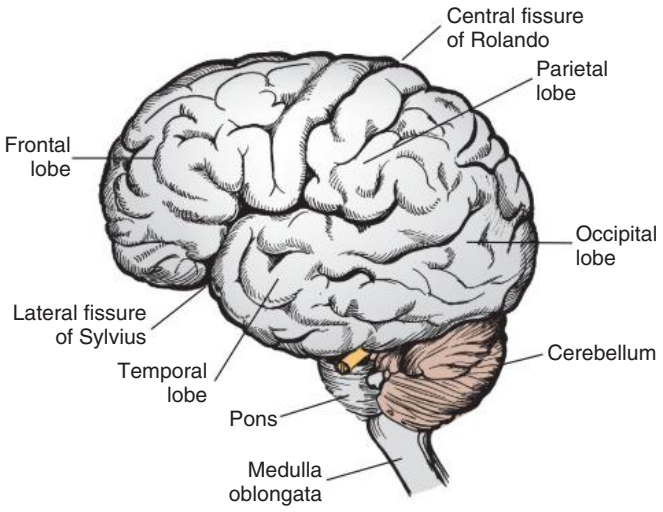
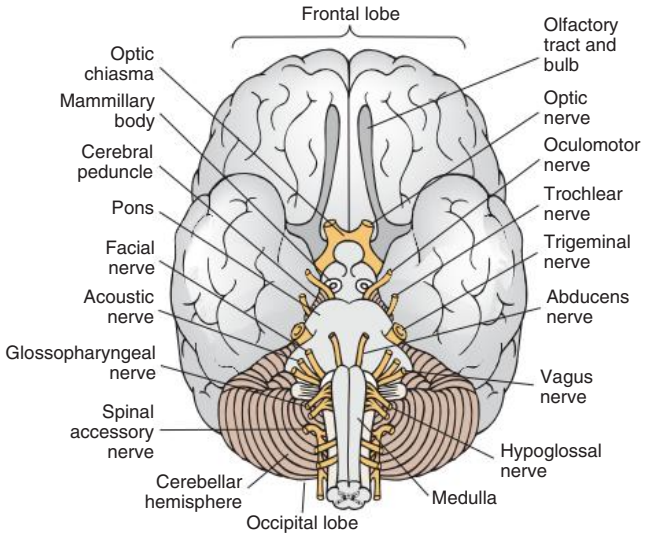
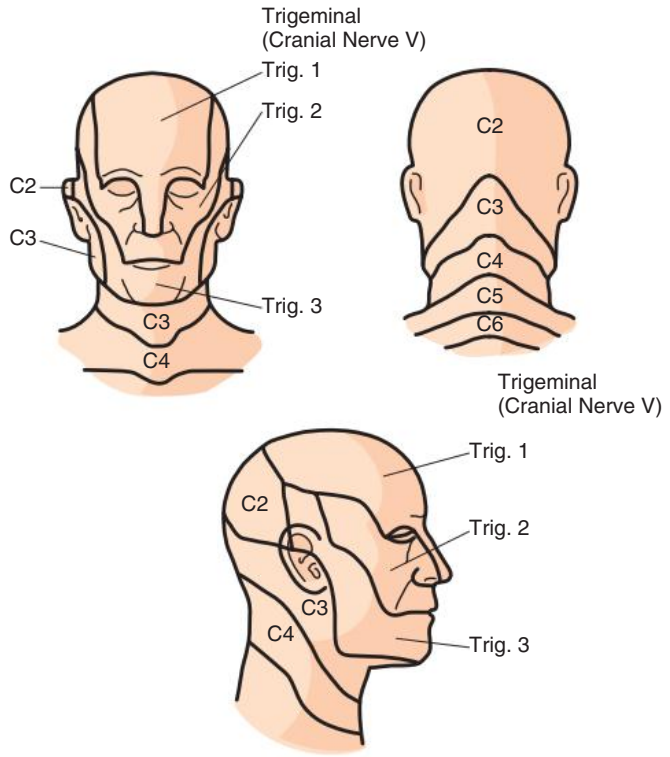
XI	Spinal accessory	Myelencephalon	Visceral motor
XII	Hypoglossal	Myelencephalon	Somatic motor



• **Fig. 37.1** Left lateral view of cerebral hemisphere.



• **Fig. 37.2** Cranial nerves.



• **Fig. 37.3** Cranial nerve dermatomes.

inner tissue is the white matter. Cranial nerve I originates here. Each hemisphere of the brain is divided into four anatomic lobes, as follows:

1. The frontal lobe lies within the anterior fossa.
2. The parietal lobe lies in the superior and anterior portion of the middle fossa.
3. The temporal lobe lies inferior to the frontal and parietal lobes within the middle fossa.
4. The occipital lobe lies posteriorly within the middle fossa.

The hypothalamus and thalamus, referred to as the diencephalon, also lie within the cerebrum to form the floor and lateral walls of the third ventricle. All afferent impulses, except smell, pass through here to the cerebrum. The optic chiasma forms the anterior border.

The diencephalon controls body temperature, emotion, hunger, thirst, sleep, and some hormones. Although it lies in the sella turcica outside the cerebrum, the pituitary body attaches to the inferior aspect of the hypothalamus.

The cerebral pedicles and the corpora quadrigemina form the midbrain, which is also referred to as the mesencephalon. The cerebral aqueduct runs through the full length of the structure. Cranial nerves III and IV originate here.

Brainstem

The brainstem lies anteriorly within the posterior fossa. It extends from the cerebral hemisphere to the base of the skull, where it merges with the spinal cord.

Pons and Cerebellum

The pons and cerebellum form the metencephalon. The pons is a bridge between the cerebrum and the medulla. It lies anterior to the bilobed cerebellum and is the origin of cranial nerves V, VI, VII, and VIII. The cerebellum lies below the occipital lobes of the cerebrum, posterior to the brainstem, within the posterior fossa. It is about one-fifth the size of the cerebrum. The cerebellum controls motion and equilibrium.

Medulla

The medulla oblongata forms the floor of the fourth ventricle and contains the origin of cranial nerves IX, X, XI, and XII. It contains the vital centers, such as cardiac, vasomotor, and respiratory function.

Ventricles

Four spaces within the brain are referred to as ventricles (Fig. 37.5). The lateral ventricles, one in each hemisphere of the cerebrum, drain into the foramen of Monro. The foramen of Monro opens into a central cavity, the third ventricle, which is connected by the aqueduct of Sylvius, with the fourth ventricle lying anterior to the cerebellum and posterior to the brainstem. CSF is a clear substance produced in the choroid plexuses, which are vascular extensions of the pia mater lining the ventricles. CSF is predominantly produced in the lateral ventricles and circulates through the subarachnoid space around the meninges covering the brain and spinal cord. The normal adult volume of circulating CSF is 125 to 150 mL. Obstruction of the CSF flow causes increased ICP.

Special Considerations in Neurosurgery

Neurosurgical procedures are classified according to the anatomic location in the nervous system: brain and cranial nerves, spinal cord and nerve roots, or autonomic and somatic peripheral nerves. Regardless of the location of the surgical site, neural tissue is handled gently to minimize functional disability from surgical trauma. Hemostasis is a critical factor to sustain the vital functions of circulation and respiration. The visibility of structures in the surgical site also should be ensured.

Diagnostics

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides a three-dimensional image of the complex structures of the brain, revealing **tumors** and aneurysms. Magnetic resonance spectroscopy is a variant of MRI that can differentiate necrotic tissue from vital tissue after the application of radiation to reduce tumor size.

Computed Tomography

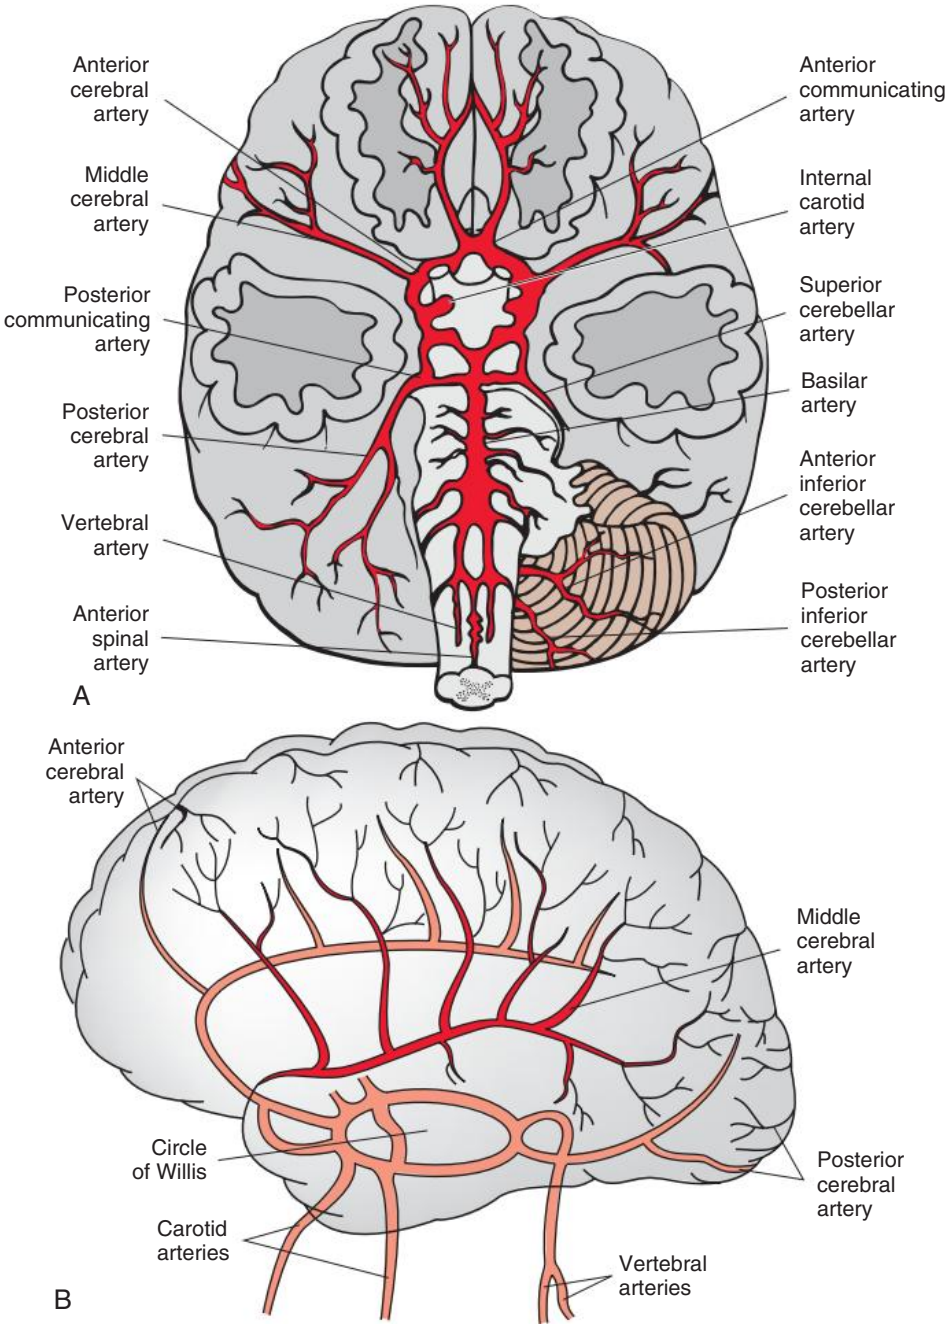
Computed tomography (CT) creates a detailed image of the brain with or without contrast media; however, CT is not as accurate as MRI for diagnosis of brain tumor types. CT is useful for diagnosis of trauma and bleeding into surrounding tissues. Sometimes CT is used to observe for tumor recurrence.

Positron Emission Tomography

Positron emission tomography (PET) depicts brain activity more so than delineation of structure. It is used to distinguish living tissue from necrotic tissue and can be used to determine tumor grade after diagnosis. Interventional radiosurgery is facilitated by PET scan data.

Digital Holography

Three-dimensional mapping is done with holograms. This investigational technique is currently being studied for application in brain mapping and tumor diagnosis.



• **Fig. 37.4** Cerebral vasculature. **A,** Principal arteries of the brain. **B,** Circle of Willis and lateral view of cerebral circulation.

Prognostics

The survivability of a brain tumor is determined by several factors:

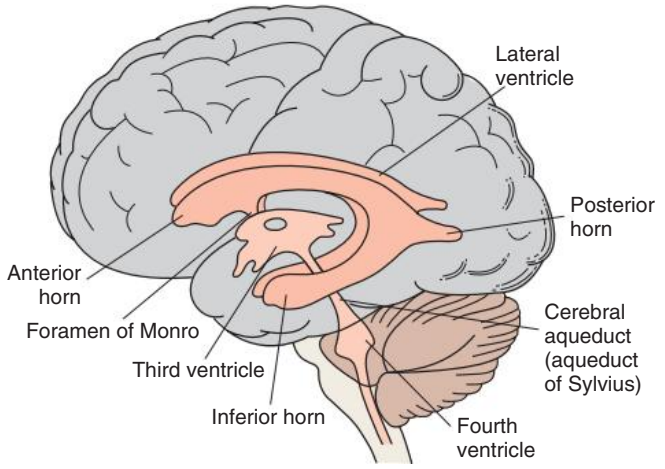
- Malignant or benign
- Cell type and location
- Duration of cell growth
- Surgical or non-surgical treatment
- Tumor grade (grades IV and V are the worst)
- Patient age; age extremes have worse prognosis
- Ability to function
- Symptomatic conditions

Methods of Hemostasis

The hemostatic methods commonly used by neurosurgeons for most procedures include the following.

Scalp Clips

The scalp is highly vascular. Bleeding is controlled with Leroy or Raney clips placed over the edges of the wound with a special clip applier as the primary incision is made. These disposable clips are used as temporary wound pressure for hemostasis and are removed during closure of the wound.



• **Fig. 37.5** Ventricular system of the brain.

Bone Wax

Bone wax is used on cranial and vertebral bones. The sterile wax is rolled into small 4 to 5-mm balls and placed on a smooth surface within reach of the neurosurgeon. Bone wax can act as a mechanical barrier to bone regrowth and healing.

Antibiotic Paste

Powdered antibiotic is mixed with saline solution or lactated Ringer's solution into a thick paste and smoothed over the cut ends of bones to seal off bleeders. Vancomycin powder is sometimes used in this way.

Compressed Absorbent Patties (Cottonoids)

Compressed absorbent patties, made of rayon, cotton, or polyester, rather than gauze sponges are used on fragile delicate neural tissues to absorb blood and fluids. They are also used for protection of wound edges and for hemostasis. Assorted sizes are moistened with normal saline solution, lactated Ringer's solution, or topical thrombin and pressed out flat on a smooth surface that is easily accessible to the neurosurgeon. Although the patties have no loose fibers, they could pick up lint if placed on a towel.

The standard for sponge counts includes counting these patties. They are retrieved before the surgical site is closed. Patties have a radiopaque thread securely attached to each one. This reminds the surgeon that they are in the wound and facilitates their removal. Care is taken not to suction patties into the suction tip. Some of the patties are as small as ¼ inch square. All patties are counted, although they are detectable by x-ray. The strings should not be cut off.

Chemical Agents

Chemical hemostatic agents may be used after resection to control bleeding from large vessels, sinuses, or the surface of a tumor bed. The scrub person moistens a gelatin sponge with normal saline solution or topical thrombin before handing it to the neurosurgeon. Microfibrillar collagen, supplied in fibers or knitted sheet form, is applied dry. The tips of tissue forceps should be dry to prevent this substance from adhering to them. Oxidized cellulose also is applied dry but is removed after hemostasis has been attained because it can interfere with wound healing.

Ligating Clips

Clips are applied on larger vessels where electrocoagulation would be insufficient or its thermal effect would be hazardous. Some permanent clips, such as intracranial aneurysm clips, are specifically designed only for neurosurgical use. Titanium is preferred because it is nonmagnetic and causes less interference with diagnostic cranial studies, such as CT and MRI. Each type and size of clip requires a specific applier.

Electrosurgery

Monopolar electrosurgical unit (ESU) current is used to cut and coagulate tissue and small vessels of dermis and epidermis. Current is conducted through hemostatic forceps, fine smooth-tipped tissue forceps, or a metal suction tip to bleeding vessels. A combination suction-fulguration tip also may be used. The monopolar current passes through the patient's tissues and returns to the generator via the return electrode.

Bipolar current is frequently used for more precision in coagulation of tiny vessels without damage to surrounding tissue. The bipolar current does not travel through the patient's tissue to a return electrode.

Lasers

Argon, CO_2, potassium titanyl phosphate (KTP), neodymium: yttrium aluminum garnet (Nd:YAG), and tunable dye lasers are selectively used in neurosurgery in conjunction with the operating microscope, endoscopes, and stereotaxis. Each type has benefits, but all have definite limitations.

Depending on the type of laser and the location and type of tumor or vascular lesion, the laser may vaporize, shrink, or coagulate tissue. Precise hemostasis, minimal damage to contiguous structures, and visualization of effects are definite advantages of laser surgery for removal of brain and spinal cord tumors. Lasers are also used to assist in microvascular anastomoses.

Ultrasonic Aspiration

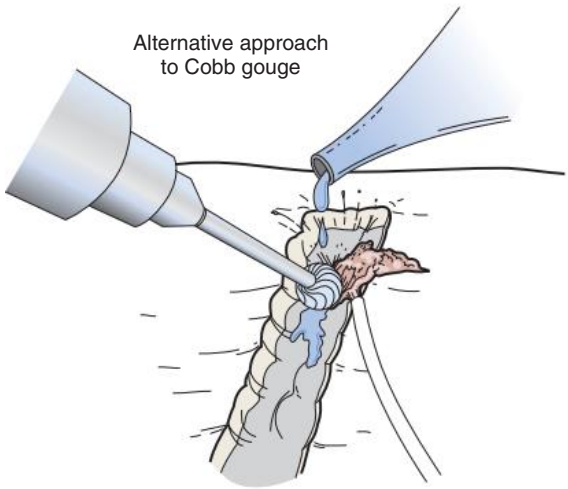
Although not technically a method of hemostasis, ultrasonic emulsification and aspiration devices fragment and remove tissue with minimal bleeding. The emulsification process assists in hemostasis of small vessels. The technique can be used to debulk or remove benign tumors in relatively inaccessible areas of the brain and intramedullary spinal cord. The high-frequency sound waves of the ultrasonic probe fragment the tumor while sparing adjacent structures, such as nerves and blood vessels. The tumor is emulsified and removed using suction. Various settings on the instrument allow the surgeon to adjust for removal of firm or calcified tumor or soft masses.

Interventional Neuroradiology

With fluoroscopy, a team consisting of a neurosurgeon and a neuroradiologist may insert a percutaneous transfemoral catheter into a strategic point in the intracranial circulation that feeds an arteriovenous malformation, an aneurysm, or a vascular occlusion. A substance such as silicone or isobutyl 2-cyanoacrylate or a detachable microballoon or coil is injected to effectively embolize the lesion or its major deep-feeding arteries. This facilitates surgical resection of the lesion by minimizing potential hemorrhage. The intravascular procedure may be done preoperatively or intraoperatively.

Adjuncts to Visibility

Neural tissues should be as clean, dry, and visible as possible without damaging them. Visibility is enhanced by the following procedures.



• **Fig. 37.6** Irrigation at the tip of the drill is important to prevent overheating the tissues. Eye protection is needed to prevent splash of bone chips and solution.

Irrigation

Most wounds are irrigated frequently with normal saline solution or lactated Ringer's solution. The scrub person should keep a bulb syringe filled and ready for use. The solution should be maintained at close to body temperature or cooler to prevent vasodilation and excessive bleeding.

The tip of the bone drill burr should be irrigated during use to prevent overheating the tissues (Fig. 37.6).

Suction

Suction is necessary to evacuate blood, CSF, and irrigating fluid from the surgical site so the neurosurgeon can identify structures. Necrotic tissue, pus, or cystic matter also may be aspirated. A Frazier tip is usually used. Caution is taken to avoid applying vacuum directly on healthy neural tissue, especially brain tissue. This tissue is protected by compressed absorbent patties. Suction should be available for all neurosurgical procedures.

Retractors

A variety of self-retaining retractors, such as Leyla or Greenberg bed-mounted styles, are used to retract scalp or skin and muscles. Dura mater is usually retracted with traction sutures. Blunt, malleable, flat, and spoon-shaped spatulas are used to retract brain tissue. Because visibility of structures is critical, a retractor with a fiberoptic lighting system incorporated into it may be used, especially for intracranial procedures.

Headlight

A fiberoptic headlight is used by most neurosurgeons for supplemental lighting in the surgical site.

Endoscope

A side-viewing fiberoptic endoscope may be used to enhance visibility at obscure angles in otherwise visually inaccessible areas. This endoscope is particularly useful for identification of lesions in the sella turcica, cerebral aneurysms, and intervertebral discs, for example. An endoscope may be used for placement of electrodes for stimulators or a catheter for radioisotopes.

The argon laser can be used through a ventriculoscope for intraventricular obliteration of the choroid plexuses and for intravascular treatment of lesions and neoplasms. The Nd:YAG laser can be used through a flexible or rigid neuroscope to vaporize a cyst. A straightforward, rigid, 0-degree scope may be used for electrocoagulation or laser obliteration of tissue and to obtain a CT-assisted **stereotactic** biopsy.

NeuroGuide Intraoperative Viewing System

The NeuroGuide intraoperative viewing system provides capabilities for viewing structures through a tiny opening in the brain for diagnostic and therapeutic procedures with minimal trauma to tissues.

Operating Microscope

The operating microscope provides an intense light and magnification for visualization of intracranial structures. Microsurgery permits removal of tumors and vascular lesions that are otherwise inaccessible or inoperable. The CO_2 laser may be used through a micromanipulator.

The microscope also is used for some spinal procedures and peripheral nerve repair. A fiberoptic camera attached to a microscope projects the surgical site onto a video monitor screen. This provides a clear view for the assistant and scrub person. In lieu of use of the microscope, the surgeon may wear binocular loupes to magnify the surgical site. Great care is taken not to bump or jar the instrument table or microscope during the procedure.

Patient Care Considerations for Craniotomy

The patient's fear of an inability to function independently as a result of intracranial surgery is paramount, either consciously or subconsciously. The brain is the core of one's being. Many neurosurgical patients do not undergo premedication, which allows neurologic assessment before induction of anesthesia or during a procedure performed with the patient under local anesthesia. The circulating nurse should be sensitive to the patient's fears and offer reassurance. Psychologic support is especially significant for a patient who is awake.

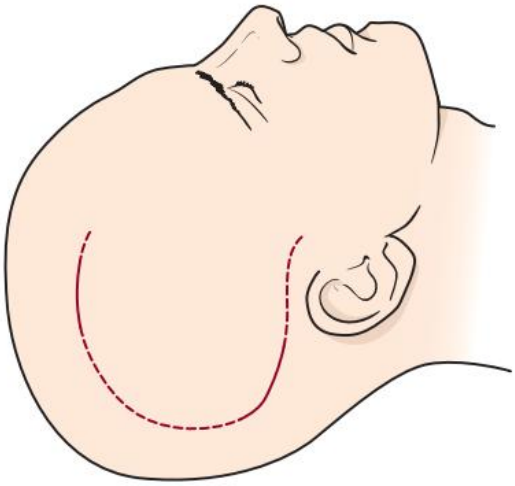
Patient Preparation

Preparation of the patient in the OR usually begins with clipping of hair with electric clippers. Hair on the head is considered the patient's personal property. When all of it is removed, it is saved. Hair removal and its disposition are documented on the patient's chart. Demarcation of the desired outline for the incision may be made on the scalp after the skin preparation and before draping. A sterile disposable skin marker is available (Fig. 37.7).

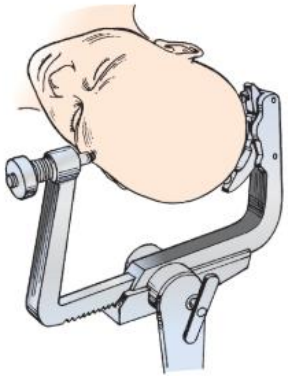
Prevention of peripheral nerve and circulatory damage requires that the circulating nurse check pressure points on the patient's body during prolonged procedures. Some microneurosurgical procedures take 10 hours or longer to complete. Gel pads or a foam mattress similar in configuration to an egg crate should be used if the patient is supine or prone on the OR bed.

Patient Positioning

The standard OR bed is used. A specialized head holder or frame is used. The incision and the type of procedure determine the head holder that is needed to position the patient. The basic support unit of a neurosurgical head positioning device attaches in place of the headpiece on the standard OR bed. The Mayfield headrest or skull clamp fits into the basic frame to stabilize the head for cranial procedures.



• **Fig. 37.7** Craniotomy incision.



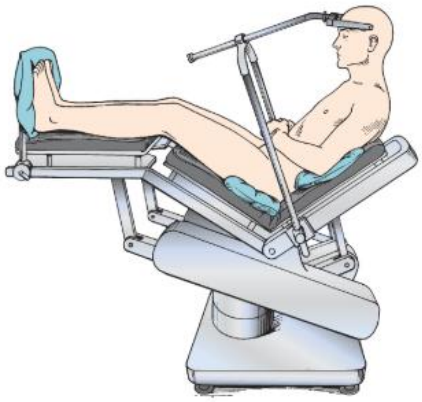
• **Fig. 37.8** Mayfield skull clamp stabilizes head for right frontotemporal craniotomy. Single pin on left and two spring-loaded pins on right penetrate outer table of skull.

The Mayfield headrest conforms to the contours of the patient's head like a horseshoe. The circular or horseshoe-shaped headrest equalizes weight distribution around the patient's face when in the prone position.

The Mayfield skull clamp provides stability that is necessary for microsurgical procedures and is desirable during lengthy procedures. This eliminates the risk for pressure-related complications around the face or eyes with the patient prone or in a lateral position. Three pins on the skull clamp partially penetrate the outer table of the skull. Pins on one side may be spring-loaded (Fig. 37.8) to join the skull and the clamp into one rigid mechanical unit. When pin fixation is used, antibiotic ointment is applied around each fixation pin to form an airtight seal. This reduces the risk for air embolism and infection. The circulating nurse should be familiar with the desired neurosurgical positions and the headrests, skull clamps, and attachments for each.

Supine Position

The supine position is used most commonly for approaches to the frontal, parietal, and temporal lobes within the anterior and middle fossae. A lateral position may be preferred for some of these surgical procedures, such as a unilateral approach to the right or left temporal lobe.



• **Fig. 37.9** Neurosurgical sitting position for posterior approach. Frame of head holder is attached to side rails of back section of OR bed. Note that legs are flexed at thighs and are approximately at level of heart. Feet are padded at right angles to legs. Subgluteal padding protects sciatic nerves.

Prone Position

The patient is anesthetized in a supine position on the transport cart and turned prone onto the OR bed. A detailed description of prone positioning is found in Chapter 26 of this text. The eyes are lubricated, and the lids are taped closed for protection. The patient's transport cart should be immediately available in the event of the need for cardiac resuscitation. The patient needs to be placed supine in a rapid manner, and the nearby cart facilitates this maneuver.

The prone position is used to access the occipital lobe. It also may be used for a suboccipital approach; however, many neurosurgeons prefer a sitting position to approach the posterior fossa.

Seated Position

The Mayfield basic frame is attached to the side rails of the OR bed to support the head for a posterior, unilateral, or nasal approach. In the seated position, the patient is at risk for pelvic venous pooling and air embolus.[2]

For a posterior approach, a head holder supports the forehead. The seated position allows greater torsion and flexion of the neck than either a lateral or the prone position and a more accessible approach to the cerebellopontine angle (Fig. 37.9).

Air embolus is a potential problem when a sitting position is used. The brain is higher than the heart in this position. Venous pressure is lower than atmospheric and can allow for entry of air into the heart via an open venous channel. Excess air in the right atrium can prevent blood from passing to the lungs for gas exchange.

The anesthesia provider may insert a central venous catheter in the subclavian or jugular vein before the procedure begins as a prophylactic measure in the event that air needs to be removed from the heart (Durant's procedure).[3]

A pneumatic counterpressure device may be used in some settings. An antishock garment (military antishock suit [MAST]) extends from the patient's rib margin to the ankles and is inflated if the patient's condition becomes hypotensive. The inflated garment raises the intracavitary pressures in the body. In lieu of a MAST garment, antiembolic stockings or sequential compression stockings are applied.

Controlled Hypothermia

Prevention of cerebral edema during **craniotomy** may be accomplished with hypothermia. Hypothermia also may be used to

decrease cerebral blood flow and venous pressure, to decrease brain volume, and to control ICP. Patients are cooled to a core temperature between 57° F and 68° F (14° C and 20° C) with surface-induced hypothermia, intravenous (IV) cooling, or a combination of both. Core body temperature can be monitored via a thermal probe placed in the esophagus or rectum or contained within the indwelling Foley catheter.

Hypothermia with elective circulatory arrest and extracorporeal cardiopulmonary bypass is an alternative when conventional approaches to the control of blood loss are unsatisfactory. The desired core temperature before extracorporeal cardiopulmonary bypass begins is 64° F (18° C). The cooling process may take 1 hour. An 18 to 24 Fr arterial perfusion cannula is placed in the right femoral artery for oxygenated blood return, and a 28 or 32 Fr venous return cannula is placed in the left femoral vein for venous drainage.

Normally the brain cannot tolerate ischemia for more than a few minutes. This time is extended with lowering of body temperature. The average circulatory arrest time is between 12 and 45 minutes at 64° F (18° C). Hypothermia decreases cellular metabolism and therefore decreases oxygen consumption by the brain and heart during interruption of circulation. Intermittent administration of cold crystalloid cerebroplegia solution also may help protect the brain during cardiopulmonary bypass and profound hypothermia.

Blood viscosity increases as body temperature decreases. Two or three units of the patient's blood may be withdrawn and replaced with chilled normal saline solution. During rewarming, this blood is autotransfused. Crystalloid priming solution from the cardiopulmonary bypass machine also causes hemodilution.

Intracranial Pressure Control

Reduction of ICP and brain volume may be accomplished with withdrawal of spinal fluid. An intrathecal catheter or Touhy needle is inserted, before prepping and draping, for the anesthesia provider to remove CSF during the surgical procedure as desired by the neurosurgeon. ICP monitoring is discussed subsequently in this section.

Position of the Instrument Table

Instrumentation is usually arranged on a Mayfield or Phalen table or on a double Mayo stand set up over the patient positioned supine or prone. The scrub person stands on a tiered platform to easily set up and reach the instruments as they are needed. The instrument table surface can be raised or lowered.

The drapes over the patient's head are attached to the table drapes. Some surgeons use a skin stapler to attach drapes to the scalp. A one-piece sheet that provides a combined sterile table cover and the patient's cranial drape with a self-adhering circular incise area is available (Fig. 37.10).

If the patient will be in a Fowler's or sitting position, the Mayfield instrument table is placed above and lateral to drape over the patient. The drapes form a tent on one side of the patient so the anesthesia provider can have access throughout the procedure.

Hemostasis

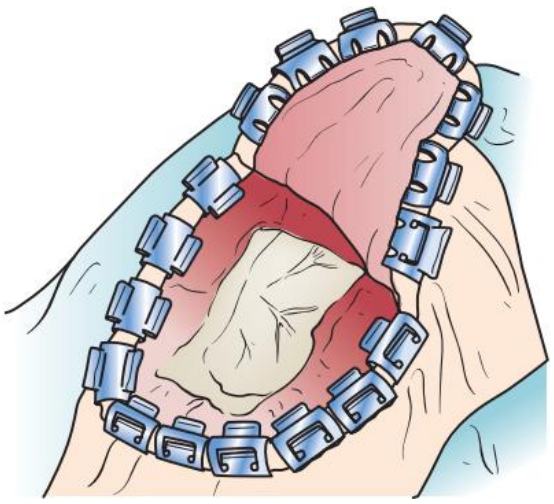
Infiltration of a local anesthetic agent with epinephrine beneath the scalp is desirable for many intracranial procedures. The epinephrine acts as a vasoconstrictor to control bleeding and the volume creates tumescence for a firmer incision line.

The scalp, extracranial arteries, and portions of the dura mater are the only structures covering the brain that are sensitive to pain; local anesthetic can provide some preemptive analgesia. Gelfoam or patties with topical thrombin may be used after the bone flap is opened. Some surgeons use rayon balls, but these are not usually radiopaque. Care is taken to account for all materials used in hemostasis.

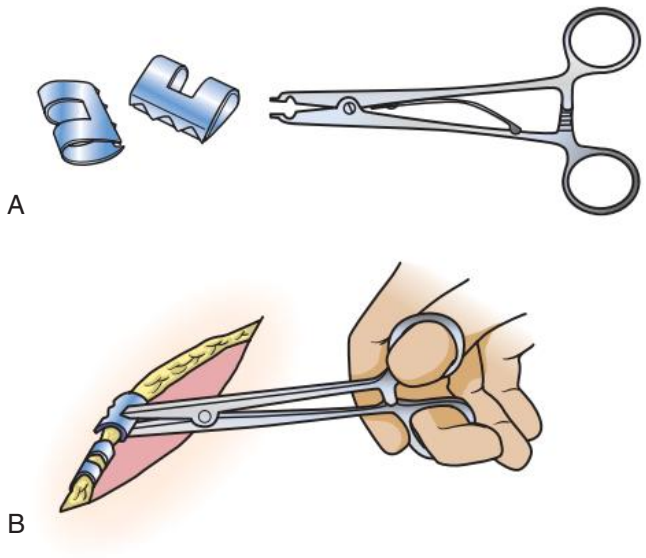
Anticipation of difficulty in achieving hemostasis with the methods previously discussed is not unusual in some procedures for removal of vascular intracranial lesions. Controlled hypotension may be initiated by the anesthesia provider, with the concurrence of the neurosurgeon, to lower the blood pressure (BP).

The surgeon incises the scalp along the predetermined line. The scalp edges are highly vascular and require careful hemostasis. Excessive use of the ESU causes death of hair follicles, so temporary plastic Raney clips are placed along the skin edges for hemostasis (Fig. 37.11). These clips are applied individually with great

• **Fig. 37.10** Neurosurgical team in place for craniotomy.



• **Fig. 37.11** Craniotomy scalp edge hemostasis with temporary plastic Raney clips.



• **Fig. 37.12** **A,** Plastic Raney clips with applier. **B,** Application of temporary plastic Raney clips.

care and with use of a special clip applier (Fig. 37.12). This same applier is used to remove the clips at the end of the procedure before skin closure. The Raney clips are disposable. Other styles are available preloaded in 10s and 20s in an applier that resembles a skin stapler.

Physiologic Monitoring

Cerebral edema (brain swelling), cerebral arterial perfusion, and ICP can be safely controlled before, during, and after the surgical procedure. These parameters are continuously monitored. An intraarterial catheter is often inserted for continuous direct arterial BP monitoring and for drawing of samples for arterial blood gas analyses.

A central venous pressure line may be established also. A pulmonary artery catheter may be inserted to measure fluid volume and diagnose or aspirate an air embolus. Capnography is used routinely. Mass spectrometry is the most sensitive method of monitoring concentrations of inspired and expired gases. This sensitive device detects any type of gas, including nitrogen.

Doppler Ultrasound Scan

A precordial Doppler ultrasound transducer is secured over the precordium (i.e., over the right side of the heart to the right of the sternum between the third and sixth intercostal spaces). This is used primarily for continuous monitoring for air embolism in the patient in a sitting position. An altered ultrasound response results if air is present in the right atrium.

A sterile transcranial Doppler ultrasound transducer monitors changes in redistribution of cerebral blood flow, such as after obliteration of a large intracranial vascular malformation. This technique is also used to monitor cerebral vasospasm. Elevation of transcranial Doppler velocities precedes clinical signs of cerebral ischemia. The transducer also can be placed over the cerebral cortex to verify the location and depth of a tumor or cyst.

Evoked Potentials

Somatosensory evoked potentials guide the anesthesia provider in handling arterial BP, ventilation, inspired oxygen concentration, and patient positioning. Changes in cortical evoked potentials can indicate cerebral ischemia and systemic hypoxia. Both cortical and subcortical sensory evoked potentials can record surgical invasion of the spinal cord, peripheral nerve, nerve plexus, brainstem, or midbrain. To avert permanent injury to the patient, the surgeon may adjust retractors, alter the approach to a tumor, or perform a subtotal tumor resection on the basis of changes in evoked potentials. The anesthesia provider may adjust the depth of anesthesia.

Auditory brainstem evoked potentials, with a stimulus to the ear, may be used to monitor the eighth cranial nerve and brainstem during surgical procedures in the posterior fossa, if performed with the patient under local anesthesia.

Visual evoked potentials may be used during the surgical procedure for pituitary tumors, optic nerve decompression, aneurysms, and some other types of lesions. A strobe light flash is used to elicit responses. The light-emitting diodes are placed over closed eyelids and secured before the patient is prepped and draped.

Intracranial Pressure

ICP rises with an increase in volume of the brain, CSF, or cerebral blood supply or with decompensation (inability to compensate for pressure changes). When an abnormal elevation is sustained, ICP prevents adequate perfusion of the cerebral cortex. The brain is deprived of its blood supply. Pressure monitoring is the only exact method for determination of a rise in ICP and impending neurologic crisis during cranial procedures or after head injury. ICP monitoring is accomplished with implantation of a ventricular catheter, subarachnoid screw, or epidural sensor.

A ventricular catheter is invasive but is the most accurate method of ICP monitoring. The cannula and reservoir are inserted into the ventricle through a burr hole or twist drill hole in the skull. Proper positioning of stopcocks is important, because incorrect placement may result in excessive CSF drainage with a sudden drop in ICP and possible brain herniation. This method evaluates volume and pressure responses and permits drainage of large amounts of CSF and instillation of contrast media and antibiotics. Catheter patency should be checked frequently. Postoperatively, the patient is observed for signs of infection, such as meningitis or ventriculitis.

A hollow steel subarachnoid screw is placed in the subdural space via a twist drill hole in the skull and a small incision in the dura mater. Although this method is used to measure ICP accurately and directly from CSF, it cannot be used to drain large amounts of fluid; it can provide access for CSF sampling. The screw may become occluded with blood or tissue. It should be checked frequently for patency.

A small epidural sensor is implanted in the epidural space of the brain through a small burr hole in the skull. The sensor is attached to a transducer, which converts CSF pressure to electrical impulses. The sensor cable is plugged into a monitor that produces a continuous readout. This is the least invasive method of ICP monitoring, but its accuracy is questionable.

Electroencephalogram

The function or organic activity of the brain may be monitored periodically throughout the surgical procedure with an electroencephalogram (EEG). Sterile subdermal needle electrodes may be inserted if surface scalp electrodes cannot be used.

Surgical Procedures of the Cranium

Craniectomy

Craniectomy is the removal (-ectomy) of a portion of the bones of the skull (cranium). After the scalp incision, the bone is perforated or removed to approach the brain. This may be accomplished through one or more (**trephine**) burr holes or twist drill holes. Each hole is drilled with an electrical or air-powered instrument or manually with a Hudson brace (Fig. 37.13). Burr holes are approximately ½ inch (13 mm) in diameter (Fig. 37.14). Some diagnostic and therapeutic procedures are performed through these holes. Additional bone may be removed with a rongeur to increase exposure of the brain for more extensive procedures, such as an approach to the cranial nerves or tumors in the posterior fossa or suboccipital region.

The bone may be cut between the burr holes with a flexible multifilament wire (Gigli saw) or air-powered craniotome. A dura guard attachment protects the dura mater. A large area of bone is raised for temporary or permanent removal. Attached to the muscle, which acts as a hinge, the bone may be turned back to expose the underlying dura, referred to as *raising a bone flap.* The bone flap may be removed and stored for later positioning. Storage can be done in a sterile container in a special refrigerator or placed in a tissue pocket created in the patient's abdominal wall.

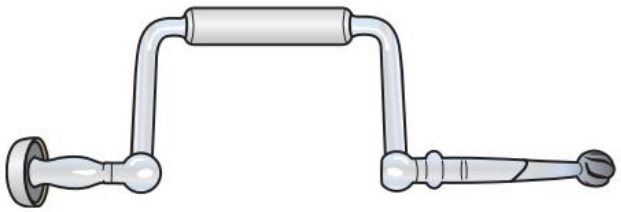
Burr holes may be covered with a soft, pliable, silicone disc-shaped sheath, with or without a channel for introduction of a hypodermic needle for medication administration. The cover may be used to eliminate a cosmetically undesirable indentation of the scalp into the created bone defect.

Postoperative access to the cranial cavity through the hole or channel in the cover can be used for drainage of fluid or instillation of chemotherapeutic drugs. ICP monitoring devices can be attached. Other types of implantable infusion pumps also are inserted through a craniectomy.

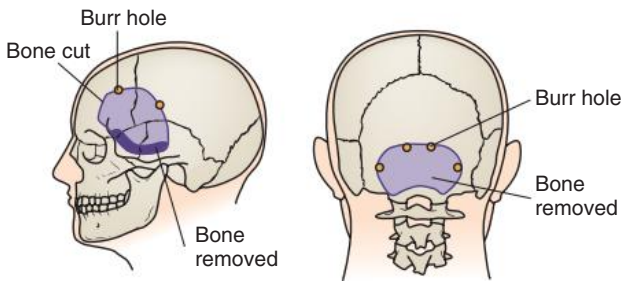
Brain Pacemaker

Electrode plates of a brain pacemaker or cerebellar stimulator are implanted through small occipital and suboccipital craniectomies. Silicone-coated polyester fiber mesh plates, each with four pairs of platinum disc electrodes, are applied to the anterior and posterior surfaces of the cerebellum. One or two receivers, implanted just below the clavicle, are attached to the electrodes on the cerebellum by subcutaneously placed leads.

Stimulation of the pacemaker electrodes is controlled by an external transmitter through an antenna placed on the skin over the subdermal receiver. This device is used to control muscular hypertonia and seizures related to cerebral palsy, epilepsy, stroke, or brain injury.



• **Fig. 37.13** Hudson brace manual drill.



• **Fig. 37.14** Burr holes for craniectomy or craniotomy.

Craniotomy

Scalp, bone, and dural flaps are raised to expose a large area of the cerebrum for exploration, definitive treatment, or excision of lesions within the brain. Raney clips are applied to the galea and over the edge of the scalp flap. The bone flap is turned as described for craniectomy by drilling four or five burr holes along the edge of the proposed bone incision and then cutting a line between the holes with a Gigli saw or a powered saw with a dural guard on the tip. Moistened sponges protect both the scalp flap and the bone flap. The dural flap is protected with large compressed patties.

For wound closure, the thin but tough fibrous dural flap is laid over the brain. Usually it is sutured with multiple interrupted stitches to provide a tight seal that prevents leakage of CSF. The bone flap may be repositioned and anchored with nonabsorbable sutures, silicone burr hole buttons, or titanium plates and screws. Absorbable screws can be used for esthetic appearance. The galea is closed with interrupted sutures before the scalp is sutured or approximated with staples.

A silicone rubber suction drain may be placed in the subdural space to drain residual fluid from a subdural hematoma or the bed of a brain tumor or to remove red blood cells in CSF after a craniotomy.

Intracranial Tumors

Intracranial tumors can originate from the neural tissues of the brain, the meninges, glandular tissue, choroid plexuses, cranial nerves, blood vessels, embryonal defects, or metastatic lesions (Table 37.2). A craniotomy may be performed to remove a circumscribed, encapsulated, slow-growing, benign brain tumor. Some of these tumors, such as a meningioma, are highly vascular. Primary or **secondary** metastatic **malignant tumors** are broadly classified as **gliomas**. These have an unregulated cellular proliferation of rapidly growing cells, which invade surrounding brain tissue.

Glioblastoma multiforme, one of the most common brain tumors, is the most malignant type. Hemorrhagic and edematous effects of a rapidly growing tumor may be an indication for a lobectomy to give the brain an area for expansion and to impede mortality. The rigid characteristics of the skull prevent its expansion or contraction; however, the brain can expand or contract.

Subdural decompression by craniectomy for reduction of ICP and papilledema may be the palliative procedure of choice. As a result of anatomic location, some **benign tumors** are considered malignant because they cannot be safely removed without severe neurologic deficits or a threat to life-sustaining functions. Microneurosurgery and stereotaxis provide access to tumors in some anatomic locations that are otherwise impossible to reach, such as in third-ventricle and pineal regions.

Cranioplasty

Traumatic or surgically created skull defects are corrected with autogenous bone grafts or a synthetic or titanium prosthesis. Large defects in the anterior or middle fossae are covered for

TABLE 37.2 Intracranial Neoplasms

Cell of Origin	Site	Age and Sex	Degree of Malignancy
Astrocytoma: Grades I and II			
Astrocyte	Cerebrum	Young adults Equal between sexes	Low malignancy; slow-growing tumor; becomes cystic; well-differentiated cell structure; average survival period is 6 years
			Most common brain tumor
Astrocytoma: Grades III and IV			
Astrocyte	Cerebrum, cerebellum, and white matter	Middle age Males > females	Highly malignant, slow-growing tumor; poorly differentiated cell structure; 20% of all brain tumors are this type; average survival period is 6 years
Ependymoma			
Cells lining ventricular system of brain and central canal of the spinal cord; most common in fourth ventricle	Fourth ventricle and distal spinal cord	Children and young adults Equal between sexes	Low malignancy; slow-growing tumor; variable differentiation of cell structure; may calcify; 10% of all brain tumors are this type; survival time is measured in months according to location of tumor
			30% of all spinal tumors
Glioblastoma Multiforme			
Glial cells	Cerebral hemispheres and corpus callosum	Middle age Equal between sexes	Highly malignant; infiltrative, rapidly growing; highly cellular with many necrotic foci; 50% of all brain tumors are this type; average survival period is 1 year
Medulloblastoma			
Uncertain, primitive bipotential cells	Cerebellum, fourth ventricle, and subarachnoid space	Children Males > females	Moderate malignancy; rapidly growing tumor; moderate differentiation of cell structure; 10% of all brain tumors are this type; average survival period is 15 months
Meningioma			
Arachnoid cell	Parasagittal and lateral convexities, sphenoidal ridge, and thoracic spinal cord	Middle age Females > males	Usually benign; encapsulated and easily separated from nervous tissue
Neurilemoma (Schwannoma)			
Schwann cells of cranial nerves and spinal nerve roots	Cranial nerve VIII in cerebellopontine angle and thoracic spinal cord	Middle age Equal between sexes	Usually benign; pain and paresthesia are common
Oligodendroglioma			
Oligodendrocyte	Cerebrum, white matter	Middle age Equal between sexes	Low malignancy; slow-growing tumor; moderate differentiation of cells; 5% of all brain tumors are this type; average survival period is 5 years

protection of the brain and for cosmetic effect. The bone flap may be removed after an intracranial procedure to allow cerebral decompression postoperatively. It is stored under sterile conditions in the bone bank until it can be placed in the skull.

Bone removed because of an extensively comminuted fracture or bone disease may be replaced with sterile polymethylmethacrylate (PMMA). This material contours better than preformed titanium plates. In sterile conditions, the sterile resin powder is mixed with the sterile liquid polymer to form a doughy mass. This is placed in a sterile plastic bag and rolled to the thickness of the skull with a roller.

While still pliable, PMMA is molded to the contour of the head and the size of the defect. When hardened, it can be trimmed with a rongeur, and the edges smoothed with a special small emery wheel mounted on the electric bone saw. The prosthesis is wired to the skull in several places. The brain expands to meet it and leaves no dead space between it and the dura.

Dural defects can be closed with autologous fascia graft, fibrin film, polyethylene film, synthetic absorbable mesh, or freeze-dried human cadaver dura mater grafts.

Intracranial Microneurosurgery

The magnification and lighting afforded by the operating microscope have refined intracranial microneurosurgical techniques and made possible approaches to many neurologic problems. A CO_2 laser may be adapted to the microscope for ablation of benign or malignant intracranial tumors. Discussions of some other microneurosurgical procedures follow.

Other Cranial Procedures

Excision of an Acoustic Neuroma

Middle fossa or translabyrinthine approaches may be used by otologists for removal of small acoustic neuromas confined in the internal auditory canal. A neurosurgeon resects an acoustic neuroma that more commonly extends into the posterior fossa of the cranial cavity. An acoustic neuroma can grow progressively into the trigeminal, facial, and abducens nerves and into the cerebellopontine angle (the area between the pons, medulla oblongata, and cerebellum). Potentially life threatening, these involvements manifest symptoms of facial weakness, paresthesia, and dysphagia.

The suboccipital retrolabyrinthine approach is preferred by most neurosurgeons. The patient is placed in a semi-Fowler or sitting position, with pin fixation in the Mayfield or Gardner-Wells frame. The operating microscope offers the potential for preservation of functional hearing. Particular caution is taken to obtain meticulous hemostasis, to spare the auditory artery if hearing is to be preserved, and to avoid trauma to or resection of the facial nerve. Facial nerve function is impossible to salvage in a percentage of patients. If the facial nerve is sacrificed, the patient may return for a facial–hypoglossal or facial–accessory nerve anastomosis 4 to 6 weeks postoperatively.

A retromastoid transtemporal approach with the patient in a lateral position or a subtemporal transtentorial approach with the patient supine may be preferred. The surgeon's decision to preserve or sacrifice the facial nerve or hearing influences the approach to an acoustic neuroma. The ultrasonic aspirator or CO_2 laser may be used to remove the tumor.

Decompression of Cranial Nerves

Microvascular decompression relieves the severe and disabling symptoms of some cranial nerve disorders, such as trigeminal neuralgia (tic douloureux), glossopharyngeal neuralgia, acoustic nerve dysfunction, and hemifacial spasm. Initial symptoms of hyperactivity in a cranial nerve can progress to loss of function. Some disorders are caused by mechanical cross compression, usually vascular, of the nerve root at the brainstem. Symptoms depend on sensory and motor functions of the nerve.

With the patient in a sitting position, a retromastoid craniectomy is performed to explore the cerebellopontine angle. A supracerebellar exposure is used for the trigeminal nerve, and an infracerebellar exposure is used for the remainder of the cranial nerves. An artery or vein that is compressing the nerve root may be mobilized away from the nerve. A tiny piece of Silastic sponge may be placed between the vessel and nerve to relieve the pulsating pressure on the nerve. A tissue sling may be created to lift the vessel off the nerve. Tumors that were not diagnosed preoperatively are excised. If vascular decompression or another pathologic condition is not evident, the nerve may be sectioned to relieve pain.

Surgery of Cranial Blood Vessels

Cerebral Revascularization

For cerebral revascularization, an extracranial artery is anastomosed to an intracranial artery for bypass of stenotic or occlusive vascular disease distal to the bifurcation of the common carotid artery. This procedure provides an additional and significant source of blood to the cerebral circulation.

An artery in the scalp, such as the superficial temporal or occipital artery or another branch of the external carotid artery, is anastomosed to a branch of the middle cerebral artery or to a cortical branch of the cerebral artery. Vessels must be 1 mm in diameter or larger for the anastomosis to work.[1] The procedure is primarily prophylactic to prevent development of a major brain attack (stroke) in patients who have had transient ischemic attacks or minor strokes with temporary disruption of brain function caused by blockage of the cerebrovascular system.

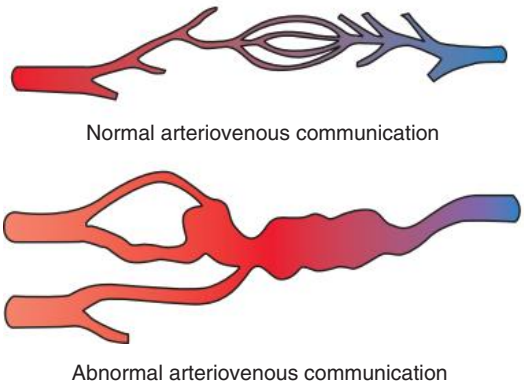
The patient is positioned supine with the head turned or is positioned laterally with the head stabilized flat on the OR bed for an approach through a temporal craniectomy. The anastomosis is made on the surface of the brain, end-to-end, side-to-side, or end-to-side of the arteries.

In some patients, plaque can be removed from the middle cerebral artery rather than the occlusion being bypassed. Cerebral embolectomy with a detachable balloon or other intravascular technique may be done to obliterate a carotid-cavernous fistula or arteriovenous malformation in conjunction with an extracranial-intracranial arterial bypass. Cranial bypass is the procedure of choice for cerebral revascularization in a patient who has a vascular lesion that cannot be treated with carotid endarterectomy.

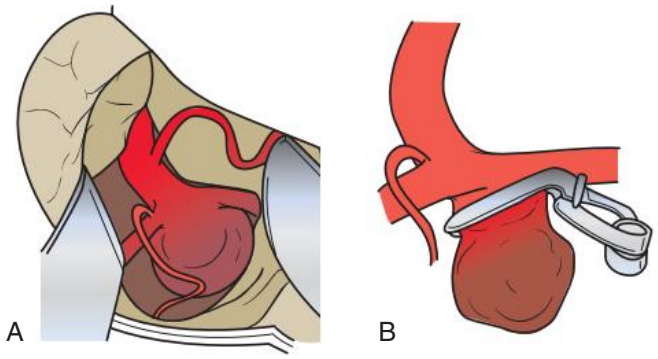
Arteriovenous Malformation

An **arteriovenous malformation** (AVM) is an abnormal communication between the arterial and venous systems that involves many dilated blood vessels (Fig. 37.15).[1] As the fistulous connections gradually enlarge under pressure, blood is diverted from surrounding brain tissue, causing scarring and compression as a result of poor perfusion. This process is accelerated by multiple small hemorrhages from the thin engorged vessels. Progressive neurologic deficits can cause seizures and life-threatening subarachnoid, intraventricular, or intraparenchymal hemorrhage.

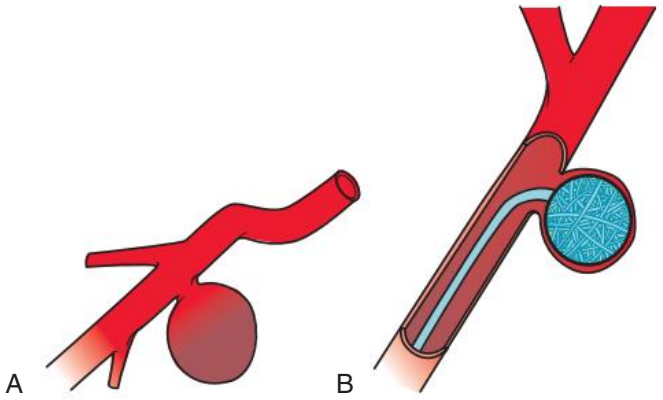
A large diffuse AVM that involves multiple vessels and high-flow **shunts** can be difficult to excise. The strategy of the neurosurgeon may be to perform a staged resection with intraoperative embolization initially to reduce the number of fistulous arteries and size of shunts.[1] For embolization, small Silastic beads may be



• **Fig. 37.15** Arteriovenous malformation.



• **Fig. 37.16 A,** Middle cerebral artery aneurysm exposure. **B,** Middle cerebral artery aneurysm with clip to prevent rupture.



• **Fig. 37.17 A,** Cerebral aneurysm. **B,** Occlusive embolization coil placed in aneurysm to prevent rupture.

introduced into an AVM via a catheter placed into the internal carotid artery. This procedure usually is done a month before surgical resection.

With the operating microscope, the surgeon carefully coagulates or clips the arteries as close to the AVM as possible. Healthy arteries that perfuse the brain beyond the AVM are preserved. At least one vein must remain patent to drain the AVM until other vessels are occluded. The preserved vein is then occluded, and the AVM is excised.

Occlusion of Aneurysms

Aneurysms of the cerebral and vertebral arteries vary from the size of a pea to the size of an orange. Most intracranial aneurysms are located near the basilar surface of the skull and arise from the internal carotid or middle cerebral arteries. Cerebral artery (berry) aneurysms are usually located on the circle of Willis at the base of the brain between the hemispheres of the cerebrum.

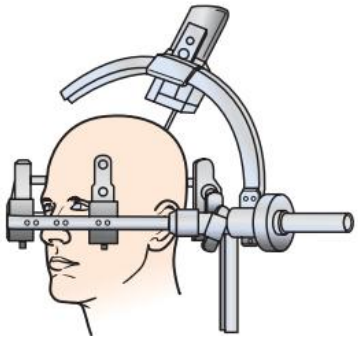
Most cerebral aneurysms are associated with a congenital defect of the tunica media of the intracranial vessel wall. Hemodynamic forces of pulsatile pressure cause enlargement, outpouching, and thinning of the arterial wall, which eventually ruptures. This is the most common source of subarachnoid hemorrhage. Most aneurysms seal spontaneously, but a surgical procedure may be indicated to prevent rebleeding. If diagnosed, an unruptured asymptomatic aneurysm may be occluded with Guglielmi platinum coils by a minimally invasive endovascular approach before rupture.

For open treatment, the patient is placed in a sitting position for suboccipital or subfrontal craniectomy and the aneurysm is exposed for occlusion. The neck (base) of the aneurysm is occluded with a low-pressure aneurysm clip or ligated if it can be isolated (Fig. 37.16). Microcoils can be placed in the aneurysm in the interventional radiation department to help prevent rupture (Fig. 37.17).[1] If it cannot be isolated, the aneurysm and parent vessel may be wrapped in fine-mesh gauze and coated with PMMA, isobutyl 2-cyanoacrylate, or other epoxy resin to reinforce the wall.

More commonly, the aneurysm is coagulated with bipolar electrosurgery or a laser. Induced hypotension may be used to decrease blood flow in the artery feeding the aneurysm. This aids in dissection and occlusion. The operating microscope is used for delicate dissection of the arteries at the base of the brain.

Stereotaxis

Stereotaxis is the accurate location of a definite circumscribed area within the brain from external points or landmarks on the skull.



• **Fig. 37.18** Stereotactic head frame.

It defines three-dimensional coordinates (planes) with which one can approach deep structures without damaging overlying structures. The technique is used to create or ablate a lesion in otherwise inaccessible parts of the brain. With determination of specific reference points on CT, PET, or MRI scans, the exact area for the target site of the lesion is calculated by a computer.[4] The computer, especially designed for stereotactic surgery, provides measurements for correct alignment of instrumentation and calculation of the depth of target tissue within the brain.

A stereoencephalotome, a specially designed mechanical apparatus, is attached to the skull with the patient in a sitting position. After this is in place, computerized data show localizers of the apparatus in relation to intracranial structures. The ventricular system provides the internal landmarks. Of the many models available, the following three basic types of stereoencephalotomes are used:

- *Semicircle arc system:* Steel screws are tapped through each of four burr holes for fixation of the head to a ring supported from a table attachment or a pedestal on the floor (Fig. 37.18). The ring is secured to arc plates. The head is moved rather than the apparatus.
- *Rectilinear system:* The apparatus can be moved back and forth and from side to side around the head to make adjustments.
- *Single arc system:* An arc over the head allows angular adjustments.

The stereoencephalotome can obstruct the surgeon's access for an intracranial procedure. A frameless stereotactic system enables the neurosurgeon to continually interact with CT scans and MRI displays via a computer linkage throughout an intracranial procedure. Known as an interactive image-guided stereotactic neurosurgery system, the system incorporates three-dimensional images

from cameras mounted over the OR bed, position-sensing probes and forceps, and a computer system. With a stereoencephalotome in place, stereotactic surgery can be performed through a burr hole, rigid or flexible endoscope, or open craniotomy.

A lesion may be made or removed by laser, high-frequency or radiofrequency electrocoagulation, cryosurgery, ultrasound, radiation, hyperthermia, or mechanical curettage. Procedures are performed with the patient under local anesthesia when patient cooperation to test motor or sensory function may be needed during the surgical procedure.[5] Various types of intracranial procedures are performed with computer-assisted stereotaxis.

Aspiration

A needle or cannula is placed into target tissue to aspirate a cyst, abscess, or hematoma. Tissue may be obtained for biopsy.

Functional Neurosurgery

For functional neurosurgery, lesions are created in the brain to reduce intractable pain or to control tremors or psychotic behavior.

Electrostimulation

Intermittent electrostimulation of the brain by stereotactically implanted electrodes can control a variety of benign intractable pain problems. One electrode is placed in the somatosensory system for evaluation of pain of central origin, and another is placed in the paraventricular gray matter for evaluation of pain of peripheral origin.

After postoperative evaluation of the effectiveness of electrical stimulation of each electrode, the patient returns to the OR to have a receiver placed under the skin on the anterior chest wall. A connecting wire is tunneled from the receiver to the electrode. An external transmitter and antenna placed over the receiver stimulate the electrode as desired by the patient.

Radiofrequency Retrogasserian Rhizotomy

Radiofrequency retrogasserian rhizotomy relieves the pain of trigeminal neuralgia, also known as tic douloureux. The fifth cranial (trigeminal) nerve carries sensory impulses for touch, pain, and external temperature from the face, scalp, and mucous membranes in the head. Trigeminal neuralgia is an intense paroxysmal pain in one side of the face. It can be controlled by damaging the gasserian (trigeminal) ganglion.

An insulated cannula with an uninsulated tip is placed through the cheek and foramen ovale and is advanced to the gasserian ganglion. The ganglion is coagulated when a radiofrequency generator activates the tip of the cannula. Several lesions can be made to achieve the desired extent of paresthesia.

Thalamotomy

The forerunner of other stereotactic procedures, thalamotomy destroys a selected portion of the thalamus for relief of pain, epileptic seizures, and involuntary tremor or rigidity of muscles (e.g., in Parkinson's disease) and occasionally for emotional disturbances. Functionally, the thalamus, located in the midbrain, is the principal relay point in the cerebrum for sensory impulses passing from lower parts of the nervous system to the cerebral cortex.

Cingulotomy

Bilateral symmetric radiofrequency electrolytic lesions are placed to disrupt pathways of the cingulum. The cingulum is a bundle of connecting fibers in the medial aspect of each cerebral hemisphere between the frontal and temporal lobes. Cingulotomies are performed for severe chronic pain, addiction, or some intractable psychoses that have not responded to other methods of treatment.

Pallidotomy

Stereotactic pallidotomy can be performed to decrease muscle rigidity associated with Parkinson's disease.

Psychosurgery

Intractable depression, obsessive-compulsive disorders, and chronic anxiety may be treated with cingulotomy as described or with frontal lobotomy. With stereotactic control, a probe is inserted into the white matter of the frontal lobe of the brain to create a lesion via cryosurgery or electrocoagulation. The lesion disrupts neural cortical/subcortical connections in the frontal lobe anterior to the lateral ventricles that control emotions.

Some surgeons implant fine electrodes that remain indwelling for weeks to months. These can be used for chronic stimulation of surrounding tissue or to create additional electrocoagulative lesions. Complications include epilepsy, indecisiveness, and altered personality. Studies have shown that memory and intellect are not impaired. Psychosurgery is performed only if other treatments, such as medication or psychotherapy, have failed to provide relief.

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) is a noninvasive form of psychosurgery treatment for depression. An electromagnetic coil is placed against the scalp and delivers continuous or bursts of magnetic pulses.[6]

Theta Burst Stimulation (TBS) is intermittent or continuous delivery of lower magnetic energy designed to provide longer lasting treatment for depression in patients not responding to TMS. Studies have shown safety for use in children and is under review by the FDA.

Intracranial Neoplasms

Computer-assisted stereotaxis helps locate and reach the margin of a deep-seated intracranial tumor either by open craniotomy or through an endoscope. Then a CO_2 or KTP laser beam or other agent can be directed to destroy the tumor while preserving healthy cerebral tissue.

Cryohypophysectomy

Creation of cryogenic lesions may be the procedure of choice for treatment of growth hormone–producing pituitary adenomas with no suprasellar extension. The cryosurgical probe is introduced into the sella turcica through a frontal burr hole. During creation of the lesion, ocular movements and visual acuity are carefully monitored.

Interstitial Radiation

Radioactive substances may be stereotactically implanted into malignant brain tumors. Multiple catheters can be placed throughout the target volume. The catheters are afterloaded with radioactive iridium192 or iodine125 seeds. The catheters are inserted percutaneously through twist drill holes. For photoradiation therapy, a hematoporphyrin derivative may be injected preoperatively and activated by argon or a tunable dye laser to create a cytotoxic photochemical reaction in tumor cells.

Interstitial Hyperthermia

Catheters and remote sensors are implanted into the tumor volume. Sufficient heat is conducted through sensors to raise the temperature within the tumor to a degree that destroys its cells.

This is effective against radioresistant hypoxic cells and poorly vascularized and metabolically inactive tumors.

Stereotactic Radiosurgery

Intense beams of high-energy gamma radiation or microwave-generated energy photons from a linear accelerator are directed to specific targets within the brain while sparing healthy brain tissue. Gamma knife stereotactic radiosurgery does not actually use a knife and is technically not surgery as the name implies.[7] This noninvasive procedure uses stereotaxis to identify the location of an intracranial tumor or AVM.

A specially designed helmet fits over the patient's head and the stereoencephalotome frame. A single high dose of cobalt-generated gamma radiation is directed through holes in the helmet. The beams are collimated and focused on the lesion. The gamma unit is a specific installation for this procedure. The treatment takes 5 to 30 minutes. It does not remove the lesion, but it can stop its growth and reduce its size.[7]

Control of Epilepsy

Epilepsy, caused by erratic electrical rhythms in the brain, manifests in a variety of intermittent disabling behaviors—most commonly, convulsive seizures. Epilepsy may result from a congenital anomaly within the brain or can develop after trauma, meningitis, or acute febrile illness. Patients with intractable seizures uncontrolled with medication may be candidates for surgery to remove the focal point of the seizures.

EEG monitoring and CT, PET, and MRI scans help with identification of the specific location of abnormal brain tissue that is causing seizures. One of two invasive procedures may be necessary if these tests are inconclusive:

- *Subdural grid implantation:* Via a frontotemporoparietal craniectomy, a Silastic grid with metal discs attached to stainless steel or platinum electrodes is placed on the cortex of the brain. The grid size varies depending on the area to be monitored. The grid is anchored to the dura mater. The electrodes are tunneled under the skin to an area outside the incision before the dura, bone, and skin flaps are closed.

  Subsequently, seizure activity from the surface of the brain is monitored for several days with an EEG monitor connected to the electrodes. The grid also maps the brain to locate areas of motor, sensory, visual, speech, and memory control. The patient returns to the OR for removal of the grid. Cortical resection also may be performed at this time.
- *Stereotactic depth electrode implantation:* By correlating CT, PET, or MRI images with reference points on the stereotactic frame, electrodes are implanted directly into the brain. These are connected to an EEG to determine the focus of seizures within specific areas of the brain. After weeks of monitoring, the patient returns to the OR for removal of the electrodes. The epileptic focus may be destroyed by creating a stereotactic lesion at this time.

  After an epileptic focus is identified, a definitive surgical procedure can be performed to stop or reduce seizure activity. The objective is to maintain cerebral capabilities for language, speech, memory, vision, movement, and other sensory and motor neurologic functions.

Cortical Resection

Epileptogenic tissue is resected from the cerebral cortex where the epileptic focus is localized. An anterior temporal lobectomy is most commonly performed. Frontal and other extratemporal sites may be resected if the epileptic focus does not interfere with neurologic functions.

Corpus Callosotomy

The corpus callosum (a fibrous band of neurons) or the anterior commissure connecting the two hemispheres in the midline of the brain is severed. This prevents passage of neuronal discharges from a focal seizure between the hemispheres, thereby preventing secondary generalized seizures.

Hemispherectomy

A hemisphere severely damaged by widespread, persistent, multifocal seizures may be removed. This radical procedure is usually performed only on children with unilateral pathologic foci, including infantile hemiplegia (palsy), hemiparesis (paralysis), and hemianopia (loss of vision). The hemisphere (i.e., half of the brain) is resected with preservation of the basal ganglia. If an abnormal hemisphere is removed at an early age, the healthy half of the brain can take over much of the missing function.

Extracranial Procedures

The cranial procedures previously discussed include access to the surgical site through the skull. A few cranial neurosurgical procedures do not require craniectomy or intracranial incision.

External Occlusion of the Carotid Artery

When an internal carotid or middle cerebral artery aneurysm cannot be reached or controlled with other surgical techniques, a carotid clamp can be applied extracranially in the neck. Progressive turns on the clamp over several days cause occlusion of the carotid artery gradually until complete occlusion of the blood supply to the aneurysm is accomplished.

Endovascular Procedures

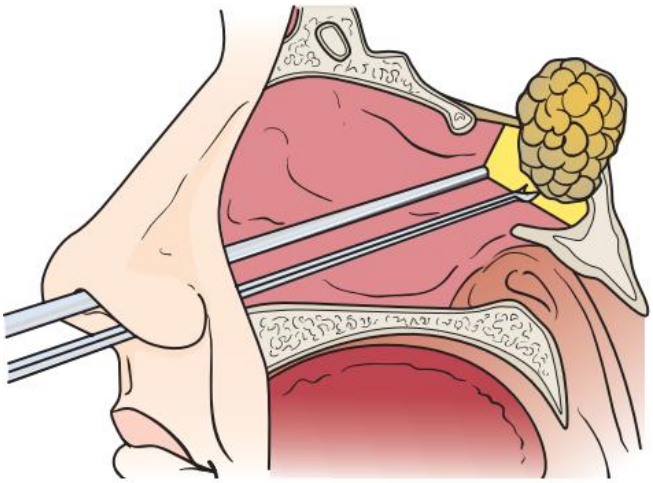
A thin catheter with a very fine guidewire can be advanced through a groin incision into a cerebral vessel to treat a problem within the brain. For example, using C-arm guidance, tiny platinum coils can be deployed or thrombotic material can be injected to seal off a cerebral aneurysm. Cerebral angioplasty uses a tiny balloon catheter to reopen the clogged or narrow lumen of a cerebral blood vessel. Stents can be placed to maintain patency.

Transsphenoidal Procedures

As a palliative surgical procedure, hypophysectomy (enucleation of the pituitary gland) may be performed for pain relief and endocrine ablation in patients with disseminated metastatic carcinoma of the breast or prostate gland or for relief of intractable pain from other types of disseminated carcinomas.

The microsurgical transsphenoidal approach also is used for removal of intrapituitary tumors or other lesions within the region of the sella turcica, a cavity of the sphenoid bone. Visual loss and endocrinopathy are the main symptoms of a pituitary tumor. Tumor tissue in the sella turcica is distinguished by both color and texture from the normal firm, yellowish anterior and red-gray posterior lobes of the pituitary.

The patient is placed in a semi-Fowler's position with the head slightly flexed and tilted so that the patient's body is out of the way when the neurosurgeon sits in front of the face to work in the midsagittal plane. The image intensifier is positioned lateral to



• **Fig. 37.19** Transnasal hypophysectomy.

the patient's head with the horizontal beam centered on the sella turcica. A video monitor is placed behind and just above the patient's head so the surgeon can look at the screen in line with the binocular of the microscope.

Video radiofluoroscopy is used as an aid in placing instruments and resecting tissue. The image intensifier is switched on and off, as needed, to minimize exposure to radiation.

The floor of the sella turcica is exposed through the sphenoid sinus. The procedure can be performed transnasally (Fig. 37.19) or through a horizontal incision made under the upper lip at the junction of the gingiva and carried deep to the maxilla. Soft tissues are elevated; bone and nasal cartilage are resected. The resected nasal cartilage is preserved on the instrument table for possible replacement. A specially designed nasal speculum is inserted in the oral incision to visualize the sphenoid sinus. This is opened wide until the floor of the sella turcica can be identified. The floor is opened with an air-powered drill. The microscope is brought into position for visualization of the pituitary and other structures and lesions inside and around the sella turcica.

Treatment of Head Trauma

A patient with severe head injury first needs a patent airway. A relaxed jaw and tongue should be raised; if necessary, suction should be applied through the mouth. An endotracheal tube may be inserted. Ultimately, a tracheotomy may be necessary.

Vital signs, BP, dilation of pupils, and level of consciousness are checked frequently. An IV osmotic dehydrating solution, such as mannitol, may be ordered to reduce cerebral edema if no evidence of intracranial hemorrhage is found. After these supportive measures have been carried out, definitive treatment is initiated:

- Scalp lacerations are thoroughly cleansed, debrided, and sutured. Because the scalp is highly vascular, lacerations bleed profusely. Hypovolemic shock is rare but possible.
- Simple linear or comminuted fractures usually require no treatment. A depressed skull fracture must be elevated when bone is pressed 5 mm or more into any part of the brain.
- A compound fracture requires debridement. The extent of the surgical procedure depends on the specific extent of injury. Dura may need to be sutured. Some macerated brain tissue may have to be excised.
- An intracranial hematoma may be present. Depending on the location, intracranial hemorrhage may require an immediate emergency surgical procedure.
- Epidural hematoma. Bleeding caused by rupture or tear of the middle meningeal artery (or its branches) forms a hematoma between the skull and the dura. Usually associated with a skull fracture, signs and symptoms of increased ICP caused by rapid compression of the brain may occur immediately or within a few hours. An arterial hemorrhage presents an extreme surgical emergency to evacuate the clot and clip or electrocoagulate the bleeding vessel through a burr hole or small craniectomy.
- **Subdural hematoma**. Bleeding between the dura mater and arachnoid is usually caused by laceration of veins that cross the subdural space. A large encapsulated collection of blood over one or both cerebral hemispheres produces increased ICP and other neurologic changes. The onset and extent of these changes depend on the cause, size, and rapidity of growth of the hematoma. Treatment may necessitate a circular burr hole or trephination. A bone flap may be raised if more extensive exploration is indicated. Subdural hematoma may be:
  - *Acute:* Usually caused by arterial bleeding, symptoms occur rapidly. The vessel is ligated with clips or electrocoagulated.
  - *Subacute:* Usually caused by venous bleeding, symptoms appear within 24 to 48 hours to 5 days after the injury.
  - *Chronic:* Symptoms do not appear until 6 or more months after the injury.
- Intracerebral hematoma. Tears in the brain substance at the point of greatest impact most commonly occur in the anterior temporal and frontal lobes. Although it is usually absorbed, a hematoma may require evacuation and debridement of necrotic tissue.

Complications of Cranial Surgery

All cranial procedures present risks for postoperative seizures and neurologic deficits. Paralysis, muscle weakness, gait disturbances, and ataxia may be temporary or permanent. Neurologic damage can follow hemorrhage, occlusion of cerebral circulation, and increased ICP.[8]

Any sudden, sustained rise in ICP raises BP to maintain the cerebral blood flow and elevates pulmonary vascular pressure. This can lead to acute neurogenic pulmonary edema. This is also a complication of venous air embolism. Both venous and arterial air embolisms can result in ventricular dysrhythmias and fibrillation.[8] Infection is always a potential complication.

Peripheral Nerve Surgery

The peripheral nervous system (PNS) includes the cranial nerves, spinal nerves, and autonomic nervous system located outside the CNS. Ganglions, a group of nerve cell bodies also located outside the CNS, can transmit either autonomic (involuntary) or somatic (both reflex and voluntary) impulses. Somatic nerves supply voluntary muscles, skin, tendons, joints, and other structures that control the musculoskeletal system. Afferent nerve fibers carry sensory impulses from the organs and muscles to the CNS. Efferent fibers transmit motor impulses from the CNS back to them. Peripheral nerve procedures are performed on both the autonomic and somatic nervous systems. The neurosurgeon may identify nerves and test function with a nerve stimulator before or after dissection or repair.

Autonomic Nervous System

The autonomic nervous system is an aggregation of ganglions, nerves, and plexuses through which the viscera, heart, blood vessels, smooth muscles, and glands receive motor innervation to function involuntarily. This system is divided into the following:

- *Sympathetic nervous system:* This thoracolumbar division, which arises from the thoracic and first three lumbar segments of the spinal cord, includes the ganglionated trunk near the spinal cord, plexuses, and associated preganglionic and postganglionic nerve fibers. The efferent fibers transmit impulses that stimulate involuntary activity in the heart, blood vessels, smooth muscle of the viscera, and all of the glands in the body.
- *Parasympathetic nervous system:* This craniosacral division includes the preganglionic fibers that leave the CNS with cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus); the first three sacral nerves; outlying ganglions near the viscera; and postganglionic fibers. In general, this system innervates the same structures but has a regulatory function opposite that of the sympathetic nervous system. These efferent fibers act to restore stability for quieter activity.

Surgical procedures most frequently performed on the autonomic nervous system by neurosurgeons are discussed here, but surgeons in other disciplines do perform some of them.

Sympathectomy

Resection or division of the sympathetic ganglions and nerve fibers of the autonomic nervous system is performed in an attempt to increase peripheral circulation or to decrease the pain of peripheral vascular disease or intractable pain of other organic origin. It may be an emergency procedure to relieve severe vasospasm after arterial embolism or freezing of an extremity.

The paravertebral ganglionic chains or nerve fibers that innervate the affected area are resected or divided. The procedure may be termed sympathetic ganglionectomy or splanchnicectomy, but usually the surgical procedure is specified by the location of the ganglions and nerves. (General and vascular surgeons also perform some of the following surgical procedures.)

Upper Cervical Sympathectomy

Upper cervical sympathectomy is done to increase the blood supply in the internal carotid arteries. Through an anterior cervical approach in the neck, the superior cervical ganglion is resected. Ptosis of the eyelid may occur postoperatively because this ganglion innervates eyelid retraction.

Cervicothoracic Sympathectomy

Cervicothoracic sympathectomy may be performed to treat Raynaud's phenomenon of the upper extremities by relieving the chronic vasoconstrictive process or to relieve angina pectoris or causalgia. Through a transaxillary-transpleural incision, the stellate ganglion of the middle cervical ganglionic chain is hemisected and the lower half resected along with the second through fifth thoracic nerve ganglions.

In select patients, video-assisted thoracoscopy is used to perform sympathectomy to treat Raynaud's phenomenon, thoracic outlet syndrome, reflex sympathetic dystrophy, and hyperhidrosis of the upper limbs.

Thoracic Sympathectomy

Thoracic sympathectomy is usually done for relief of the chronic intractable pain of biliary and pancreatic disease. Through a posterior paravertebral incision over the transverse processes of the thoracic vertebrae, the ganglions of the sixth through twelfth thoracic nerves are resected and the splanchnic nerves divided.

Thoracolumbar Sympathectomy

Thoracolumbar sympathectomy is performed for the treatment of essential hypertension. Usually done in two stages, bilateral resection is necessary to reduce BP by altering the vascular tone and denervating the viscera. With the patient prone or in a lateral position, a paravertebral incision parallel to the vertebral column extends from the ninth rib downward and then curves anteriorly toward the iliac crest. The lower half of the thoracic and the first through third lumbar chains with the ganglions and splanchnic nerves are resected.

Lumbar Sympathectomy

Lumbar sympathectomy may be of some value in the treatment of lower extremity vasospastic disease, such as Raynaud's phenomenon and Buerger's disease, ischemic ulcers as a result of vasospasm of the peripheral vessels, and some types of causalgia. Usually through a flank incision, the lumbar chain and ganglions located in the retroperitoneal space between the vertebral column and the psoas muscle are resected from above the second to below the third ganglions.

Presacral Neurectomy

The hypogastric nerve plexus may be resected for relief of idiopathic intractable dysmenorrhea and pelvic pain. Some gynecologists perform this procedure during pelvic surgery.

Vagotomy

Truncal vagotomy is total vagal denervation of all structures below the diaphragm. Selective vagotomy is performed more frequently to denervate a specific branch of the vagal nerve.

Somatic Nervous System

As cranial and spinal nerves extend out from the CNS into plexuses and peripheral nerve branches throughout the body, the somatic nervous system provides involuntary control over sensations and both voluntary and involuntary control over muscles. Loss of sensation and muscular control occurs distal to the site of severed or compressed nerve fibers. Sensation and function are restored only if regeneration of nerve axons takes place distally from an unobstructed axis cylinder proximal to the site of disruption.

Nerve injuries in the lower extremity tend to be a result of a major impact, such as an automobile accident; upper extremity injuries are more often associated with industrial accidents. Nerve injuries usually are associated with multisystem trauma such as fractures and lacerations. An injury may occur at any point along a peripheral nerve (e.g., from penetrating trauma that severs the nerve or blunt trauma that produces contusions or traction to the nerve). Lower extremity nerves do not recover as rapidly as do upper extremity nerves.

Most peripheral nerve surgery is performed to repair traumatic nerve injury in an extremity. Dissection is also done to remove tumors or relieve pain. Etiologic factors determine the location and length of the skin incision.

Neurorrhaphy

Neurorrhaphy (suturing of a divided nerve) must provide precise approximation of the nerve ends if function is to be restored. Primary repair may be accomplished by suturing the epineurium,

or outer sheath. With magnification of the operating microscope, accurate fascicular alignment and epineural end-to-end suturing of larger nerve bundles constitute the desired technique to enhance regeneration of function. For a successful result, nerves are not repaired under tension. Primary repair soon after injury may be advantageous to align the fascicles.

A tumor, such as a neurofibroma or posttraumatic neuroma, is excised. If the nerve ends can be brought together without tension, they are anastomosed. Silastic membrane may be wrapped around the anastomosis to prevent adhesions with the surrounding tissue.

Neurolysis

Neurolysis (freeing of a nerve from adhesions) relieves pain and restores function. Release of the transverse carpal ligament overriding the median nerve in the wrist affords relief of carpal tunnel syndrome, for example.

Neurotomy, Neurectomy, and Neurexeresis

Neurotomy is division or dissection of nerve fibers. Neurectomy is excision of part of a nerve. Neurexeresis is extraction or avulsion of a nerve. These procedures may be performed to relieve localized peripheral pain.

Spinal Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Describe the anatomy of the vertebral column and spinal cord.
- Describe the implications of dermatome and myotome distributions.
- Discuss the implications of an individualized plan of care for each type of spinal surgery.
- Differentiate between the types of spinal positioning devices and operating room beds.
- Compare the salient points of spinal surgery that apply to orthopedic and neurologic procedures.

KEY TERMS AND DEFINITIONS

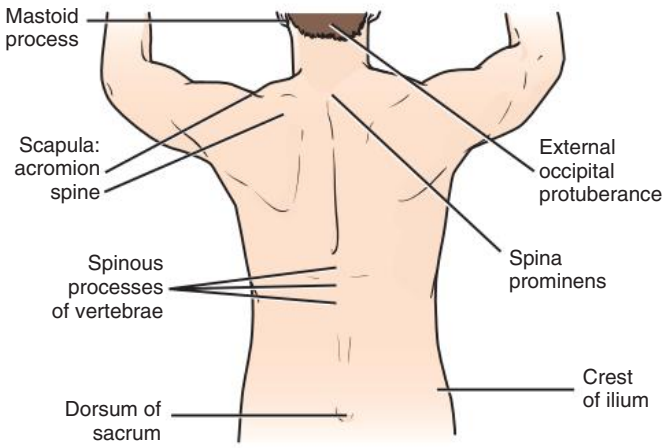
Anterior approach Entering the body through the front of the neck, chest, or abdomen.
Approach Method of incising and accessing the body. The approach is planned according to the type of procedure and location of the disease or injury. Knowledge of the approach helps the circulating nurse and scrub person plan the positioning and instrumentation for the surgical procedure.
Decompression Release of spinal pressure by cutting away of segments of the vertebral bone.
Dermatomes Levels of cutaneous sensory innervation from specific areas of the spinal cord to the peripheral nervous system.
Hemiplegia Injury to one side of the nervous system that results in decreased motion on the affected side of the body.
Idiopathic Unknown or uncertain origin.
Kyphosis Exaggerated thoracic curvature of the spine.
Lordosis Exaggerated lumbar curvature of the spine.
Myotomes Levels of muscle innervation from the spinal cord.
Osteoporosis Wasting and demineralization of bone.
Paralysis Decreased ability to move voluntarily.
Paraplegia Injury between the levels of T1 and T8; with injury between the levels T9 and T10, the individual may be able to sit up although lower limbs are affected.
Posterior approach Entering the body through the back of the neck, chest, or lower spine.
Quadriplegia Injury above the level of T1 that results in inability to move all four limbs.
Radiculopathy Pain that travels up or down a nerve pathway.
Reflex sympathetic dystrophy (RSD) Also known as Complex Regional Pain Syndrome (CRPS). Chronic intense pain from tissue damage, injury, or nervous system dysregulation.
Retroperitoneal Behind the peritoneal cavity without entering the sac.
Scoliosis Lateral curvature of the spine. Can be combined with kyphosis (kyphoscoliosis).
Spondylosis Bony degeneration of the vertebral column with mineral deposits.
Stagnara wake-up test The patient is awakened during the surgical procedure and asked to move his or her feet. The patient does not feel pain and is given an amnesic medication.
Stenosis Narrowing of a passage.
Thenar The web space between the index finger and the thumb.
Transoral approach Entering the body through the mouth to the back of the pharynx.
Transperitoneal Through the peritoneal cavity.

Anatomy and Physiology of the Spinal Cord and Vertebral Column

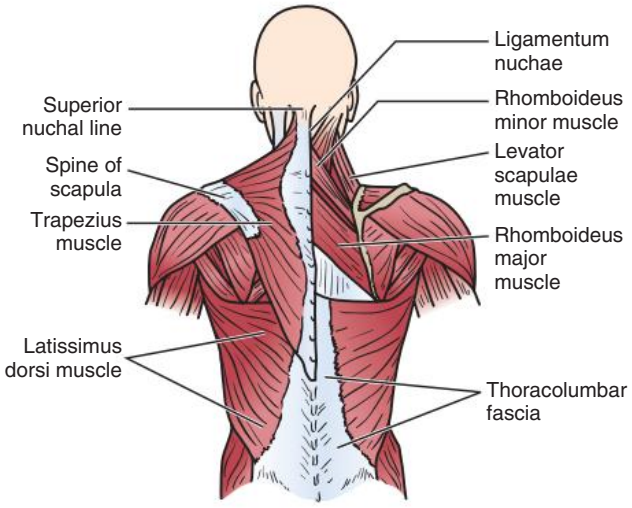
The vertebral column and spinal cord make up the posterior aspect of the trunk of the body. The relationship between the bones and nerves is evaluated first from a topographic perspective with assessment of the alignment of specific external landmarks (Fig. 38.1). The external dorsal musculature frames the margins of the surgical landmarks used in planning the posterior incision for spinal surgery (Fig. 38.2).

Curvatures of the Spine

The configuration of the spinal curvature depends on chronologic and **idiopathic** factors. Each age group, as shown in



• **Fig. 38.1** Topographic landmarks for spinal surgery.



• **Fig. 38.2** Dorsal surface with muscular borders.

Fig. 38.3, *A,* displays a different set of normal spinal curves based on physiologic development. Abnormal curvatures can be age related but sometimes are idiopathic without consideration for age. Examples include kyphosis and lordosis.[1] (Fig. 38.3, *B*).

The Spinal Cord and Spinal Nerves

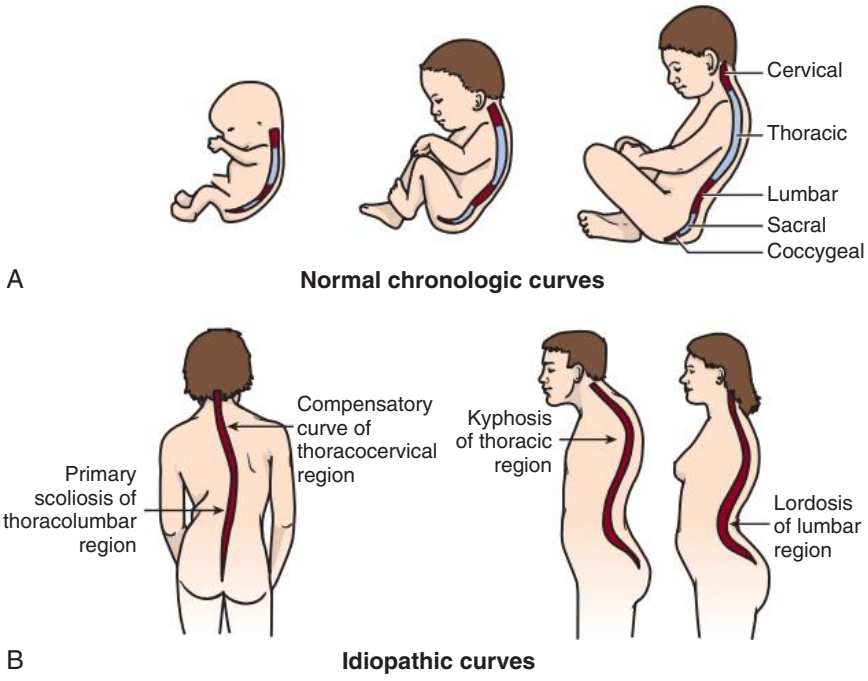
The spinal cord is between 17 and 20 inches (43 to 51 cm) long and passes through a central canal in the vertebral column to the level of the second or third lumbar vertebra (Fig. 38.4). Pairs of spinal nerve roots branch off to each side of the body from 31 segments of the spinal cord as it passes through the vertebrae.

The spinal nerves are as follows:

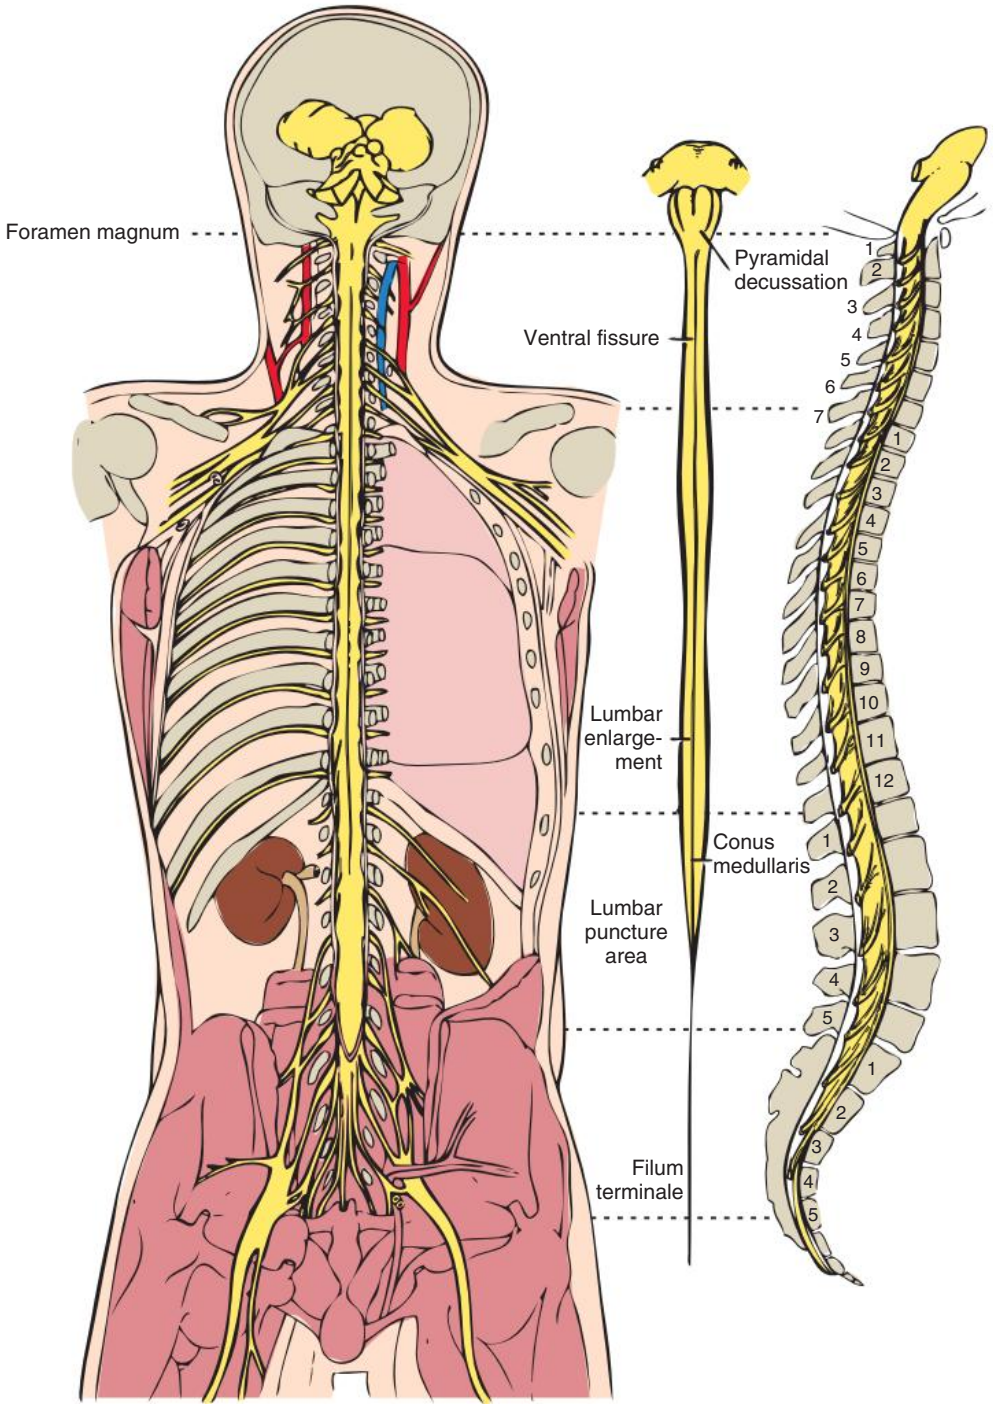
- Eight pairs cervical
- Twelve pairs thoracic
- Five pairs lumbar
- Five pairs sacral
- One pair coccygeal

The spinal nerves carry sensory and motor impulses between the central nervous system (CNS) and the peripheral nervous system (PNS). Reflex sympathetic dystrophy (RSD) or Complex Regional Pain Syndrome (CRPS) can cause chronic pain from dysfunction or interruption of the nervous system pathways. The cord is composed of gray matter (cell bodies) on the inside and white matter (nerve fibers) on the outside. This is the exact opposite of the substance of the brain. The ventral nerve roots are the motor axons to the muscles and glands, and the dorsal nerve roots are the sensory dendrites (Fig. 38.5). The dorsal root ganglion is easily entrapped by the bony vertebrae and causes pain and disability.

The cephalad portion of the cord begins at the base of the brain at the foramen magnum. The first thickened area of the spinal cord is at the C7-T1 junction, forming the brachial plexus. Compromise of the brachial plexus caused by bony impingement



• **Fig. 38.3** Natural and pathologic spinal curves. **A,** Normal chronologic curves. **B,** Idiopathic curves.



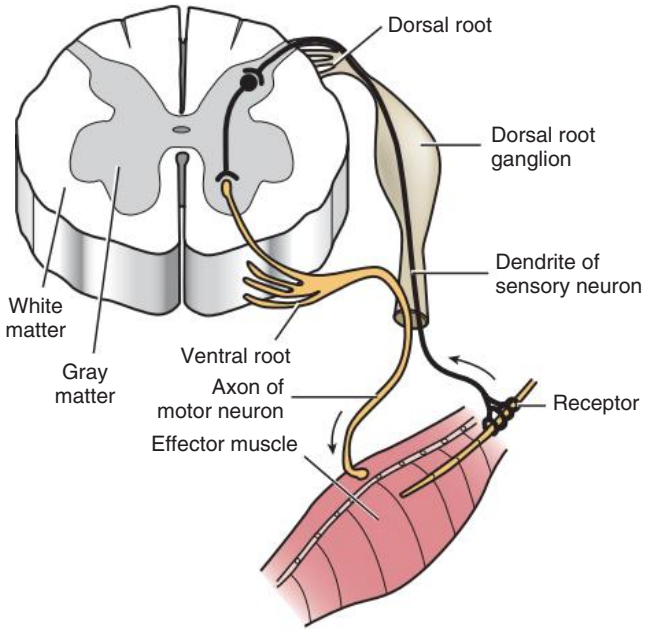
• **Fig. 38.4** Spinal nerves. (Modified from Mettler FA: *Neuroanatomy,* ed 2, St. Louis, MO, 1948, Mosby.)

of the cervical or upper thoracic vertebrae results in arm and hand pain and muscular weakness with **thenar** wasting.

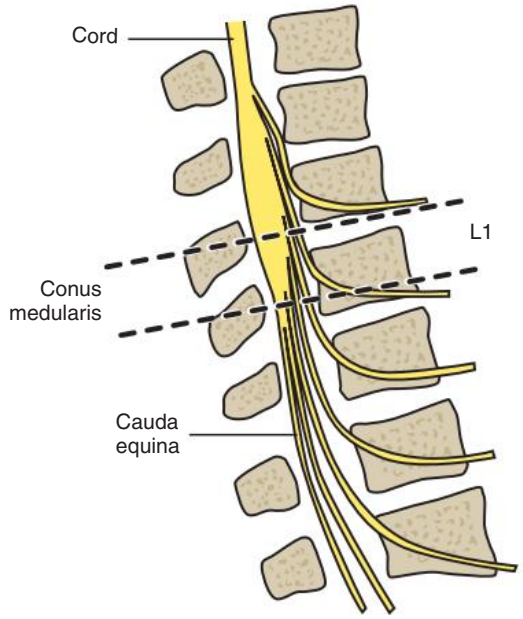
The caudal portion of the spinal cord thickens and ends at L1 to form the conus medullaris before terminating in a fibrous tail known as the cauda equina (horse's tail; Fig. 38.6). The nerve fibers that extend beyond L2-L3 form the lumbosacral plexus.

The blood supply to the spinal cord arises from the vertebral artery. The radicular artery of Adamkiewicz supplies blood to the lower third of the cord. Occlusion of this artery causes paraplegia. Venous drainage is through the intervertebral vein that drains into the azygous venous system.

The meninges cover the cord to the level of the second or third lumbar vertebra. They terminate in a fibrous band (filum terminale) that extends through the lumbar vertebrae and sacrum and attaches to the coccyx. The dura is not attached or continuous with the central canal of the vertebral column.



• **Fig. 38.5** Spinal innervation of the body.



• **Fig. 38.6** Terminal portion of the spinal cord.

Vertebrae

All vertebrae have similar bony characteristics that form a circular canal to house the spinal cord.[1] The structure of a vertebra includes the following:

- A thick cylindric body that bears a portion of the weight of the torso.
- Two posterolateral extensions that form the proximal bony vertebral (neural) arch. These extensions form thick pedicles that connect to flatten laminae posteriorly. The laminae connect at the spinous process, forming a circle. Each pedicle has a notch superiorly and inferiorly to seat the vertebrae above and below.
- A transverse wing-shaped spinous process that is formed by the connection of the posterior laminae. The central foramen shapes the spinal canal.

The bony structure of the vertebral column extends from the foramen magnum at the base of the skull to the coccyx (Fig. 38.7, *A*). The 33 vertebrae, which provide support for the body, vary in size and shape according to location and are separated by flexible discs over the anterior surface of the body (Fig. 38.7, *B*). Each disc is composed of two parts: an exterior annulus fibrosus and an interior gel referred to as the nucleus pulposus.

The seven cervical vertebrae are in the neck and form the secondary curvature. They are lighter weight with a smaller disc-bearing body. The top two cervical vertebrae, C1 atlas and C2 axis, have clearly distinct landmarks. The atlas laminae form a circle around the odontoid process of the axis so the head has a wide range of circular and linear motion (Fig. 38.8). The atlas-axis complex has no disc or spinous process and is considered to be the strongest vertebrae of the cervical portion of the vertebral column.

The 12 thoracic vertebrae articulate posteriorly with the ribs to form a cage around the thoracic organs, forming a primary curvature. The spinous processes are low profile and smaller than the lower vertebrae. The body and discs of the thoracic vertebrae are thinner and are designed to bear minimal weight.

The five lumbar vertebrae are posterior to the retroperitoneal cavity and are designed to carry the heaviest load of the entire vertebral column with the least amount of flexibility. The body and disc of each lumbar vertebra are thick and form a secondary curvature. Fig. 38.9 illustrates the combined lumbar vertebra-disc unit.

The five sacral vertebrae are fused in the adult to form the sacrum, and the four fused coccygeal vertebrae form the coccyx (Fig. 38.10). Collectively, these two sets of fused vertebrae form the posterior aspect of the pelvic girdle. Each vertebra is connected to the other by a series of ligamentous fibers (Fig. 38.11). The vertebral column measures about 28 inches (71 cm) in the average-size adult.

The physiologic relationship between the spinal cord, spinal nerves, and bony vertebral column affects multiple body systems if the curvature is misaligned or some pathology changes the size of a foramen or joint. Fig. 38.12 illustrates the major organ systems and the corresponding spinal nerves that can cause problems with physiologic functioning.

Special Considerations for Spinal Surgery

Because of the proximity of the vertebral column to the spinal cord, both neurosurgeons and orthopedic surgeons perform surgical procedures in this area. Many surgeons have attained subspecialty board certification in spinal surgery. Both disciplines use power drills, power saws, microscopes, and computer imaging to correct problems in the spinal column; however, many surgeons feel that spinal surgery is a specialty unto itself because of the multidisciplinary approaches applied in the correction of spinal problems.

Diagnostics

For diagnosis of spinal conditions, computed tomography (CT) is used to detect abnormal bone. CT and magnetic resonance imaging (MRI) are used to evaluate spinal injuries.[2] MRI and myelography outline soft tissue abnormalities, such as disc degeneration, protrusion, or rupture.[3] Because it is noninvasive, MRI demonstrates improved diagnostic quality over myelography.

• **Fig. 38.12** Physiologic relationship between the spinal cord, spinal nerves, and vertebral column.

Positioning for Spinal Surgery

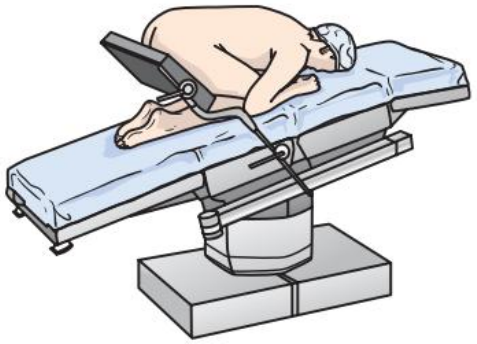
Positioning for spinal surgery can require the patient to be placed in either the supine or the prone position, depending on the type of **approach** necessary for the planned procedure. Most facilities have specialized operating room (OR) beds that accommodate the modifications needed for adequate exposure of the surgical site. Some surgical body positions provide distraction of the vertebrae for more direct access to specific regions of the spine.

Considerations for patient positioning include prevention of untoward injury, such as pressure areas, pinch points on jointed tables, falls, wrong site surgery, and venous stasis. Ischemic pressure insult to the area around the eye can result in blindness.

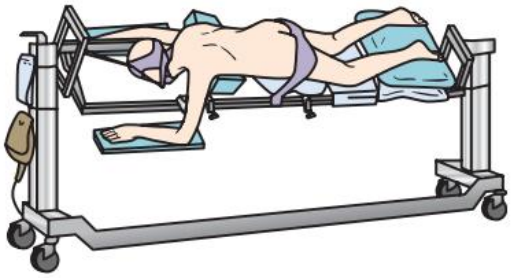
Positioning a patient in the prone position is a multistep procedure. The patient is given general anesthesia on the transport cart, intubated, and catheterized. A minimum of four people is needed to turn the anesthetized patient into the prone position onto the specialized OR bed.

A few prone positions simulate kneeling or crouching, which means the patient may be in a full lift and body flexion before coming into contact with the surface of the OR bed. Fig. 38.13 shows the kneeling-crouching position used by some surgeons for lower spine procedures. This posture constricts the patient's circulation and increases the risk for embolization.

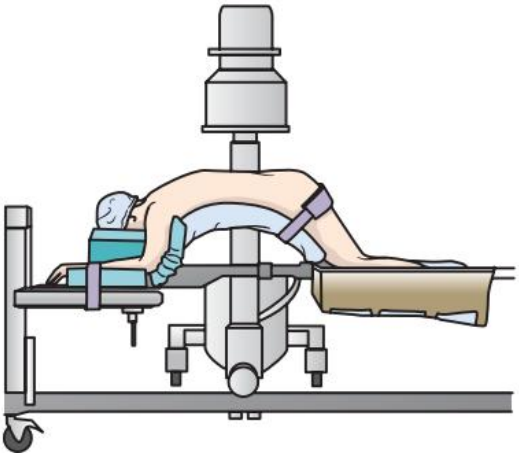
The Jackson table (Fig. 38.14) and the Jackson-Wilson table with the central arch (Fig. 38.15) are used for posterior spinal



• **Fig. 38.13** Kneeling-crouching position for spinal surgery.



• **Fig. 38.14** Jackson spinal table.



• **Fig. 38.15** Jackson-Wilson spinal table.

incisions. Each type of specialty spinal table allows the surgeon to position the patient for optimal vertebral position and exposure of the surgical site.

Anesthesia Considerations

The anesthesia provider monitors and manipulates the patient's physiology. The patient's airway, breathing, and circulation are under constant surveillance by gross visual examination and by technologic devices. Airway and breathing are compromised by the prone positions used for the posterior spinal approach. The patient's chest excursion is decreased, and the intraabdominal pressure is released by allowing the abdominal cavity to rest in a dependent position. The loose abdomen permits the vena cava to remain at a low pressure, preventing excess venous oozing around the vertebral column and cord.

Airway

The patient under general anesthesia who is intubated and placed in a prone position is at high risk for loss of a patent airway. The shape of the trachea and the bifurcation of the bronchi create a complex scenario in which the tip of the endotracheal tube can slip into one bronchus, aerating only one lung. The opposite lung is not adequately ventilated, and the level of oxygen saturation decreases. The patient can become hypoxic. The anesthesia provider should remain vigilant about the endotracheal tube position within the trachea and the level of oxygen saturation in the patient's blood.

Instruments Used for Spinal Surgery

Surgical instruments used for spinal surgery with the **posterior approach** are designed to be used in narrow, deep incisions. The incisions used for surgery of the posterior spine involve paramedian dissection and retraction of several muscle layers. These incisions are very deep and do not always offer a visual advantage to the surgeon and team. The scrub person can prepare for this type of incision by providing medium to large self-retaining retractors in pairs because a matching pair is used in the cephalad and caudad margins. Some surgeons prefer an angled or jointed Weitlaner or Beckman style retractor.

An assortment of bone debulking rongeurs (Kerrison and Cloward) and curettes with a variety of jaw angles (forward biters, back biters, side biters, up biters, and down biters) are used to remove segments of lamina and spinous process. High-speed drills are sometimes used to reduce bony bulk

Graspers used include bayonet-style forceps with and without bipolar energy. Sharp dissectors used for soft tissue such as the dura include No. 3 and 7 scalpels with several No. 10, 11, and 15 blades. Blunt dissectors such as Penfields and other periosteal elevators are commonly used. Manual retractors are size-appropriate and angled to provide a clear field of vision for the surgeon. Nerve hooks are used.

Other standard medium and long instruments are used throughout spinal procedures for the posterior and anterior approaches. Keep in mind that any **anterior approach** requires basic soft tissue sets such as laparotomy instruments and retractors in addition to instruments specific to spinal procedures. Micro instruments are used for microscopic procedures.

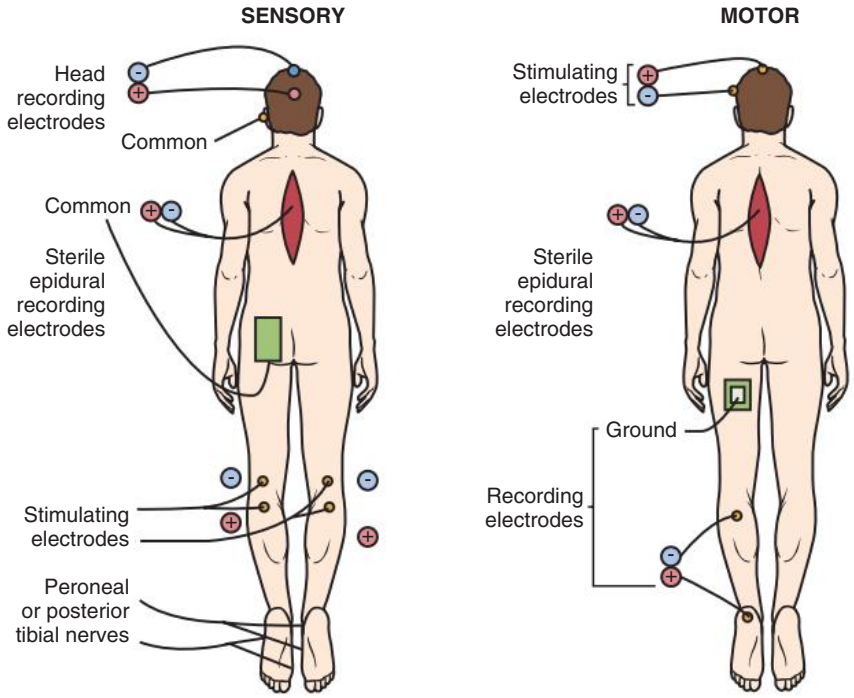
Intraoperative Neural Monitoring of the Spinal Cord

Some spinal surgeons prefer to monitor sensory and motor activity of the brain and spinal cord during surgery (Fig. 38.16). Intraoperative neural monitoring during the procedure gives the surgeon an early indication of the condition of the cord and spinal nerves as each layer of soft or compact tissue is manipulated.[4]

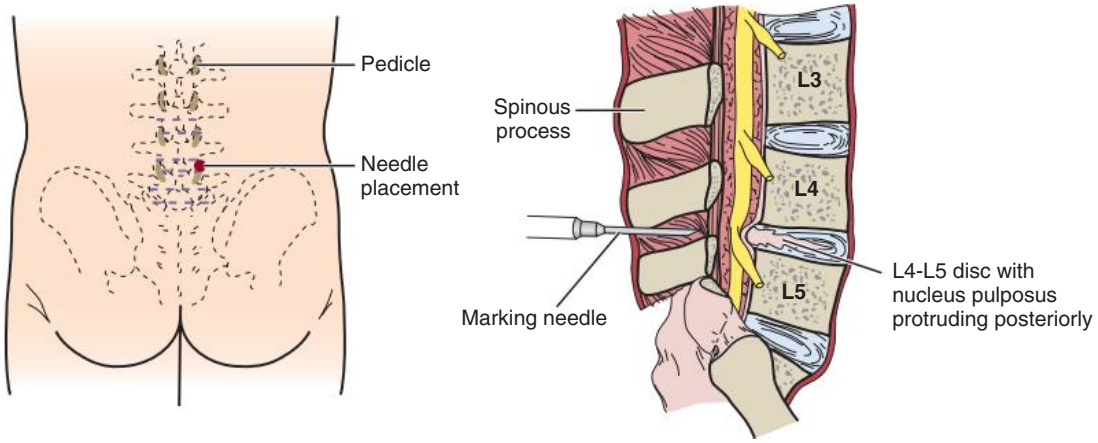
Dermatomal mapping and **Stagnara wake-up tests** also are reliable techniques for monitoring of spinal cord function. In the latter test, the patient must be awake enough to respond to the surgeon's command to move the foot.

Radiologic Use during Spine Surgery

The surgeon usually has a scout x-ray performed. A spinal needle is inserted into the patient's back to the level of the vertebrae targeted for the surgical procedure. The metal needle serves as a marker and confirmation that the procedure is being performed



• **Fig. 38.16** Intraoperative spinal cord monitoring.



• **Fig. 38.17** Needle localization of surgical level.

at the correct level of the spine (Fig. 38.17). After the primary incision, some surgeons place an instrument in the intended spinal level and take a confirmation x-ray before proceeding with the surgical procedure.

Additional x-rays may be taken during the procedure if hardware or appliances are implanted into the bone or surrounding tissue. The follow-up x-rays before closure provide documentation of the spinal procedure level and structural integrity of implants.

Modeling with Scans

Preoperative CT or MRI images can be used to create a three-dimensional computer model of the affected vertebrae and discs. The computer model allows the surgeon to see the target vertebrae and discs from all directions before incising the skin.

Microscope

The operating microscope was introduced in the late 1960s. Microdiscectomy is a discectomy performed with the operating microscope that is displayed on a video monitor. The video monitor enables the entire team to see the surgical site and anticipate the surgeon's next steps.

Robotic-Assisted Spinal Surgery

Precision tissue manipulation and dissection are made possible by robotic-assisted instrumentation.[5] Some of the systems in use offer the surgeon a greater freedom of hand and wrist motion in close quarters. Some maneuvers made with robotic instrumentation are not possible in the realm of human range of motion. The use of three-dimensional imaging can help surgeons place screws or disc implants into precise position. The surgeon's

armamentarium is greatly expanded by using robotics for extremely delicate procedures.

Hemostasis

Meticulous hemostasis is necessary in the vertebral and spinal canals. Hematoma formation can create pressure and cause irreparable damage to the nervous system. Compressed cottonoids or patties are used for clearing blood and for applying topical agents such as thrombin. Cottonoids are counted and accounted for in the same manner as other sponges. Topical thrombin can be used for superficial oozing. Thrombin is never injected because it causes a fatal systemic thrombotic response.

Care is taken to avoid leaving absorbable hemostatic agents in any neural or bony space. Most absorbable agents swell in response to absorption of blood and cause compression in a constricted area. Pressure on the spinal cord or nerves can cause **paralysis** or other permanent deficit. The U.S. Food and Drug Administration (FDA) has issued an advisory concerning retained absorbable hemostatic materials in neural spaces. The material expands as it absorbs blood, causing pressure between the neural tissue and bone. Pressure on the neural tissue can result in permanent injury.

Bipolar electrosurgery is commonly used to minimize the amount of neural tissue involved with the effects of radiofrequency coagulation. Hemostasis for the cut edges of bone can be attained with bone wax or a paste made of powdered antibiotic and saline solution. Bone wax is not resorbed and can act as a mechanical barrier to osteogenesis in some individuals.

Graft Materials and Stabilization of the Vertebrae

Spinal fusion may be indicated to stabilize the vertebral column after spinal injury or excision of bone. Either a posterior or an anterior approach may be used to place the bone grafts. A combined anterior and posterior spinal fusion may be required for severe deformities. The anterior fusion is performed first. Unless the lesion or bone fragment to be removed is on the right side of the vertebral column, an anterior thoracolumbar approach is used through an incision with the patient in the right lateral position (left side up). A **retroperitoneal** incision is made for an anterior lumbar approach. These approaches are safer on the left side because the surgeon works near the aorta, which is more resistant to inadvertent injury than is the vena cava on the right.

Bone grafts are placed in the intervertebral spaces or along the spinous processes to bridge over or to stabilize the defect. The rib removed for an anterior thoracolumbar approach is used for grafting. Homogeneous cancellous bone from the bone bank may be needed to provide a larger quantity of bone than can be obtained from the rib or an autogenous graft from the crest of the patient's ilium.[6]

Cancellous bone rather than cortical bone is usually preferred for spinal fusion. Bone grafts may be used with or without internal fixation devices. The goals of spinal fusion are to achieve stability, rigidity, and correction of deformity. The combined use of internal fixation devices with bone grafts may facilitate postoperative care and early ambulation.

Complex procedures are performed for sublaminar wiring, pedicle screw fixation, and internal vertebral stabilization or fusion. Many spinal implant systems are available. All have the common goal of immobilizing spinal segments; each offers significant biomechanical advantages, but all have potential complications. The surgeon chooses the most appropriate device for the location, approach, and type of deformity and instability. For example, the posterior body and ligamentous structures in the cervical spine may be disrupted by a flexion-compression type of injury. Interspinous wiring and bone grafting provide posterior neck fusion for stability.

In the thoracolumbar spine, pedicular screw and plating systems can be used in conjunction with spinal fusion in treatment of fractures, spondylolisthesis, and idiopathic scoliosis. The following may be used to provide **decompression** of spinal nerve roots and vertebral alignment after posterior thoracolumbar spinal fusion:

- Cotrel-Dubousset rods, hooks, and screws
- The Texas Scottish Rite Hospital (TSRH) system of pedicle screw fixation with rods and cross-links
- Luque rods and sublaminar wires
- Wisconsin spinous process wires

Kaneda, Zielke, Dwyer, or Dunn devices are used when an anterior approach is preferred. Each device has its own set of instrumentation for installation; these are not interchangeable.

Pathology of the Vertebrae and Spinal Cord

Disc Degeneration and Rupture

Compression on the Spinal Cord or Nerve Roots

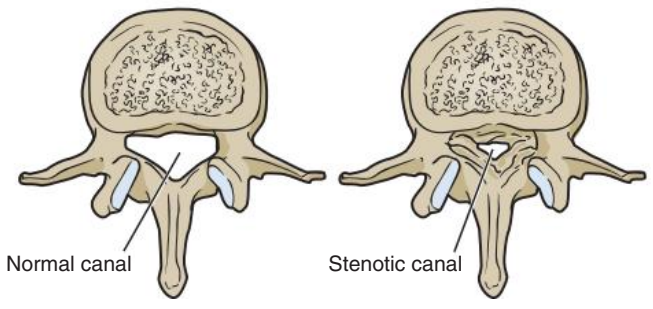
The central canal of the vertebral column can become narrowed and cause compression on the cord (Fig. 38.18). Urgent decompression is necessary if the pressure begins to cause symptoms. Decompression is performed by removing segments of bone at the affected site. Patient's with stenosis and spondylosis may be candidates for decompression surgery. Prolonged pressure on the spinal cord and nerves can cause permanent damage and loss of motor function and sensation.

Vertebral Deformity and Degeneration

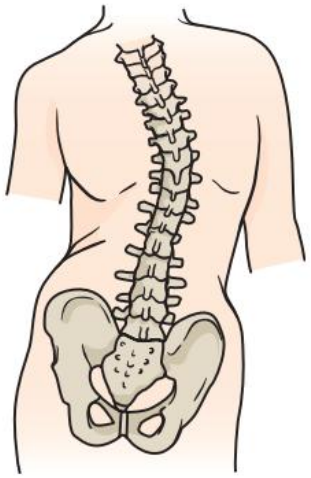
Scoliosis

An idiopathic lateral curvature of the spine is **scoliosis**. It is more common in young females, although it can develop in later years with other bony deformities of the spine (Fig. 38.19). The diagnosis is made by having the individual bend forward and observing the linear direction of the spinal bones (Fig. 38.20). The curvature worsens with time. Any curvature of 40% or more requires correction. (Additional information can be found at www.scoliosis.org.)

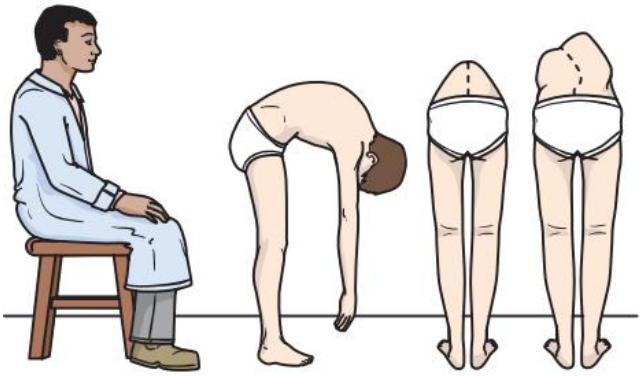
Many body systems are affected by scoliosis. Digestion can be impaired. Chest excursion and respiratory effort are altered by the deformity that occurs in the ribcage (Fig. 38.21). Extreme curves can cause disruption in lung growth, causing fibrosis of the lung tissue. The patient has an altered and unsteady gait.



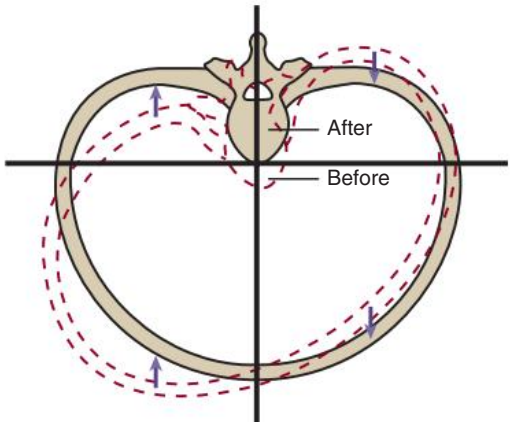
• **Fig. 38.18** Stenosis of the vertebral canal.



• **Fig. 38.19** Scoliosis.



• **Fig. 38.20** Abnormal vertebral alignment.



• **Fig. 38.21** Configuration of rib deformity in scoliosis.

Surgical options include several types of rodding instrumentation, hardware systems, and biografting using allograft or autograft material. Each has a certain amount of failure risk and should not be used in the presence of osteoporosis. After a period of years, the graft material may be solid enough to remove the hardware.

Most surgeons prefer to leave the rods in place. The surgical approach can be anterior or posterior depending on the type of instrumentation used and the type of correction desired. The most commonly used surgical scoliosis correction systems are as follows:

• **Fig. 38.22** Harrington rods.

1. Harrington rigid metallic rods used for the correction of spinal curvature greater than 60% were introduced in the 1960s. The rods are placed using a posterior approach. The patient is in a body cast for about 6 months postoperatively (Fig. 38.22). The rods can fracture over time because the main fixation is at the ends of the rods.
2. Luque rods are flexible L-shaped bilateral rods wired to the vertebral column to reverse the abnormal angle of the spine by 10%. A higher risk for injury exists because each custom curved segment is wired close to many levels of the spinal nerves. The patient does not need a brace postoperatively.
3. Cotrel-Dubousset features flexible rods with hooks and set screws that use biomechanical principles to reverse the abnormal spinal bends. This system preserves the natural curves of the spine. The system is complex and may require the patient to wear a brace after surgery. This system can be used for kyphoscoliosis.
4. Zielke instrumentation is similar to Cotrel-Dubousset but is used for double curvatures. An anterior approach is commonly used. A body brace is worn postoperatively.
5. The TSRH system preserves the natural curves with a series of rods and hooks affixed with nuts and bolts to correct lateral rotation of the vertebrae. These rods can be used for kyphoscoliosis. A brace is not always necessary postoperatively.
6. The Isola system is a series of rods and drop-in screws that provide a stable correction of spinal curvature using an anterior transthoracic approach with the patient in a lateral position. Each disc is removed and grafted. Each vertebral body is drilled and has a screw placed for fixation of the rods. These rods can be used for kyphoscoliosis of 40 degrees and may not

require a body brace after surgery. This system can be used for adolescents and adults.

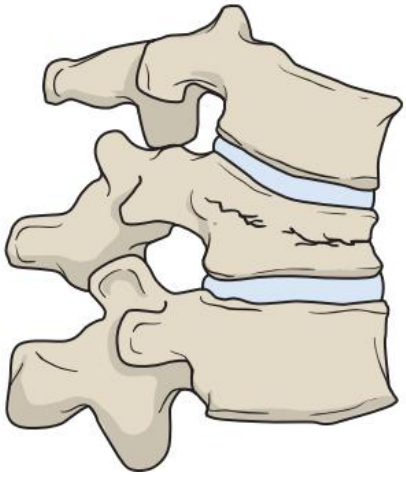
7. Drummond instrumentation uses a Harrington rod on the concave side of the spine and a Luque rod on the convex side. Each vertebra is individually wired. The patient wears a cast or brace postoperatively.
8. Vertical expandable prosthetic titanium rib (VEPTR) implants are used when the skeletal anatomy is immature and still growing. The distal aspect of the rods is affixed with screws, and the proximal ends are attached to pedicle hooks and distraction locks. The rod is cut longer than needed and bent into a corrective contour. Bone graft is used. These rods are also referred to as *growing rods* and can be used after 6 months of age.[7] Postoperatively, the child wears a noncorrective body orthosis for 3 months. Every 6 months, the child is brought back to surgery and the proximal distraction locks are loosened and moved up the length of the rods to accommodate the increase in height. The VEPTR rods allow for spine lengthening and prevent thoracic instability.
9. Magnetic spinal growing rods for children with early-onset scoliosis have become popular because the lengthening process can be done without numerous invasive surgical procedures. After the initial rod placement, the rods can be adjusted as an office visit with an external magnet placed on the child's back. The rods can be lengthened in a few minutes and require lengthening every few months.[7]

Kyphosis

Osteoporosis is a degeneration and demineralization of bone that causes compression of the vertebral bodies at regions of spinal curvature[8] (Fig. 38.23). The flattening of the vertebral body causes a loss of height and decreases the accommodation of the movement of the spinal cord and major organ systems (Fig. 38.24). Respiratory effort can be compromised by a decrease in thoracic space.

Kyphoplasty is performed percutaneously with the introduction of a catheter and balloon assembly into the collapsed vertebral body (Fig. 38.25, *A*). The balloon is expanded with a radiopaque contrast media to reproduce and outline the vertebral height and then is removed and replaced with bone cement. The cement hardens to maintain the space created by the kyphoplasty balloon (Fig. 38.25, *B, C*).

• **Fig. 38.23** Areas of compression treated with kyphoplasty.



• **Fig. 38.24** Compressed vertebral body.

Spinal Tumors

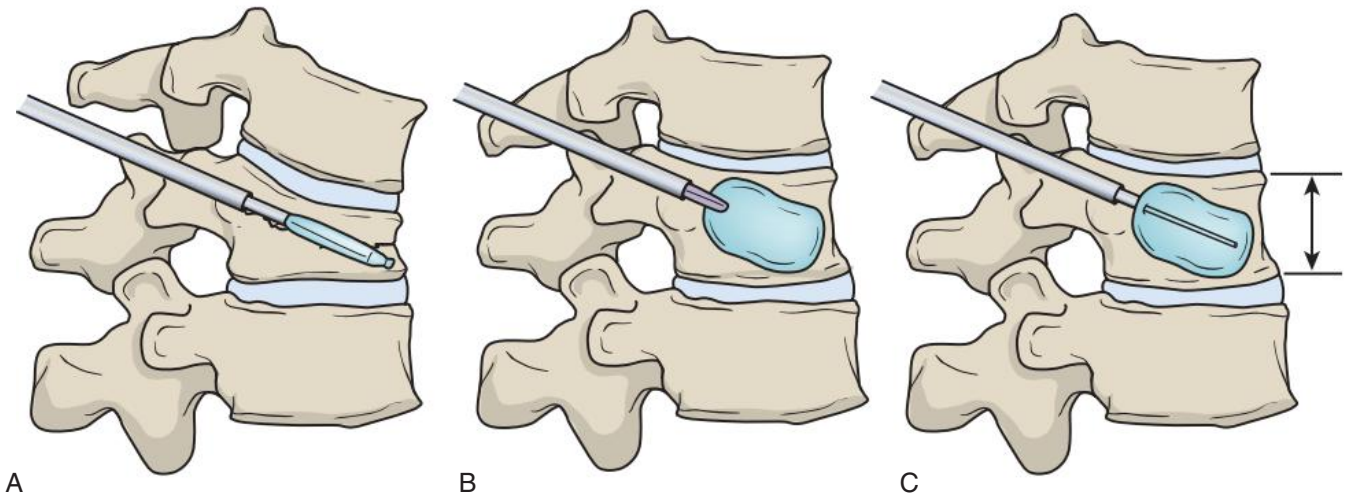
Spinal tumors may begin with slowly progressing problems such as bladder or bowel weakness and vague symptoms such as back pain and **radiculopathy**. Thoracic intraspinal tumors represent higher rates of morbidity in the presence of spinal cord atrophy and arachnoid scarring. The diagnostic process is prolonged because the symptoms are not consistent.

Most spinal tumors are readily diagnosed with MRI, and, if they metastasize, they travel to the bone first. Other cancers such as prostate, lung, and breast metastasize to the vertebrae through hematologic routes and can infiltrate the dura to the cord. About 55% of spinal tumors are metastatic in origin. Symptoms usually are related to spinal cord pressure.

The posterior segment of the vertebral arch is removed to expose the dura over the involved section of the spinal cord. The dura is incised and retracted with sutures. The tumor is excised, and the dura is closed tightly to prevent leakage of cerebrospinal fluid (CSF). Both intrinsic and extrinsic spinal cord tumors can be removed by laser with decreased tissue trauma. The laser is especially useful in areas difficult to reach by dissection, such as the foramen magnum or anterior spinal cord.

Tumors of the spinal area are classified as one of the following types:

1. *Extradural:* Outside the dural layer of the meninges. Many of these are benign, such as lipomas, chondromas, granulomas, and abscesses.
2. *Intradural:* Under the dural layer of the meninges, not invasive in the spinal cord. These tumors are frequently well circumscribed and slow growing. They arise from the cells of the proximal nerve roots. They can be noted with myelograms.
3. *Hemangioblastoma:* Vascular tumor in neural tissue. More common in 30 to 40-year-old men (2:1). These tumors can be associated with von Hippel-Lindau disease. Hemangioblastomas are more common in the cervical or thoracic areas.



• **Fig. 38.25 A,** Introduction of kyphoplasty catheter. **B,** The balloon on the kyphoplasty catheter is expanded. **C,** Bone cement is used to displace the kyphoplasty balloon and maintain vertebral height.

4. *Astrocytoma (glial tumor):* This tumor of the spinal cord is rare and is more often found in 30 to 50 year-old men, than women. The appearance on MRI is very cystic and thickened. Large segments can be removed with irrigation-aspiration systems such as the CUSA.
   a. *Diffuse fibrous type:* More difficult to remove. Most spinal astrocytomas are this type.
   b. *Circumscribed:* More clearly defined and with a better prognosis for excision. Less invasive to surrounding tissue.
5. *Intraspinal intramedullary:* Slow-growing tumor inside the tissues of the spinal cord. More common in females. These grow more aggressively in children than in adults. Cervical and thoracic areas are the most common primary sites. Sacral tumors tend to metastasize readily to bone.
6. *Ependymoma tumors:* These tumors arise from the ependymal cells that line the central canal, from the ventriculus terminalis of the conus, and from the filum terminale with cells disseminated by the CSF. Some are encapsulated with many superficial vessels. Total removal of an encapsulated tumor may eliminate the need for postoperative radiation.
   a. Myxopapillary ependymal tumors arise exclusively in the filum terminale and the conus medullaris and are more common in young males.
   b. Metastasis from areas of the brain.

Spinal Trauma

During World War I, 80% of soldiers with spinal cord injuries died within the first 2 weeks of the wounding. Little was known about special spinal treatment and surgical decompression, so most of the wounded died of complications associated with the spinal cord injury, not the actual damage to the cord. Immobility and infection were leading causes of death. By World War II, specialized units were developed in response to scientific understanding of the cord and its function, greatly increasing the survival rate.

Vertebral fractures, with or without dislocation, can cause spinal cord compression that denervates nerve tracts below the injury. Spinal cord injury also may be caused by penetrating or stretching trauma or by damage to blood vessels that supply the cord. Spinal cord injuries are classified as follows:

- *Complete:* The patient lacks sensation, proprioception (position sense), and voluntary motor function below the level of the spinal cord damage. Lesions above the fifth cervical vertebra (C5) cause partial to complete diaphragmatic paralysis. Injury in the cervical region results in **quadriplegia** (i.e., functional impairment from the neck down). Lumbar cord injuries lead to **paraplegia** (i.e., excluding paralysis of the upper extremities). Spinal cord injuries and brain injuries such as a stroke can cause **hemiplegia** (i.e., paralysis on one side of the body).
- *Incomplete:* Some sensory, proprioceptive, and motor impulses are present. Loss of function depends on the extent and location of the injury. This is sometimes seen at the lower aspect of the cord below L1 in the region of the cauda equina. Bowel or bladder function can be affected without impairing mobility.

Spinal cord edema or hematoma can cause a cord lesion to ascend and worsen the neurologic deficit. Resultant paralysis may be relieved if the surgical procedure to remove bone fragments or to drain a hematoma compressing the spinal cord is done within a very short time after injury. Results are frequently discouraging.

Damage to the cord may be too extensive for return of function, or at best, return may be incomplete. Care is taken in moving and positioning the patient to avoid further paralysis. The patient should be log rolled (i.e., turned or lifted without flexing of the vertebral column).

A lumbar puncture with pressure readings may be done. If a block in the flow of spinal fluid is present, a laminotomy or laminectomy is done to decompress the spinal cord in a patient with complete paralysis or partial paralysis that is becoming progressively worse. A laminectomy also may be done to remove bone fragments. Internal fixation may be combined with decompression for thoracolumbar fractures.

Temperature control and monitoring of fluid and electrolyte balance are essential to the outcome for the patient with a spinal cord injury. The patient loses thermoregulatory ability after injury and tends to assume the temperature of the environment. Lack of vascular adaptation affects fluid balance. Pulmonary edema and left ventricular failure can occur. Pulmonary embolus also is a potential complication of immobility.

Technologic advances in surgical treatment, stabilization, and electrical stimulation have given patients with spinal cord injuries hope for regaining partial or full function.

Surgical Procedures of the Spine

Discectomy

Intervertebral disc injuries can happen anywhere along the vertebral column but usually occur between the lumbar vertebrae and are caused by lifting heavy objects or by twisting the spine. The nucleus pulposus can herniate or rupture through a tear in the annulus fibrosus and posterior ligament (Fig. 38.26). This protrusion, referred to as a herniated disc or ruptured or slipped disc, compresses the spinal nerve roots or spinal cord within the spinal canal against the vertebra. This causes pain along the **dermatomes** from the lumbar or sacral region to one or both lower legs (Fig. 38.27). Pain may radiate down the sciatic nerve pathway to the leg. Muscles can be affected causing multiple symptoms from weakness to paralysis when nerve impulses are disrupted from a **myotome** pathway. During the surgical procedure, the herniated nucleus pulposus or ruptured portion of the annulus fibrosus is excised (Fig. 38.28).

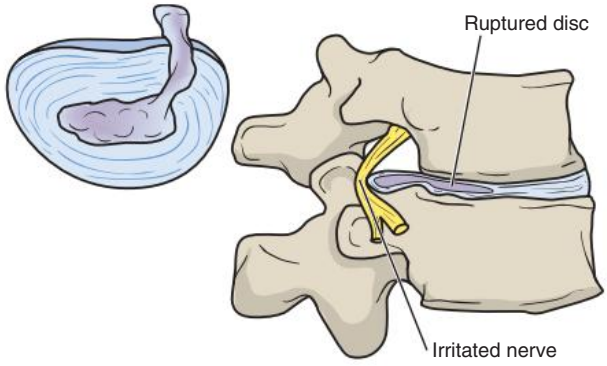
Microdiscectomy or percutaneous discectomy may be used to remove a herniated lumbar nucleus pulposus with minimal surgical manipulation. Microdiscectomy permits exposure of the herniated nucleus pulposus through a 1 or 2-inch (2.5 or 5-cm) incision without extensive manipulation of the paraspinal muscles or removal of a large section of lamina. The skin incision is shorter than required for a standard laminectomy; therefore recovery time is decreased.

Percutaneous Discectomy

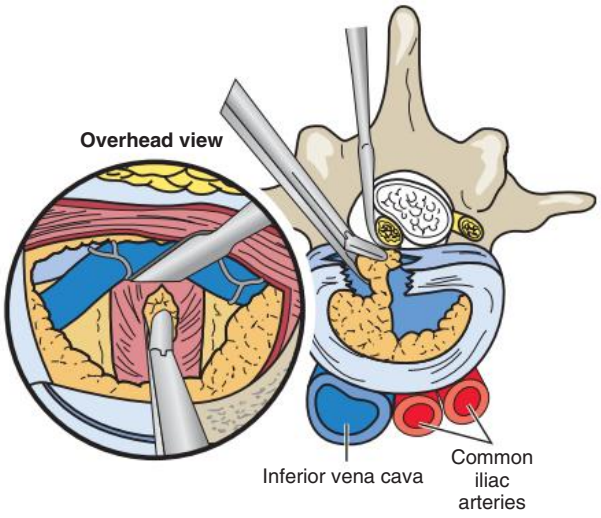
Percutaneous lumbar discectomy (nucleoplasty) is an endoscopic procedure to remove a focal bulge–type herniated disc, usually at the level of L4-L5. It is done with the patient under local anesthesia, usually with intravenous (IV) sedation because the patient must be alert enough to assess radicular pain in the leg. The patient may be either prone or in a lateral decubitus position. A trocar is inserted through the skin and soft tissue into the disc capsule. Under fluoroscopic control, a cutting probe (Nucleotome) is inserted through the outer cannula. The herniated nucleus pulposus is excised and aspirated to relieve pressure on the spinal nerve root.

Total Disc Replacement

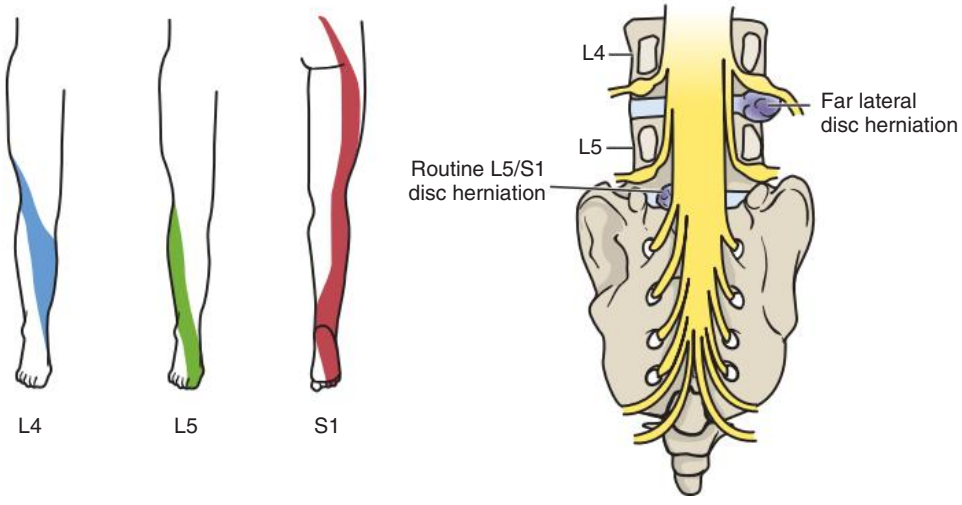
Total disc replacement (TDR) can be done for lumbar or cervical discs with an artificial material. Discs made from metal, ceramic, and viscoelastic materials are available. Disc replacement has been approved for up to two levels. (More information can be found at www.spine.org.)



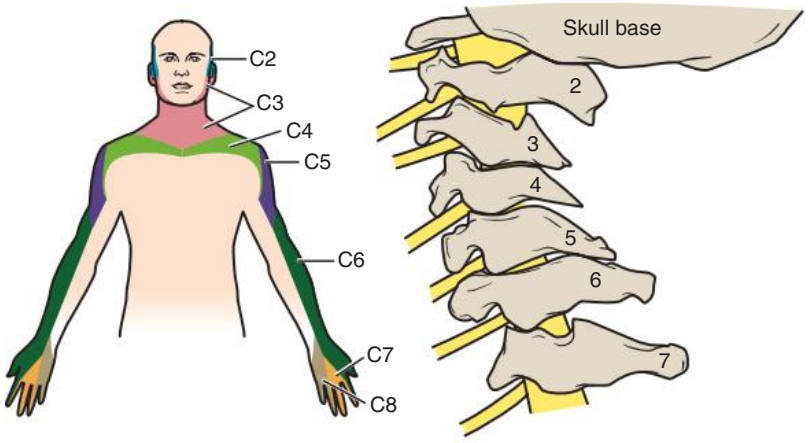
• **Fig. 38.27** Ruptured disc.



• **Fig. 38.28** Ruptured disc is excised.



• **Fig. 38.26** Herniated disc at L5-S1 causes pain along the associated dermatomes.



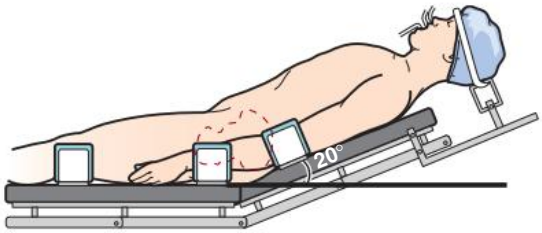
• **Fig. 38.29** Cervical dermatome.

Cervical Spine

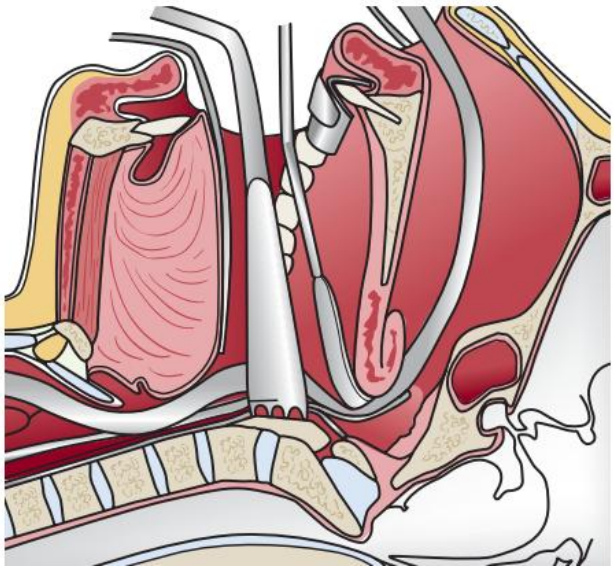
The cervical dermatome distribution is one of the prime indicators of the location of the injury or pathologic lesion (Fig. 38.29).

Transoral Approach

In the **transoral approach** the patient is positioned supine with the backrest of the OR bed elevated approximately 20 degrees. The head is stabilized in a headrest, and the airway is intubated with a nasotracheal tube (Fig. 38.30). The retractors are placed in the pharynx to retract the tongue and the soft palate. The uvula is retracted upward using a transnasal loop. The teeth are protected by tooth guards or moist sponges (Fig. 38.31). The transpharyngeal incision is made to access the retropharyngeal space. The high cervical spines C1-C2 can be repaired or stabilized.



• **Fig. 38.30** Position for transoral cervical surgery.



• **Fig. 38.31** Transoral retractors.

Anterior Cervical Approach

The anterior cervical spine can be exposed through a transverse skin incision in the neck and dissection through the cleavage plane between the carotid artery and the esophagus (Fig. 38.32). The anterior cervical incision is created along the lateral muscular cleavage line or transversely across the anterior neck (Fig. 38.33). Medium self-retaining retractors are placed in the incision at right angles to provide exposure of the vertebral body while displacing the esophagus and trachea (Fig. 38.34). Care is taken to identify the nerves and vessels. Anterior cervical dissection can cause complications with speech and swallowing postoperatively.

The spinous processes and laminae remain intact when the anterior approach is used. A ruptured intervertebral disc or a fracture-dislocation with bone fragments compressing the cervical spinal cord or nerve roots can be completely explored at the level of the vertebral body (Fig. 38.35). Removal of the posterior margins of the vertebral bodies may be indicated to complete the decompression of the nerve root.

The operating microscope is a valuable adjunct to anterior cervical intervertebral discectomy and for an anterior approach to other cervical spinal lesions. A bone graft may be placed between the vertebral bodies for interbody fusion.

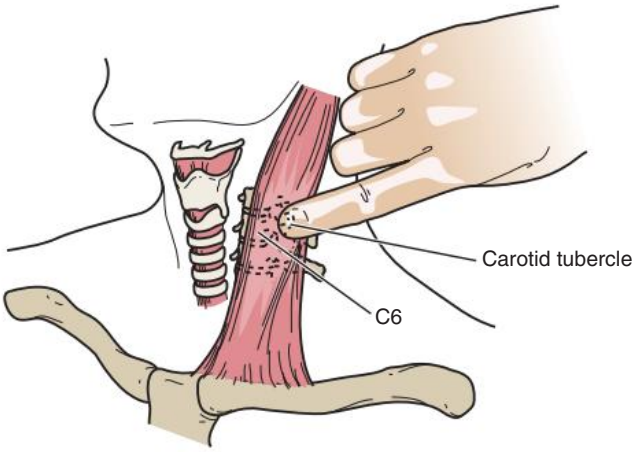
Posterior Cervical Approach

The lower posterior cervical spine can be accessed with the patient in the prone position and the head stabilized in a head-positioning frame. The incision is made vertically over the cervical spinous processes (Fig. 38.36). The laminae are removed (Fig. 38.37), and the remaining cervical spinous processes are stabilized with plates and screws to minimize instability (Fig. 38.38).

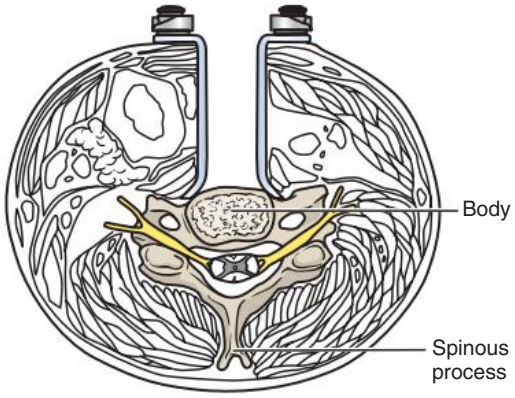
Thoracic Spine

Anterior Thoracic Approach

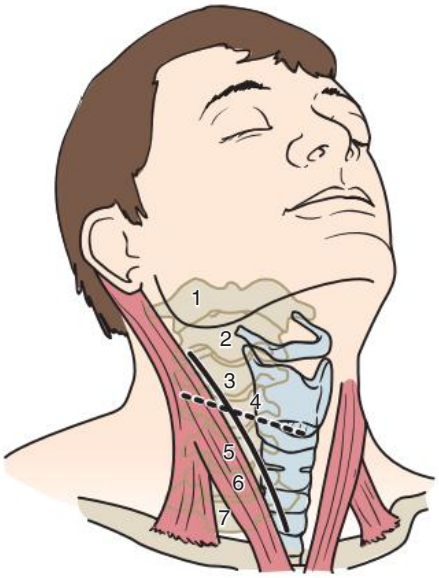
An anterior approach is used for thoracic vertebral disc herniations, spinal cord tumors, or vertebral body fractures. A thoracic surgeon assists with a transthoracic approach. Fractured bone



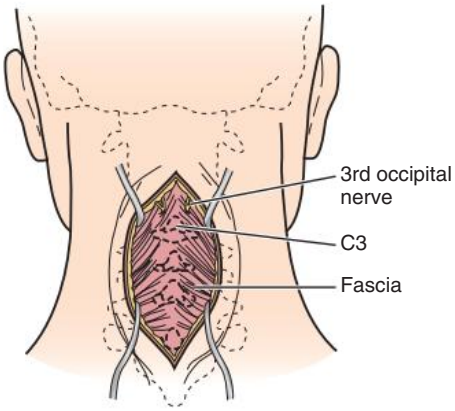
• **Fig. 38.32** Surgical landmarks for anterior cervical approach for cervical spine surgery.

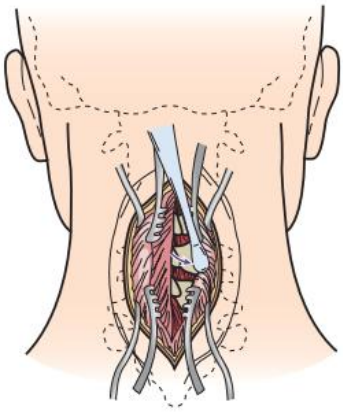


• **Fig. 38.35** Cross-section of retracted tissue at the level of the cervical vertebrae.

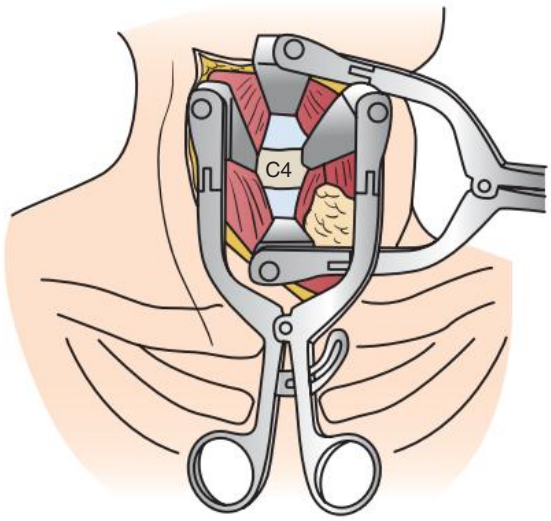


• **Fig. 38.33** Anterior cervical incisions.





• **Fig. 38.36** Posterior cervical incision and laminectomy.

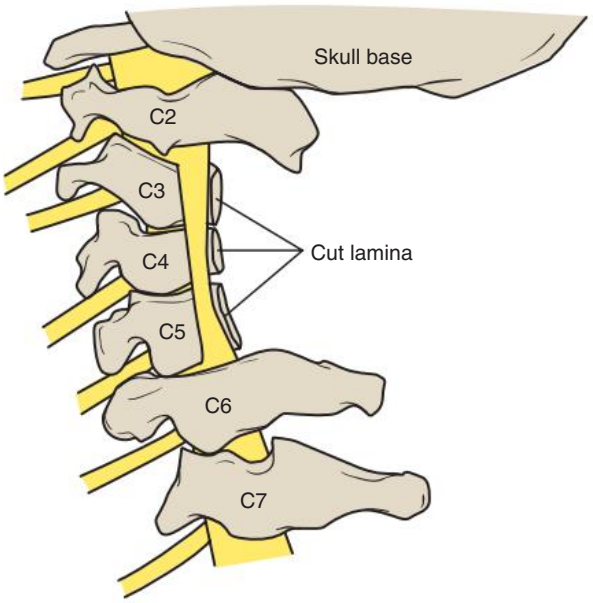


• **Fig. 38.34** Medium self-retaining retractors are placed at right angles.

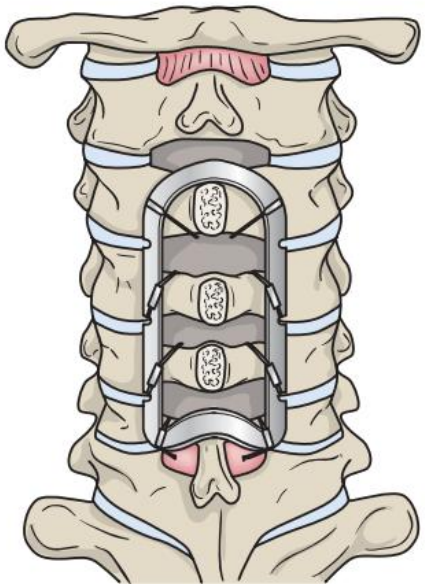
fragments can be stabilized with anterior spinal fusion or placement of posterior rods by costotransversectomy in the thoracic region. Thoracoscopic approaches can be used.

Posterior Thoracic Approach

Posterior thoracic spinal procedures do not involve a full thoracotomy. Positioning is similar to that used for lower posterior spinal procedures, and the incision is performed in the same manner as a lumbar incision.



• **Fig. 38.37** Posterior cervical laminectomy at three levels.



• **Fig. 38.38** Posterior cervical stabilization after laminectomy.

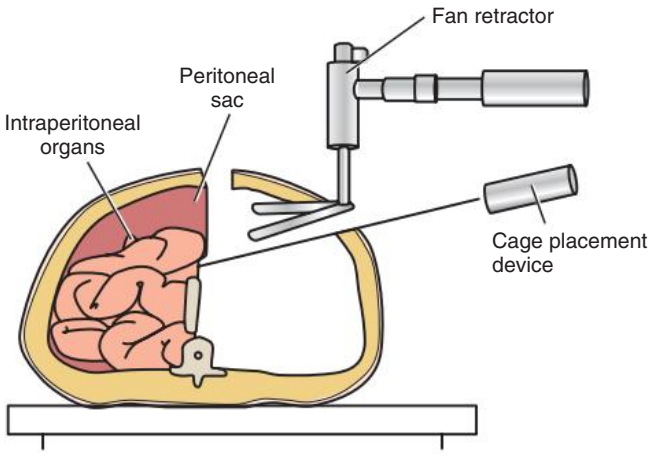
Lumbar Spine

Anterior Transperitoneal Lumbar Approach

The anterior **transperitoneal** approach is performed on a supine patient through an abdominal incision, like a laparotomy, that enters the peritoneal cavity. Large table-mounted self-retaining retractors are used to provide exposure.

Anterior Retroperitoneal Lumbar Approach

The anterior retroperitoneal approach is performed on a patient in a supine or lateral position and involves an incision into the abdomen that is used to dissect the planes behind the peritoneal cavity from the abdominal wall (Fig. 38.39). The peritoneal cavity is displaced laterally and retracted away from the retroperitoneal space.



• **Fig. 38.39** Supine anterior retroperitoneal approach.

The retroperitoneal method is used for endoscopic spinal surgery and placement of interbody metallic cages for stabilization (Fig. 38.40). The cages are small titanium or carbon fiber frames packed with bone graft material and inserted between the bodies of the vertebrae. The graft-filled cages can be placed anteriorly (Fig. 38.41, *A*) or posteriorly (Fig. 38.41, *B*) through the disc space between the vertebral bodies or can be positioned vertically in the anterior interbody space (Fig. 38.41, *C*).

The endoscopic method of cage placement is commonly performed with the patient in a lateral position. The team is strategically positioned around the OR bed so the monitors are in a clear range of vision (Fig. 38.42).

Posterior Lumbar Approach

Removal of the spinous processes and lamina from one or more vertebrae is performed to expose an intervertebral or spinal cord lesion. A posterior laminectomy is usually carried out through a vertical midline skin incision with the patient positioned prone (Fig. 38.43). The patient may be positioned prone on a Jackson table or Wilson or Andrews frame to arch the spine forward for reduction of epidural blood loss by lowering the intraabdominal pressure on the vena cava. Obese patients require additional consideration for redundant body tissues and the weight limits of special spinal frames.

The extent of the incision depends on the number of lumbar laminae to be removed. Fascia and muscles are retracted to expose the spinous processes and laminae. These are sharply debulked and dissected with a rongeur, as necessary, for exposure of the spinal cord dura, spinal nerve roots, or an interlaminar lesion. An intervertebral disc, spinal cord tumor, bone fragments, and extradural or intradural foreign bodies are removed after the laminectomy is completed.

Cages can be placed during an open spinal procedure as part of the stabilization after a laminectomy. Fig. 38.44 shows an interbody cage packed with bone graft material and stabilization with plates and screws. Fig. 38.45 shows an L5-S1 fusion with bone graft for fusion with stabilization with short rods and screws.

39 Ophthalmic Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify the pertinent anatomy of the eye and surrounding structures.
- Describe the procedures performed on the eye for glaucoma.
- Discuss the advantages and disadvantages of intraocular lens implantation.
- Describe the actions of mydriatic and miotic drugs.

KEY TERMS AND DEFINITIONS

Aphakic Without a natural or prosthetic lens.
BSS Balanced salt solution used for eye irrigation.
Capsulorrhexis During cataract surgery a continuous circular rent is created in the anterior capsule to allow removal or phacoemulsification of the nucleus of the opacified lens.
Cataract Cloudy or yellowed lens of the eye.
Cyclodialysis Surgical opening between the anterior chamber and the suprachoroidal space to decrease elevated pressure within the eye in glaucoma.
Discission Cut into soft tissue such as a cataract.
Gonioscopy Examination of the anterior chamber with a special lens.
Haptic Tiny flexible prong used to secure a prosthetic intraocular lens.
IOL Intraocular lens.
Phacoemulsification Irrigation and aspiration of a cataract using ultrasonic vibrations.
Pneumoretinopexy Repositioning of a detached retina by use of a gas or air bubble in the vitreous.

Anatomy and Physiology of the Eye

A thorough understanding of the anatomic structure and physiology of the eye is fundamental to a comprehension of the surgical procedures.

The eyeballs are framed bilaterally by the bony orbits. Each orbit comprises seven separate bones: the maxilla, palatine, frontal, sphenoid, zygoma, ethmoid, and lacrimal bones. Foramina, fissures, and grooves provide stability and access for vessels, nerves, and attachments. Adjacent anatomic structures include the lacrimal apparatus medially, the extraocular muscles and their attachments, and the sinuses.

The globe, or eyeball, is situated within the bony orbit and is surrounded by a padding of fatty tissue. Its position is maintained by extraocular muscles and fascial attachments. The sclera, the white outer tissue layer of the globe, is contiguous with the transparent avascular cornea anteriorly. The conjunctiva is the mucous membrane that lines the inner side of the upper and lower eyelids and the exposed portion of the sclera, except for the cornea (Fig. 39.1).

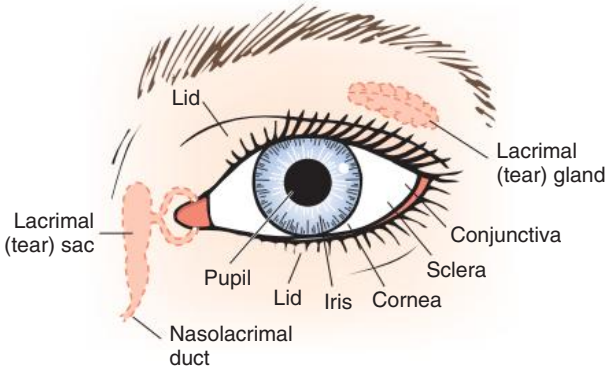
The eyeball is divided into two segments: anterior and posterior. The anterior segment of the eye includes the cornea, the anterior chamber filled with aqueous fluid (humor), the circular pigmented iris, and the lens. The lens consists of a clear, transparent, gelatinous protein encased in a capsule. It is supported by a series of suspensory ligaments called zonules. The posterior segment, the portion of the eye behind the lens, contains the vitreous fluid (which must be clear for vision), the retina, and the choroid linings, which are the vascular nourishing layers (Fig. 39.2).

Innervation of vision and sensory transmission is derived from the second cranial nerve (optic nerve) (Fig. 39.3). Motor innervation extends from the third cranial nerve (oculomotor nerve) to the rectus muscles. The superior oblique muscles are innervated by the fourth cranial nerve (trochlear nerve). The lateral rectus muscle is innervated by the sixth cranial nerve (abducens nerve).

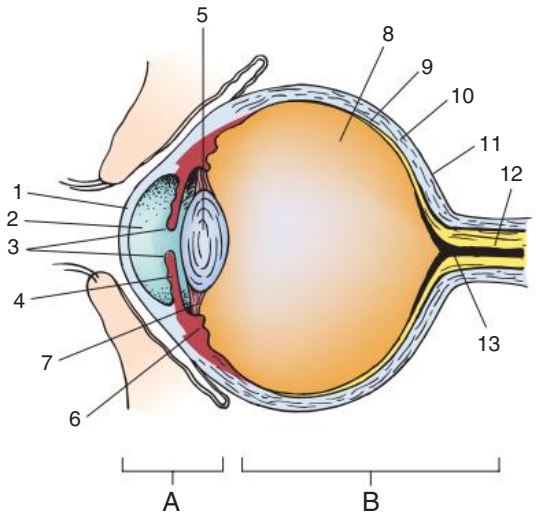
The arterial supply of the eyeball, muscles, and eyelids comes from the ophthalmic artery, which is a branch of the internal carotid artery and drains into the superior and inferior ophthalmic veins. The retina has a separate blood supply that is derived from the central retinal artery. Drainage is through the retinal vein.

The physiology of vision requires the following:

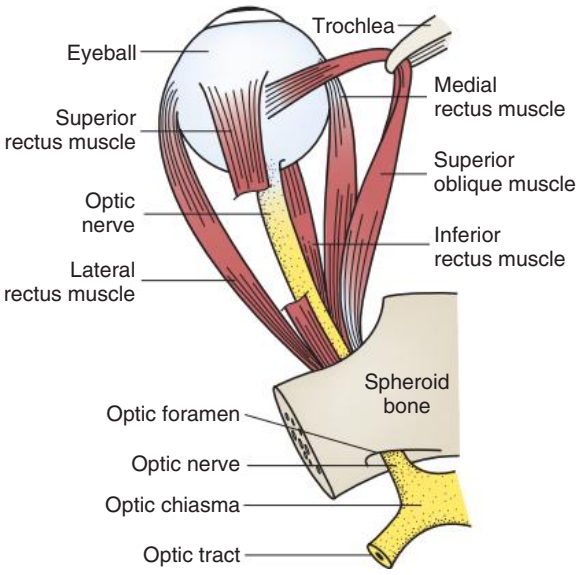
- Functioning visual apparatus
- Source of light
- Intact neurovascular communication with the brain
- Interpretation by the brain of what is seen



• **Fig. 39.1** Front view of eye.



• **Fig. 39.2** Anatomy of the eye. **A,** Anterior segment. *1,* Cornea; *2,* anterior chamber; *3,* pupil; *4,* iris; *5,* lens; *6,* ciliary body; *7,* zonule. **B,** Posterior segment. *8,* Vitreous body; *9,* retina; *10,* choroid; *11,* sclera; *12,* optic nerve; *13,* central retinal artery.



• **Fig. 39.3** Location of optic nerve in relation to eye muscles.

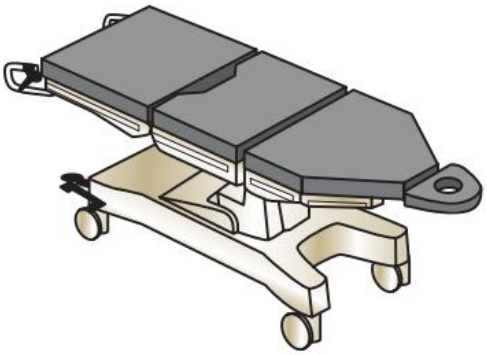
The eye resembles a camera with a compound lens system. Light rays emanating from an object in the field of vision are transmitted to the eye, where they traverse the optical system to reach the retina. The retina corresponds to the film of the camera. The area of highest sensitivity for details is called the *macula,* which is located approximately in the center of the retina at the posterior pole. The intensity of light is automatically determined by the size of the pupil, which is controlled by the iris muscles. The iris functions like the shutter of a camera.

The optical system comprises the transparent cornea, or window of the eye; the aqueous fluid behind the cornea; the pupil, or opening in the colored iris; and the lens. The naturally flexible lens focuses light rays by bending them to form an image on the retina—the innermost layer of the eye that contains the visual sensory nerve endings. These cells are connected to nerve fibers that converge toward the brain to become the optic nerve. The sensory cells translate patterns of light into nervous impulses, which are transmitted to the brain via the optic nerve. The occipital portion of the brain interprets the images of light rays registered on the retina.

Ophthalmic Surgical Patient Care

Impaired vision may produce prolonged severe stress and alter the patient's self-image. Most patients with impaired vision are older adults.[1] When caring for these patients, the health care provider should reassure them, exercise patience, give directions clearly, anticipate needs, and check their comfort level. Specific patient care considerations include but are not limited to the following:

1. Urinary urgency can be a problem in geriatric patients or in patients receiving diuretic medication. Although the patient should void before coming to the operating room (OR), offer the patient the use of a bedpan or urinal before he or she transfers to the OR bed. Severe urinary urgency can cause increased intraocular pressure (IOP) during the procedure. Strain and gross movement are dangerous and are to be avoided.
2. The surgeon and circulating nurse verify the intended surgical site with the patient and with the office records. After confirmation and to avoid error, some surgeons place an indelible mark on the side of the patient's neck that corresponds to the affected eye.
3. The patient is placed in the supine position on the OR bed so the head and body are aligned. Most ORs use a dedicated ophthalmic OR bed that can be used during the procedure and to transport the patient to the postprocedural recovery area (Fig. 39.4). The top of the head is in line with the edge of the OR bed for accessibility. The head should not be turned greatly in either direction; the head is stabilized in a ring-shaped pillow (donut). The patient's gown is untied at the neck to prevent pressure. Any obstruction to venous circulation can cause undue increased IOP, which can produce a loss of vitreous humor when the eye is opened. To assist venous return from the head, the OR bed is tilted so the patient's head is elevated by 5 to 10 degrees. For long procedures, an egg crate–type or gel pad mattress may be placed on the bed. Additional padding may be needed to position kyphotic or lordotic patients.
4. Skin preparation and draping procedures are performed according to routine. Sterile plastic drapes are often placed over woven textile drapes to contain lint, especially before lens implantation. A patient with a drape over the face is often apprehensive and afraid of suffocating. To help eliminate the

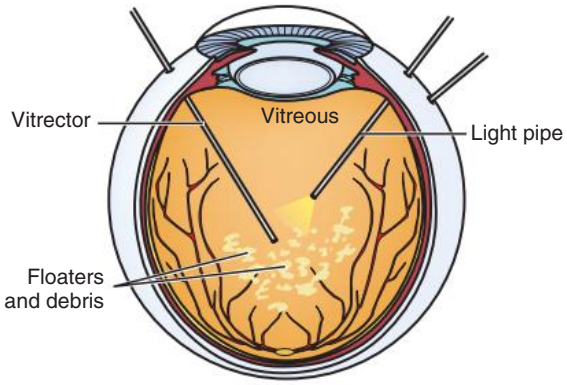


• **Fig. 39.4** Dedicated ophthalmic bed.

• **Fig. 39.5** Creating a tent with the surgical drape and the Mayo stand for patient comfort.

feeling of claustrophobia, the drape can be placed over a Mayo stand or clipped to an intravenous (IV) pole to create a tentlike space above the patient's nose and mouth (Fig. 39.5). Oxygen is delivered via nasal prongs or insufflated to the facial area beneath the drape at 6 to 8 L/min. An electrosurgical unit (ESU) is not to be used in an oxygen-rich environment because of the increased risk for ignition.

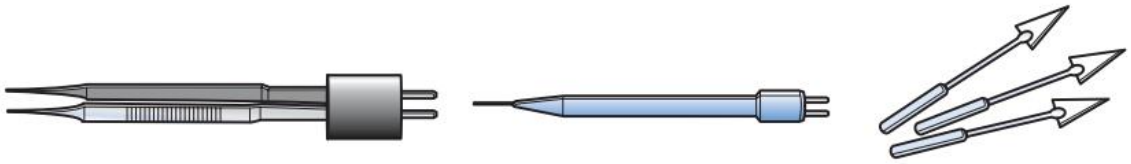
5. A quiet, stimulant-free environment is provided for the awake patient who is receiving a local anesthetic.
6. Because the patient has no defensive blink reflex to protect the retina from light exposure, some surgeons use a sterile, opaque pupillary shield to protect the patient's retina from phototoxic damage caused by prolonged exposure to illumination of the microscope. Some scopes have a sensor near the eyepiece that dims the light source when the surgeon is not looking directly into the scope. The light reverts back to the desired intensity when the surgeon is positioned at the eyepiece.
7. The team should prepare for emergencies by anticipating problems. Fast action can make the difference between a seeing eye and a nonseeing eye postoperatively. The following are potential complications:
   a. A systemic reaction to medications or local anesthetic drugs and cardiac arrest.
   b. A loss of vitreous, which requires the removal of vitreous from the anterior chamber with a vitreotome to prevent prolapse of the wound, severe inflammation, or an updrawn pupil.



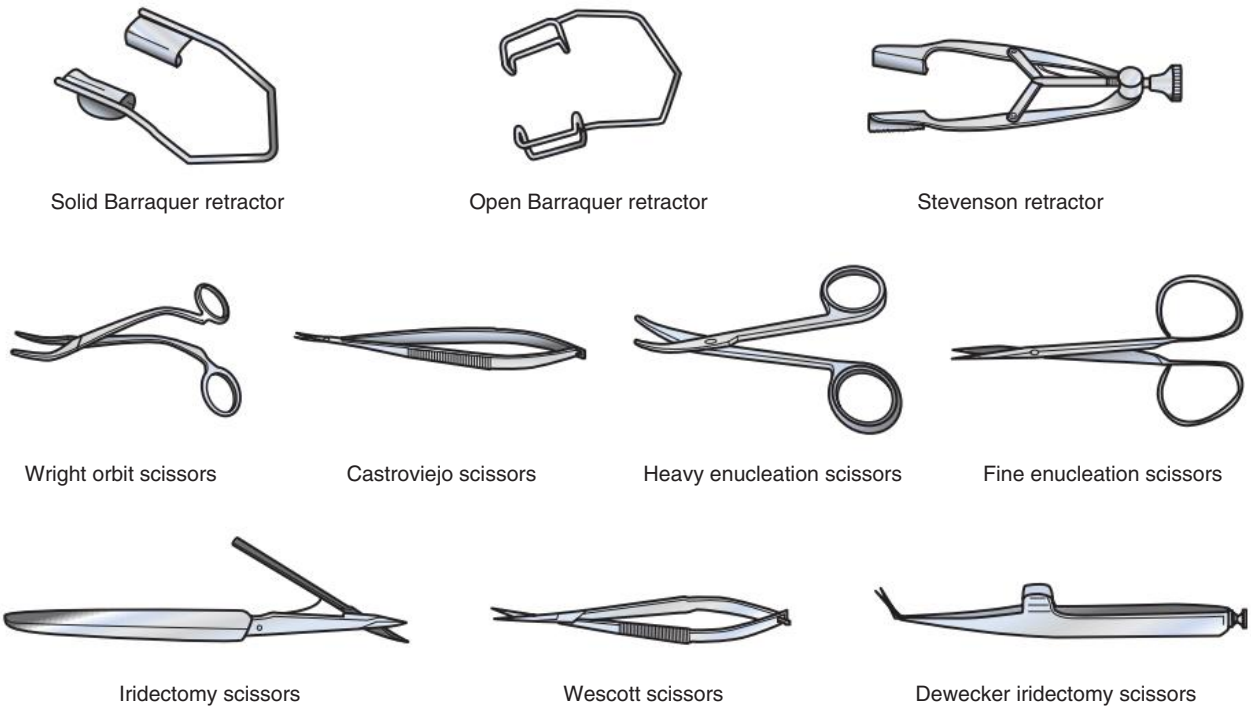
• **Fig. 39.6** Pars plana vitrectomy for emergency bleeding.

   c. An expulsive hemorrhage or an expulsion of ocular contents, which requires a sharp knife (e.g., Beaver blade, Wheeler knife) for fast cutdown into the pars plana area and an 18-gauge needle or cannula attached to a syringe to aspirate blood and reduce pressure in the vitreal compartment in an effort to save the eye and vision (Fig. 39.6).
   d. Instrument failure. Hand aspiration devices should be available for immediate use.
8. A wide variety of fine-size absorbable and nonabsorbable sutures may be used. The scrub person follows the manufacturer's recommendations for handling these delicate materials and needles with the appropriate needle holders. Many surgeons use sutureless techniques. Special techniques are used in microsurgery.
9. Hemostasis is attained with bipolar cautery and a bipolar eraser pencil. Sponges are spear shaped and consist of precut compressed cellulose on sticks (Fig. 39.7).
10. No foreign material should be introduced into the surgical site. Particulate matter from gloves, instruments, or sponges should be avoided. To remove any debris or impurity, intraocular lenses (**IOLs**) are soaked and rinsed in balanced salt solution (**BSS**) and sometimes lubricated with sodium hyaluronate (Healon) before insertion.
11. Inflammation should be kept as minimal as possible because even slight inflammation may result in total functional loss. Steroids are often administered locally, subconjunctivally, and, sometimes, systemically. The eye may respond violently to the slightest amount of trauma. All drugs and solutions should be clearly labeled.
12. Antibiotic drops are often instilled topically for 24 hours preoperatively and postoperatively.
13. A sterile eye pad is commonly applied at the conclusion of the surgical procedure. A protective plastic or metal shield may be secured over the eye pad to guard against mechanical injury. Absorbable corneal shields may be used.
14. The patient should not be permitted to participate in the move from the OR bed after intraocular procedures; this prevents a sudden rise in IOP and/or dislocation of the IOL implant.
15. Arm restraints are essential for infants and young children. Restraints are applied to adults only under extreme circumstances, such as disorientation. The use of side rails preoperatively and postoperatively is standard procedure for all patients undergoing ophthalmic surgery.

An important aspect of postoperative care is informing the patient not to get out of bed alone. A fall or injury to the eye can



• **Fig. 39.7** Instruments for hemostasis of the eye. *ESU,* Electrosurgical unit.



• **Fig. 39.8** Eye instrumentation: self-retaining lid retractors and scissors.

nullify an otherwise successful surgical procedure. The patient must not do anything to increase IOP (e.g., bend over at the waist, lift heavy objects). Deep breathing postoperatively is encouraged, but coughing is avoided because it could increase IOP and rupture the suture line. The patient should report any postoperative pain, swelling, redness, or discharge. The outcome of ophthalmic procedures includes a cosmetic as well as a functional aspect.

Special Features of Ophthalmic Surgery

The patient undergoing ophthalmic surgery faces impairment or loss of vision if the outcome of the surgical intervention is unfavorable. Special features of ophthalmic surgery aim to prevent such a loss. Surgical procedures on the eye are extremely delicate and require precision instrumentation, a steady hand, and quiet surroundings. The operating microscope, all accessory equipment, and microinstruments should be set up and checked before the surgical procedure. The outcome of the procedure depends on the condition of the instruments.

Ophthalmic Instrumentation

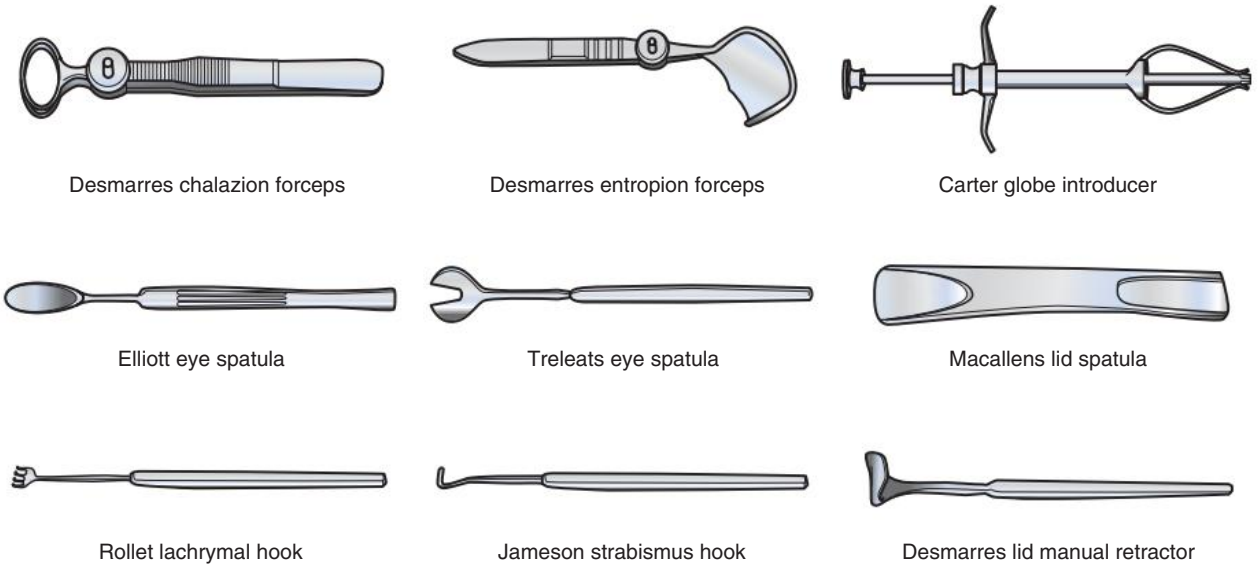
The tips of these expensive, fragile microinstruments should be protected and handled with extreme care before, during, and after use. Eye instrumentation is unique to the specialty. Only with rare exception are any of the following used in any other type of surgery:

- Self-retaining lid retractors and scissors (Fig. 39.8)
- Graspers and manual retractors (Fig. 39.9)
- Enucleation and measuring devices (Fig. 39.10)
- Punctum plug and forceps (Fig. 39.11)
- Corneal trephine (Fig. 39.12)

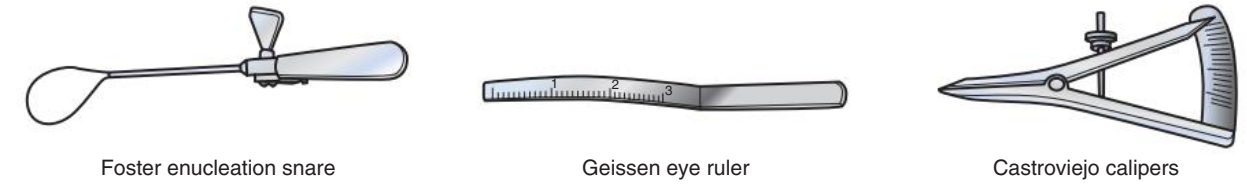
Operating Microscope

Ophthalmic surgeons use the operating microscope for intraocular procedures. When the operating microscope is used, the OR bed should be mechanically secure, and the patient's head should be stabilized. Inadvertent movement is not tolerated because of the minute surgical field. The headrest should be narrow so that it does not obstruct the surgeon's approach to the surgical site from the sides of the vertical column of the microscope. The patient is instructed about the importance of remaining still during the surgical procedure. Otherwise, the patient could easily move out of the field of vision under the microscope or precipitate a complication.

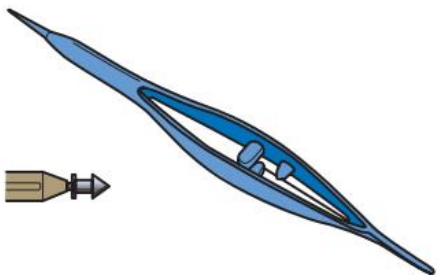
The assistant observes the surgical procedure through an assistant's ocular and irrigates the cornea with BSS to prevent drying (Fig. 39.13). The assistant should bring to the surgeon's attention any potentially unsatisfactory situation that the surgeon cannot observe from his or her position. Some scrub persons are trained



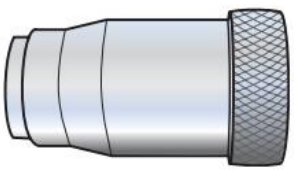
• **Fig. 39.9** Eye instrumentation: graspers and manual retractors.



• **Fig. 39.10** Eye instrumentation: enucleation and measuring devices.



• **Fig. 39.11** Punctum plug and forceps.



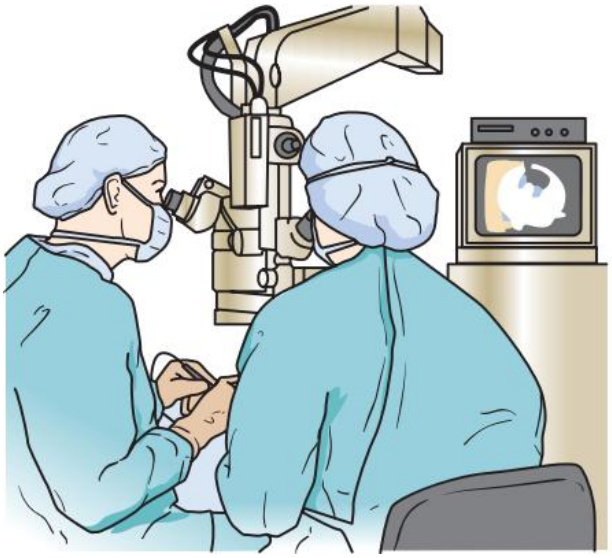
• **Fig. 39.12** Corneal trephine for cadaver tissue procurement.

to first-assist. The surgeon and the assistants should limit their caffeine intake before the procedure to promote steady hands when using microinstrumentation under the microscope.

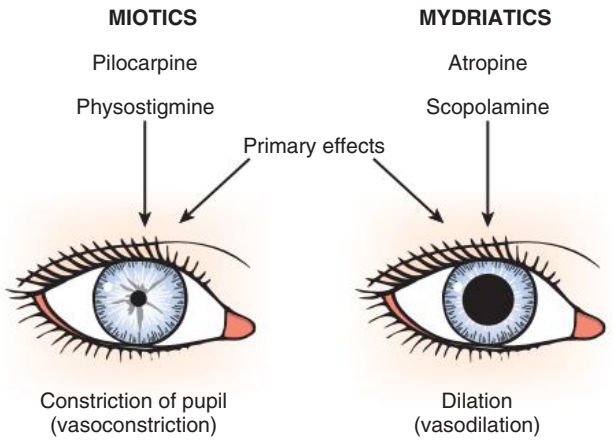
The surgeon will focus the microscope in a manner that permits a foot pedal–controlled zoom function without blurring the assistant's vision or the camera and video equipment. Many surgeons who use corrective eyewear will adjust the oculars for accommodation with the eyes against the eye cups to avoid having the discomfort of spectacles.

Ophthalmic Drugs

Many drugs are critical to the preparation of the eye for the surgical procedure. Orders for patient preparation often contain common



• **Fig. 39.13** Surgeon and first assistant using a ceiling-mounted microscope.



• **Fig. 39.14** Effects of miotic and mydriatic drugs.

abbreviations that identify the eye(s) to receive drops: OD (right eye), OS (left eye), and OU (both eyes); however, The Joint Commission (TJC) has advised that the use of abbreviations can lead to human error and recommends not using them in the interest of patient safety. Before skin preparation, the circulating nurse instills the medications and anesthetic drops as ordered. The following procedures should be observed when instilling eye drops:

1. Wash your hands.
2. Identify the correct medication, eye, and patient.
3. Check for allergy or sensitivity.
4. Explain the procedure to the patient.
5. Tilt back the patient's head and tell the patient to look up. While gently pulling down on the lower lid, instill the medication in the middle third of the inner aspect of the lower lid. Release the lid while the patient slowly closes the eye to retain the drop; let the patient close the eye between repeated drops. In a struggling child, have a parent tilt the child's head back and close both eyes. Instill the medication at the inner canthus. The drop will roll into the eye as the child opens it.

   Some medications, such as atropine, may have a systemic effect. To prevent drainage into the tear duct, nose, and stomach, gently blot excess fluid. In small infants or young children, systemic absorption is avoided by applying finger pressure over the lacrimal sac region (inner canthus) of both eyes simultaneously for 1 minute.
6. Administer only the specified number of drops.
7. Read the label on the vial before each instillation.
8. Each patient should receive a fresh, single-use, disposable vial of medication that is discarded after use.

Mydriatic and Miotic Drugs

Medications may be given to alter the size of the pupil (Fig. 39.14), including the following:

- *Mydriatic drops:* 2.5% or 10% phenylephrine (Neo-Synephrine) to dilate the pupil.
- *Mydriatic-cycloplegic drops:* 1% cyclopentolate hydrochloride (Cyclogyl), 1% atropine, and 0.25% scopolamine (Isopto Hyoscine) to dilate the pupil, paralyze the ciliary body, diminish the reaction to trauma, and prevent anterior synechiae (e.g., adherence of iris to the lens). These drugs are longer acting than phenylephrine.
- *Miotic drops:* 2% pilocarpine to constrict the pupil.

Local and Topical Anesthesia

Except in children and select patients, local and topical anesthetics are commonly used for ophthalmic surgical procedures. Most surgical procedures are scheduled as monitored anesthesia care or attended local. An anesthesia provider monitors the patient and administers oxygen and/or supplements the local anesthetic if necessary. IV midazolam (Versed) and/or fentanyl (Sublimaze) or propofol (Diprivan) is often given to relax the patient. The sedative effects of these agents increase the patient's tolerance to procedures. If a general anesthetic is used, the usual general anesthesia routines are followed.

Local anesthesia consists of the following:

1. Topical instillation of anesthetic drops. The drug used may be 0.5% proparacaine (Ophthaine), 0.5% tetracaine (Pontocaine), or 2% lidocaine (Xylocaine MPF [methylparaben-free]). Most surgeons prefer to use this method in combination with moderate sedation.
2. Local infiltration by injection of the lids and tissue around the eyes with anesthetic medication.
3. Retrobulbar block. An absolutely quiet eye is necessary, especially at high magnifications of the microscope. When general anesthesia is used, some surgeons administer a retrobulbar block for immobility and to lower IOP. A popular solution for this block consists of a mixture of equal parts of 2% or 4% lidocaine and 0.75% bupivacaine, 3.75 units/mL for penetration. A 25-gauge × 1½-inch (3.8-cm) needle with a sharp, rounded point (e.g., Atkinson needle) and a 5-mL syringe are used. The surgeon inserts the needle behind the eyeball to anesthetize the globe and paralyze the muscles. The patient is asked to look up and away from the injection site and is told that a slight burning sensation may accompany the injection. Up to 5 mL of solution may be slowly and carefully injected.

   Retrobulbar block may be followed by intermittent massage of the eye to soften it, lower IOP, and facilitate surgical manipulation during **cataract** extraction, especially when insertion of an IOL is being contemplated. Massage is continued until the IOP is lowered to a satisfactory level (e.g., 10 to 12 scale reading on sterile Schiøtz tonometer).
4. Peribulbar anesthesia. This is an alternative to retrobulbar injection. With this method, injections are made in the soft tissue superior and inferior to the globe rather than behind it.

A greater amount of the same anesthetic solution used for retrobulbar injection is used for peribulbar anesthesia. With this procedure, adequate anesthesia is obtained without the risk for retrobulbar hemorrhage.

Ophthalmic Solutions

Extreme and constant care must be used with ophthalmic solutions. Nearly all of these solutions are colorless and may be stored in similar receptacles. These solutions are immediately and individually labeled by the scrub person; the solution is discarded if the identification is missing. Solutions for intraocular use must be separated from all other solutions. Ideally, these solutions should be filtered with micropore filters before injection.

Epinephrine or other sympathomimetics may have side effects when used with some anesthetic agents. Therefore the surgeon should check with the anesthesia provider before using medications intraoperatively. Medications that may induce vomiting are also avoided. Any straining or gross movement may cause intraocular hemorrhage, a sudden rise in IOP that results in a loss of vitreous, or the expulsion of ocular contents through the wound; all of these conditions can cause blindness.

Ocular Surgical Procedures

For convenience, surgical treatment of the eye can be divided into the following two main classifications:

1. *Extraocular:* Conditions affecting the exterior surface of the eye, eyelid, or orbit.
2. *Intraocular:* Conditions pertaining to the interior contents of the eye.

Extraocular Procedures

Eyelid

The anatomy of the upper and lower eyelids is described in Fig. 39.15.

Excision of Neoplasm of the Eyelid

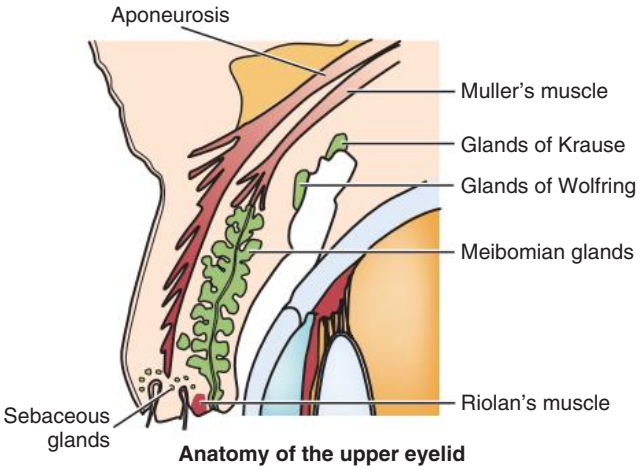
Tissue may be excised with a knife, an ESU, diathermy, or cryosurgery. An extremely common but benign tumor of the lid is the chalazion—a cystic alteration of one of the oil-secreting meibomian glands in the lid (Fig. 39.16, *A*). The resulting accumulation of oil forms a hard tumor of the lid and requires excision. The excision is usually an office or ambulatory surgical procedure. Chalazion is differentiated from a stye (hordeolum) by the location on the lid. Styes are small infected lash follicles along the lash line (see Fig. 39.16, *B*).

After removal of a malignant lesion of the lid, plastic procedures such as Z-plasty, sliding flaps from adjacent areas, or full- or partial-thickness flaps from the opposing lid are used to close the defect.

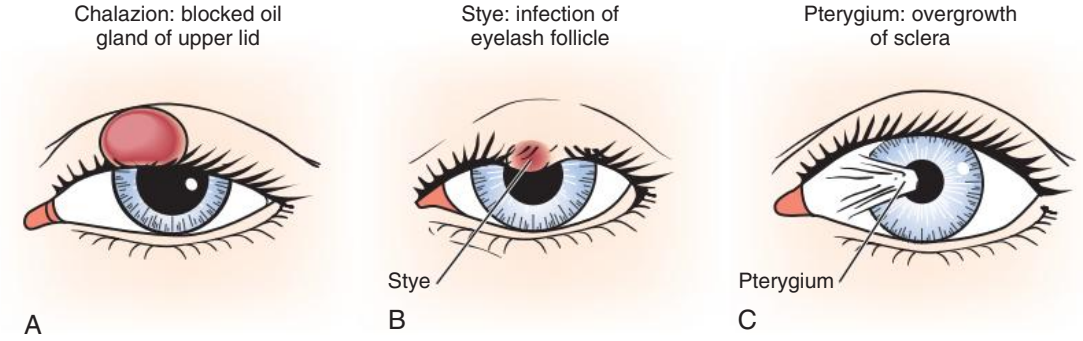
Correction of Ptosis

Ptosis, a drooping of the upper lid, may be acquired in adulthood but is more commonly congenital. For the levator aponeurosis procedure, an incision is made on the front surface of the lid to expose the tarsus and the aponeurosis. The tarsus is sutured to the aponeurosis, and the skin incision is closed.

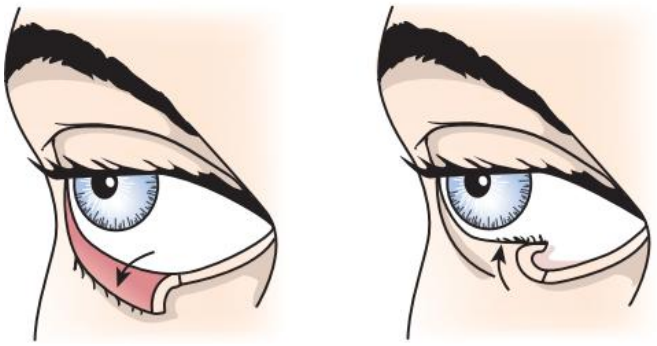
For the frontalis suspension procedure, the anterior surface of the upper lid is incised at the crease, and two smaller incisions are



• **Fig. 39.15** Normal anatomy of the upper and lower eyelids.



• **Fig. 39.16** Common benign lesions of the eye commonly treated with surgery.



• **Fig. 39.17** Ectropion and entropion are surgically treated to realign the eyelash line for normal function.

made above the eyebrow. A graft of fascia or synthetic material is attached to the tarsus and passed through the deep lid tissue and brought out through the eyebrow incisions. The graft material is secured, and the skin incisions are closed.

Repair of Acquired Malformation of the Eyelid

Conditions such as senile ectropion or entropion most commonly affect the lower lid (Fig. 39.17). Ectropion is a condition in which either the upper or lower lid is everted (turned out) to expose the conjunctival surface. Entropion is the opposite condition, in which the lid margin is inverted (turned in). As a result, the eyelashes often abrade the cornea. Various procedures may be used to correct both conditions.[2]

Blepharoplasty

A common result of aging is the stretching of the eyelid skin and the bulging of orbital fat from between the muscle fibers of the lids. Both conditions cause cosmetic disfigurement or baggy lids and, in extreme cases, may obstruct vision. In blepharoplasty, redundant folds of skin and herniated pockets of fat are removed, and defects in the muscle layer are repaired. Transconjunctival blepharoplasty is performed by making a small incision into the conjunctiva of the lower lid and removing fat pads. Small bleeders are cauterized with a disposable electrosurgical pencil. Blepharoplasty is commonly performed by plastic surgeons and is described in Chapter 40.

Lacrimal Apparatus

Lacrimal Duct Dilation

Lacrimal duct dilation is performed for excessive tearing. A series of probes, graduated in size, are introduced one by one into the duct system to permit freer drainage of tears. Dacryoadenitis is an inflamed lacrimal gland. Infection is usually caused by bacteria or viruses. Ophthalmologists recommend that patients with inflamed eyelids use dilute baby shampoo to cleanse lashes and lids.

Dacryocystectomy

Extirpation or removal of the lacrimal sac in the lower lid is performed for chronic dacryocystitis. This procedure does not reestablish the tear drainage system.

Dacryocystorhinostomy

Construction of a new opening into the nasal cavity from the lacrimal sac is performed to correct congenital malformation of or trauma to the nasolacrimal duct. A new tear drainage system is constructed.

Extraocular Muscle

Procedures on the oculomotor muscles, which control eye movement, are performed to correct misalignment that interferes with the ability of the two eyes to remain in simultaneous focus on a viewed object. The surgical procedures correct muscle imbalance by strengthening a weak muscle or weakening an overactive one. Although commonly performed on children, these muscle procedures may be required in adult patients for the following:

- Untreated childhood strabismus (squint)
- Unsatisfactory result from a childhood surgical procedure
- Trauma to the brainstem or to the orbit with resultant muscle injury or paralysis
- Systemic disease (e.g., thyroid exophthalmos) and muscle paralysis
- Cerebrovascular accident with resultant muscle paralysis

Orbit

Decompression

Decompression is the treatment for severe exophthalmos, or a protrusion of the eyeball, that does not respond to medical treatment.

Orbital Tumors

Depending on the location of the orbital tumor, exploration may be approached through a lateral wall or the roof of the orbit. This procedure may involve a multidisciplinary team of surgeons.

Surgical Removal of the Eye

After removal of an eyeball, the patient is fitted with an artificial eye to restore cosmetic appearance. A spherical implant, such as silicone, plastic, tantalum, or hydroxyapatite, may be used to line the orbit and provide support for a prosthetic eye. The eye muscles are sutured to the implant, thereby providing natural movement, allowing the growth of surrounding tissue, and preventing the lower lid from sagging. The type of prosthesis that can be used depends on the procedure used to remove the eyeball.

Enucleation

Enucleation is the complete removal of the eyeball and the severing of its muscular attachments.[3] The muscle stumps are preserved, with the space between the stumps forming a pocket for the spherical plastic artificial eye. Overlying fasciae and conjunctivae are closed to hold the prosthesis in the socket. The contraction of eye muscles causes the prosthesis to move in the socket, simulating normal eye movements.

Eye prostheses are usually round or oval and can be textured or smooth. Some have pegs upon which the colored iris cap attaches. Others contain a magnet that adheres to the back of the visible colored iris portion. Sizes can be between 12 and 22 mm.

Evisceration

Evisceration removes the contents of the eyeball only; the outer sclera and muscles are left intact for attachment to a prosthesis. This procedure reduces the danger of transmitting an intraocular infection to the orbit and brain. Predisposing factors for evisceration include destruction of the eyeball by injury or disease and absolute glaucoma (hard blind eye).

Exenteration

Exenteration is the removal of the entire eye and orbital contents, including tendon, fatty, and fibrous tissues. This procedure is

performed for a malignant tumor of the lids or eyeball that has extended into the orbit. Extensive plastic reconstruction is necessary before an artificial eye can be fitted.

Cornea

Although it consists of resilient tissue, the continually exposed cornea is especially susceptible to injury and infection.

Cauterization

Cauterization with chemicals or heat is sometimes used for a corneal ulceration that does not respond to antibiotics. This is sometimes performed for herpes simplex virus infections of the corneal epithelium. Cauterization may be used in conjunction with topical antiviral agents.

Pterygium

Pterygium is a benign growth of conjunctival tissue over the corneal surface. Although usually slow growing, pterygia can become fairly aggressive, especially in southern climates. A significant decrease in visual acuity secondary to induced astigmatism and corneal scarring can result from the abnormal growth. A popular surgical technique devised for the eradication of pterygia is the bare sclera method. This method involves excision of the entire pterygium, leaving an area of bare sclera. Beta radiation may be used as an adjunct to surgical treatment (see Fig. 39.16, *C*).

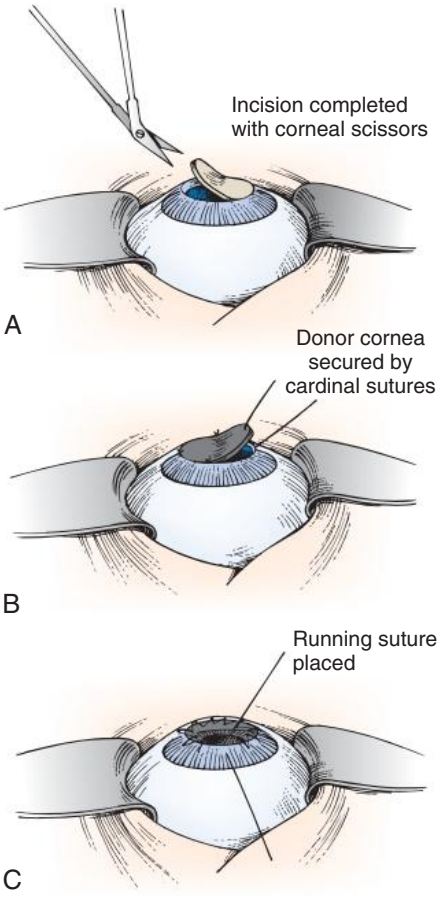
Corneal Transplantation (Keratoplasty)

With keratoplasty, a damaged cornea is removed and replaced with a healthy cornea from a human donor (Fig. 39.18). The cornea must be clear to permit light to enter and focus on the retina. Thus this procedure is indicated when scars or opacities on the cornea reduce or destroy vision by preventing the transmission of a clear image. Corneal opacity may result from degenerative changes, scars from chemical burns, perforated corneal ulcers, trauma, or edema after a cataract surgical procedure. In addition, ocular surgery, such as phacoemulsification, vitrectomy, and IOL implantation, has the potential to damage the corneal endothelium.

Because the cornea is avascular, keratoplasty is the most successful transplantation procedure and has considerably less rejection phenomena than all other tissues except bone. The greatest advance in technique to reduce the rate of rejection and the restriction of activity during convalescence has been the use of the operating microscope and microsutures. Continuous 10-0 or 11-0 nylon sutures are left in situ with minimal tissue reaction. The following two types of grafts are used:

1. *Full-thickness grafts:* The common type. The entire diameter of the corneal graft (6.5 to 8 mm) is replaced (penetrating keratoplasty).
2. *Partial-thickness or lamellar grafts:* Less popular. Only the top layer of the cornea, not its entire depth, is replaced (lamellar keratoplasty).

An opaque cornea is an optically nonfunctioning one. The goal is to provide recipients with the highest quality corneal tissue. A fresh, healthy cornea cut from the promptly enucleated eye of a relatively young donor within 4 to 6 hours of death is considered the best for transplantation. The cornea should be transplanted to the surface of the recipient eye, which has a healthy retina and optic nerve, as soon as possible to preserve viability and to prevent opacity. The acceptable times for collection of tissue after death and transplantation may vary among eye banks. The National Institutes of Health have established the National Eye Institute for further research.[4] (More information is available at www.nei.nih.gov.)



• **Fig. 39.18** Corneal transplantation (keratoplasty). **A,** Damaged cornea is excised with corneal scissors. **B,** Donor cornea is secured by cardinal sutures. **C,** Continuous suture remains in situ.

Donor tissue criteria include the following:

1. The consent for enucleation must conform to state laws. A certified eye bank technician may enucleate the eyes.
2. Medical information about the potential donor is evaluated. Some conditions that preclude the use of donor tissue are an unknown cause of death, previous intraocular surgery, Reye's syndrome, lymphosarcoma, rabies, and transmissible diseases such as hepatitis, human immunodeficiency virus, and Creutzfeldt-Jakob disease. Donor information must be documented on the donor screening form that accompanies the tissue. A copy should be filed at the eye bank.
3. The endothelium, the very sensitive inner single layer of corneal cells, must be kept intact for eventual transparency of the graft. The entire donor globe is removed. Important factors to optimize the success of the transplant include sterile technique, the removal of as much conjunctiva as possible from the donor globe, avoidance of damage to or contamination of the removed eyes, and use of appropriate transport containers and preservation methods.
4. The donor's eyes are cooled as soon as possible to prevent deleterious effects. The placement of ice bags over the eyes promptly after death slows the metabolism of corneal cells. In general, the sooner the enucleated eyes are refrigerated, the better the quality of the donor tissue. Enucleated eyes are placed in a controlled environment at the eye bank.
5. The donor's cornea is carefully evaluated for epithelial defects, clarity, the presence of any foreign body, or any evidence of

jaundice or infection. Endothelial cell count is a determining factor in estimating the prognosis of the transplant. The higher the count and the more regular the cellular pattern, the better the tissue. Age is not a deterrent if tissue is acceptable for transplantation, but donors younger than 70 years are preferred. The evaluation form must be completed and must accompany the tissue. The transplant surgeon also may receive specular microscopic photographs of the endothelium. Donor tissue preservation methods include:

a. *Preservative medium.* Optisol-GS sterile buffered tissue culture contains the antibiotics gentamicin and streptomycin and allows refrigerated storage for 3 to 7 days. Intermediate-term corneal storage in Chen Medium at 4° C for 2 weeks has rapidly gained popularity without consequence to the tissue. Chen Medium also contains streptomycin and gentamicin, but it contains 7% dextran to eliminate the bicarbonate and reduce the amount of sodium chloride required to maintain a high metabolic profile in the corneal tissue. In the OR, the surgeon should inspect the container before using the cornea. If the cornea is cut to size for use with a trephine, the remaining corneoscleral rim should be placed in a culture medium and sent to the laboratory for culture. The incidence of positive cultures is low. The cornea should not be used, and the eye bank should be notified if the medium is turbid or contaminated, such as by a crack in the container.

b. *Cryopreservation.* Both cryopreserved corneal and scleral tissue can be used for transplantation or for patching purposes. In general, their use is limited to emergency procedures when fresh tissue is not available. Usually this tissue is used less than 6 months after cryopreservation. Precise freezing and defrosting methods are of crucial importance in preventing injury to the endothelium. Corneal metabolism resumes with defrosting; therefore when the solution is thawed, the team should work rapidly because of the extreme time limitation. The tissue should be placed immediately within its natural anatomic environment to enhance the potential for successful grafting.

Regardless of the storage method, tissue preferably is used as soon as practical after donation. In the OR, adequate preparation, teamwork, and standardized transplantation procedures are imperative. The recipient eye is trephined to receive the donor cornea. A separate sterile donor table is set for the surgeon to use in preparing the donor tissue to the exact measurement needed for the recipient eye. During the procedure, gentamicin, cefazolin, and methylprednisolone are administered under the conjunctiva.

After the surgical procedure, a tissue recipient information form is completed to indicate how the tissue was used. This form is mailed to the eye bank, where it is kept on file. If the tissue is contaminated, the donor number and source can be easily traced. Information on the forms includes recipient medical information; previous keratoplasties; the date, type, and details of the current surgical procedure; and the estimate of success.

The patient is instructed to report any symptoms, such as redness, light sensitivity, vision loss, or pain. A patch is worn for 1 to 4 days. Protective eyewear should be worn during the day, and a firm patch should be worn for sleeping for several months postoperatively. Sutures can be removed after a few months or may be left in permanently.

Suitable corneal tissue is in limited supply, which places restraints on transplantation. Numerous eye banks in the United States constitute the Eye Bank Association of America, which is tangentially associated with the International Eye Bank. These groups are central clearinghouses for the distribution of accessible tissue. They follow a stringent code of ethics in their functions to inform the public of the need for eye donations, to procure donated eyes, to assist in the optimal use of donor corneas locally, or to arrange for transportation to an area of greater need. More than 85,411 cornea transplants were recorded in 2018.[5] Tissue procurement is facilitated by the following:

- Distribution of donor forms from eye banks and organ donation organizations.
- Organ donation consent forms affixed to driver licenses. Family consent is still required before procurement.
- Education of medical and health care personnel to alert them to ask families of deceased patients for donations. Some state laws require a donation request.

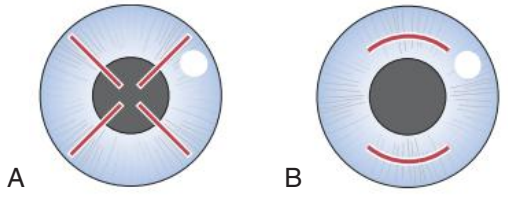
Phototherapeutic Keratectomy

In phototherapeutic keratectomy (PTK), scar tissue is removed from the cornea with an excimer laser. This procedure restores vision that has been blocked by scars from an infection, injury, or inherited condition. PTK may obviate the need for a corneal transplant.

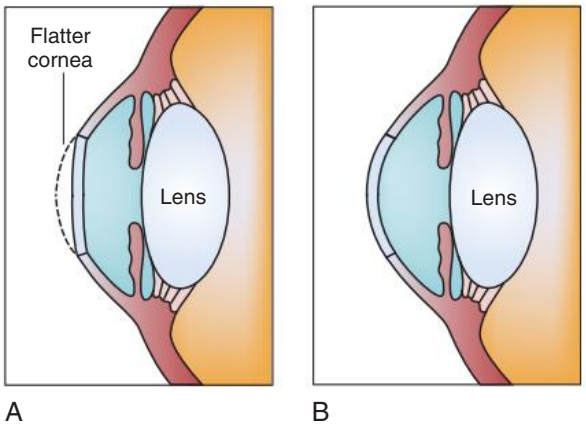
Refractive Keratoplasty

Refractive keratoplasty (corneal reshaping) includes a group of surgical procedures designed to alter the shape and refractive power (i.e., focusing power) of the cornea to minimize the optical problems of myopia, aphakia, keratoconus, hyperopia, and astigmatism:

1. Radial keratotomy reduces myopia (nearsightedness) by making multiple small radial incisions in the cornea to approximately 90% of its depth (Fig. 39.19). These incisions allow stretching and flattening of the anterior corneal surface, which corrects the refractive error by reducing corneal curvature and bringing light to a focus closer to or on the retina (Fig. 39.20).
   Radial keratotomy is performed on patients who have occupational requirements for a visual acuity level without the use of glasses or contact lenses, such as certain airline, police, and firefighter positions. The procedure also may be performed for cosmetic reasons. Potential complications include perforations of the cornea, permanent corneal scarring, glaring or variable vision, injury to the lens (causing cataract), and infection. Long-term results are somewhat unpredictable but are improved with microsurgical techniques. This procedure should be limited to patients with healthy eyes. Only low amounts of nearsightedness can be corrected with this procedure.
2. Keratomileusis and keratophakia procedures modify corneal refractivity by using a computerized technique to insert a lathed button of corneal tissue into the cornea. If the patient is the donor (keratomileusis), the anterior lamellae of the cornea are removed, reshaped by cryolathing, and then sutured



• **Fig. 39.19** Corneal incisions for visual improvement of myopia. **A,** Radial keratotomy (RK). **B,** Astigmatic keratotomy (AK).



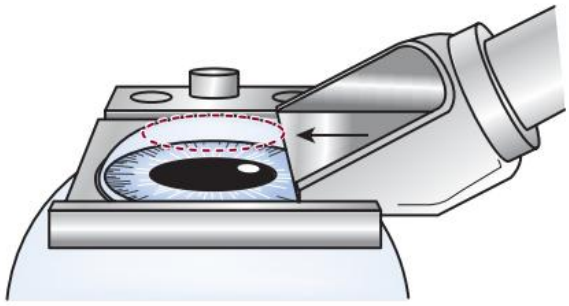
• **Fig. 39.20** Side view of incised corneas. **A,** Radial keratotomy (RK). **B,** Astigmatic keratotomy (AK).

in place. For keratophakia, the tissue is obtained from another donor and may be preserved.

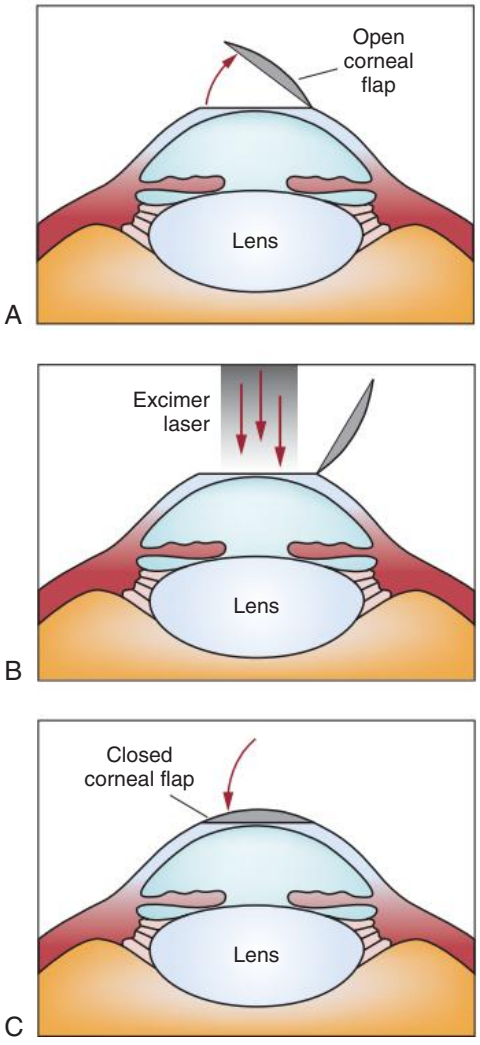
The lenticule is cryolathed during the surgical procedure, inserted intralamellarly into the recipient cornea, and sutured into place.

Keratomileusis and keratophakia require a highly specialized, experienced team and costly equipment—the computer and the cryolathe for shaping the corneal button. With keratophakia, research is ongoing to develop other materials that may be used in place of human donor tissue. Plastic with a very high water content (similar to continuous-wear contact lens material) has been used.

3. Epikeratophakia is performed to correct extreme refractive errors such as aphakia (absence of lens, which induces extreme hyperopia), myopia, or keratoconus (cone-shaped cornea, which causes extreme astigmatism). The recipient corneal epithelium is removed, and a previously cryolathed and preserved donor button of corneal tissue is sutured onto the corneal surface of the recipient.
4. Corneal sculpting (photorefractive keratectomy [PRK]) is performed to reshape the corneal surface or to remove scars or other surface irregularities. The excimer laser is used to reshape the front corneal contour to correct nearsightedness, farsightedness, and astigmatism. The laser beam removes minute amounts of corneal tissue with each pulse wave without burning through or heating the tissue.
5. Laser-assisted in situ keratomileusis (LASIK) is performed to correct myopia (nearsightedness). A combination of excimer laser and keratome is used to remove layers of the cornea. A small flap is raised in the center of the corneal dome (Fig. 39.21). The laser is used to remove microlayers of tissue. The flap of corneal tissue is replaced without the need for suturing (Fig. 39.22).
6. SMILE (small incision lenticule extraction) was approved by the U.S. Food and Drug Administration (FDA) in 2016 for correction of nearsightedness. The procedure can correct up to −10.00 diopters. The procedure is similar to LASIK but uses a femtosecond (FS) laser to make a tiny flapless incision into the corneal lenticule to reshape the cornea.[6] FS lasers are in the infrared light range and work similar to neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. The pulse duration is extremely short and precise. Healing requires no stitches and has few side effects.

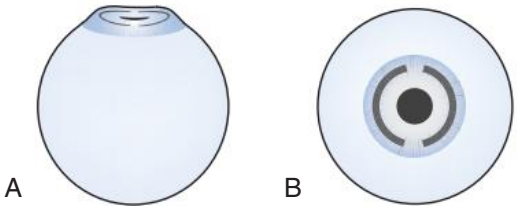


• **Fig. 39.21** Keratotome used to raise the corneal flap for laser in situ keratomileusis (LASIK) surgery.



• **Fig. 39.22** Laser in situ keratomileusis (LASIK). **A,** Top layer of cornea is opened like a flap with keratome. **B,** Excimer laser removes thin layers of exposed corneal surface. **C,** Cornea is replaced.

7. Intrastromal corneal rings can be placed to elevate the border of the cornea, causing the central portion to recede (keratoconus). This implantable device was approved for use in 1998 and consists of two arc-shaped segments made of polymethylmethacrylate (PMMA) that are implanted in the circumferential stroma of the cornea. It can be removed surgically if vision correction is not satisfactory (Fig. 39.23).



• **Fig. 39.23** Intrastromal corneal rings are used to form a depression in the center of the cornea for correction of myopia. **A,** Intrastromal corneal ring in place. The center of the cornea flattens. **B,** Two arcs form a circle under the edges of the cornea.

Intraocular Procedures

Iris

Some ophthalmic surgeons subspecialize in anterior segment surgery on the iris and lens or in posterior segment surgery on the vitreous body, retina, and sclera. Both types of surgeries require specialized instrumentation. Most surgeons use the operating microscope for intraocular procedures.

Excision of Iris Prolapse

Prolapse may follow an eye laceration or a surgical procedure on the anterior segment. Fresh prolapses may be reduced mechanically during the surgical procedure or pharmacologically with drugs. Older prolapses should be excised to avoid an intraocular infection.

Glaucoma

Glaucoma is a disease characterized by abnormally increased intraocular fluid pressure; it often involves the iris. If uncontrolled, glaucoma progresses to atrophy of the optic nerve, hardening of the eyeball, and blindness. The incidence of glaucoma in people older than 40 years increases with each decade. There is a familial predisposition to the disease.

IOP is estimated in one of the following three ways:

1. A Schiøtz tonometer records the depth of indentation of the cornea by a plunger of known weight. The degree of indentation is calibrated on the tonometer to correspond to the IOP. The normal numeric value is 10 to 22 mm Hg. The tonometer can be sterilized for use in the OR for preoperative pressure measurement.
2. An applanation tonometer attached to a biomicroscope (slit lamp) records the force required to flatten a specified area of cornea. This method is considered to be the most accurate. The normal value is 10 to 21 mm Hg.
3. An air-puff device measures the force of a reflected amount of air blown against the cornea.

Patients suspected of having glaucoma undergo additional testing. Tonography continuously measures the rate of aqueous outflow with an electric tonometer. Visual fields detect diminished peripheral vision. **Gonioscopy** determines the structure of the angle between the iris and the cornea. Two basic types of glaucoma are classified anatomically by the size of this angle: (1) narrow-angle or angle-closure glaucoma and (2) wide-angle or open-angle glaucoma.

If the angle is narrow, the iris may mechanically obstruct the outflow of aqueous humor. This will cause the pressure within the eye to rise and will precipitate an attack of acute glaucoma—an emergency situation that is very painful. Surgical intervention, usually a laser iridotomy, affords relief. It is always necessary to widen the angle for this condition and reduce pressure to avoid damage to the optic nerve. Surgical iridectomy occasionally is necessary.

Wide-angle or open-angle glaucoma is the most common type of glaucoma. It is a chronic type, is often of insidious onset, and may cause permanent visual loss before being detected. The obstruction is not mechanical but is a physiologic lack of ability to filter aqueous. Surgical procedures for this type of disease are performed only if medical and laser therapies are unsuccessful. Laser therapy to the trabecular meshwork (trabeculoplasty) offers an alternative to conventional surgical procedures for some glaucoma patients. One of the following surgical procedures may be preferred:

- Iridectomy (excising a sector of iris) or iridotomy (cutting a small opening in the iris) is performed to deflate the mechanical obstruction, thus increasing drainage by permitting the normal outflow of aqueous from the posterior to the anterior chamber. Another use of iridectomy is to create a new optical pupillary opening to improve visual acuity for patients with corneal or lens opacity caused by injury or cataract not associated with glaucoma.
- Filtering-type procedures, of which there are many variations, such as trephining and trabeculectomy, create an artificial fistula between the angle of the anterior chamber and the subconjunctival space to bypass the usual blocked outflow channels. Iridectomy is usually performed as part of the procedure to eliminate blockage of the fistula by the underlying iris. The Nd:YAG laser may be used to reopen filtering sites that have scarred closed after previous surgery for glaucoma. The holmium:yttrium aluminum garnet (Ho:YAG) laser may be used to create an opening in the sclera (sclerostomy) to promote filtration.
- Cyclodialysis, cyclodiathermy, and cyclocryotherapy are performed to diminish aqueous secretion by the ciliary body. **Cyclodialysis** involves severing the blood supply of the ciliary body. Cyclodiathermy and cyclocryotherapy use the application of heat or cold, respectively, for the same purpose.

Secondary glaucoma is often a complication of an inflammation such as iritis, which usually responds best to medical treatment. On the other hand, neoplasm, vascular obstruction, trauma, or hemorrhage and other causes of obstruction to aqueous drainage may require surgical intervention. Treatment is directed to the primary cause.

Congenital glaucoma, from an inherent defect in the trabecular meshwork or a systemic disorder, manifests soon after birth.

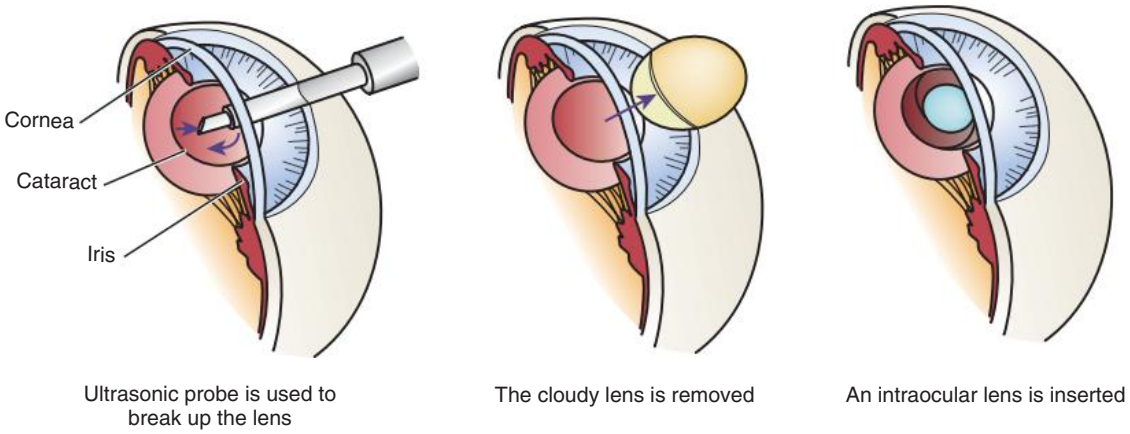
Cataract

A cataract is an opacification of the crystalline lens, its capsule, or both. The more or less opaque lens does not transmit clear images to the retina. Symptoms are related to the location and configuration of the opacity. The cause may be a known metabolic or systemic disease, toxic material, radiation, trauma, or genetic factors, or the etiologic factors may be unknown. People are more prone to develop degenerative cataracts with advancing age. Although cataracts often develop in both eyes, each cataract tends to mature at a different rate, and only one is removed at a time. Most ophthalmologists perform cataract surgery as an ambulatory surgical procedure.

Cataracts may be classified as one of the following:

- Congenital
- Senile or primary
- Secondary, resulting from local or systemic disease or eye injury

Surgical removal, followed by appropriate optical rehabilitation, is the only treatment. The surgical procedure to be performed is determined by the patient's age and type of cataract. The procedure is selected according to visual requirements, general health, and the potential for rehabilitation. Cataract extraction with implantation of an intraocular lens is the most frequently performed



• **Fig. 39.24** Removing the cloudy lens and placing an intraocular lens in its place.

surgical procedure in adults, and the advent of microsurgery has revolutionized this procedure (Fig. 39.24).

Extracapsular Extraction

With extracapsular extraction (ECCE), the lens is delivered through a small incision in the region of the limbus (the junction of the cornea and sclera). The anterior capsule is incised with a cystotome (a miniature hook-shaped knife) or with a **capsulorrhexis** forceps. The nucleus is delivered by manual expression, or it may be aspirated by phacoemulsification. The remaining cortex is extracted by irrigation-aspiration, sparing the posterior capsule, which is left in place. Automated mechanical irrigation-aspiration devices generally are used. Some surgeons prefer a manual technique using a two-way cannula and syringe. The wound is closed with a few sutures.

ECCE with preservation of the posterior capsule has revolutionized the practice of artificial lens implantation. The implant can be placed at the time of cataract extraction. It resides in the posterior chamber behind the iris and rests on the posterior capsule. The implant is therefore positioned in almost the identical location of the lens it replaces.

The physiologic advantage of ECCE, with or without phacoemulsification and/or lens implantation, is protection of the vitreous and retina by the clear posterior lens capsule, which then serves as an anatomic barrier between the posterior and anterior segments of the eye. Occasionally the posterior capsule remains opaque. Nd:YAG laser capsulotomy is performed at a later date to provide an optically clear opening.

The following innovations have enhanced the advantages of ECCE:

1. An operating microscope with coaxial illumination to clearly view the posterior capsule during aspiration.
2. A phacoemulsifier to remove the nucleus through a tiny (3 to 3.5-mm) incision. The smaller wound facilitates healing and causes less distortion of corneal curvatures.
3. An automated irrigation-aspiration system with an electronic sensor to remove all cortex remnants. This minimizes local foreign protein reaction.
4. An Nd:YAG laser to atomize posterior capsule opacity. The laser achieves a better result than discission/needling, which requires a second surgical intervention. The laser can be used immediately postoperatively, or the procedure can be delayed. The laser can be used under a drop of local anesthetic without requiring an incision and without causing blood loss.
5. An intraocular foldable lens designed to achieve insertion into the posterior chamber through a small incision.

Intracapsular Extraction

Intracapsular extraction (ICCE) is not commonly used unless the natural lens is displaced. Advance planning is necessary on the rare occasions in which it is performed. The entire lens, intact within its capsule, is delivered through a moderate-sized incision made in the region of the limbus. Before delivery, an iridectomy or multiple iridotomies are performed, chiefly to prevent iris prolapse and preserve communication between the anterior and posterior chambers. Depending on the surgeon's preference, the lens is grasped by a forceps, suction device, or cryoextractor.

A miniaturized, sterile disposable cryoextractor facilitates removal of fragile or dislocated cataracts. The cryoprobe freezes onto the surface of the cataract, thus obtaining secure adherence. The freezing technique greatly reduces the inadvertent rupture of the capsule during extraction. The scrub person should have a BSS irrigator available for use in case it is necessary to unfreeze an unintentional attachment of the cryoextractor to the iris or cornea. The wound is closed watertight with multiple sutures, commonly 10-0 nylon.

With ICCE, the visual axis is free of remnants that might proliferate or opacify to obstruct vision. The success rate for regaining vision is high, but the popularity of this procedure has waned. Fluorescein angiography has identified a number of patients who developed cystoid macular edema postoperatively, resulting in marked loss of visual acuity. ICCE may also be followed by retinal detachment.

Linear Extraction

Linear extraction is performed in young adults. In this procedure, a small incision is made through the limbus. The anterior capsule is incised, and the major portion of it is excised with a cystotome. The soft cataract material is irrigated from the anterior chamber.

Phacoemulsification

Although the aspiration technique is commonly used in young people, it was not successful in older adults with senile cataracts until the late 1960s. At that time a sophisticated machine, the phacoemulsifier, was developed to break up (fragment) and remove firm, insoluble lens nuclei. This machine, with components for ultrasonic vibration and irrigation-aspiration, permits extracapsular extraction through a very small incision in the limbus. All functions are controlled by foot pedal.

The handpiece of the phacoemulsifier consists of a disposable, hollow, titanium alloy needle surrounded by a silicone sleeve. The needle is inserted into the anterior chamber after removal of the anterior capsule with a cystotome. The activated needle breaks up the lens with ultrasonic vibrations; the linear motion of the ultrasonic vibrations is created by electrical impulses. This process generates heat. A cooling pump circulates coolant, either fluid or air, through the power cord.

While the lens is thus emulsified, a constant flow of BSS irrigating solution through the sleeve prevents heat buildup. The irrigation-aspiration flow is automatically regulated to maintain anterior chamber depth. The aspirator removes the fragments. After the cortex (material surrounding the lens nucleus) is removed by irrigation-aspiration, the posterior capsule may be polished with an instrument to remove any residual cortex. The posterior capsule is left intact unless an opacity remains, in which case it may be incised during the initial surgical procedure or at a future time. The limbal incision can be closed with one stitch. Alternative methods do not require any suturing.

Appropriate checks should be made before use of the handpiece, and the integrity of the vacuum and irrigating systems must be confirmed. The handpiece should be disassembled for cleaning and sterilization and then reassembled on the sterile field before use. The handpiece can be steam sterilized as a single unit. Care is taken to prevent biomaterials from being aspirated into the handpiece. Cleaning should be meticulous, and instrumentation must be sterilized after patient use.

In computerized machines, the phacoemulsification and aspiration settings are preset. To avoid error, the scrub person and circulating nurse work closely with the surgeon to monitor the various functions of the machine in use. They should also observe the transparent tubes for the flow of aspirate. Aspirated fluid is contaminated and is discarded postoperatively in the same manner as all blood or body fluid.

Phacoemulsification has the following advantages:

- It dramatically shortens convalescence time. The patient usually returns to full activity in 1 or 2 days.
- It uses a small incision and minimal sutures, which promotes healing.
- It retains the posterior capsule of the lens to preserve a more physiologically normal condition. The occurrence of post–lens extraction edema and retinal detachment is thereby diminished.
- The posterior capsule supports an implanted IOL. Postoperative astigmatism is minimized.[7]

Phacoemulsification also has the following disadvantages:

- It is not suitable for all patients. Contraindications are corneal disease, a dislocated lens, a shallow anterior chamber, difficult-to-dilate pupils, and completely hard, stonelike cataracts.
- It requires special techniques that, if not thoroughly mastered, may precipitate surgical complications such as temporary or permanent corneal damage (opacification), prolapse of the lens into the vitreous, and vitreous loss.
- It may injure the cells because of the necessary substantial amount of anterior chamber irrigation. Corneal cells are very sensitive to manipulation and can respond by loss of function.
- It requires meticulous technical monitoring of the machine. The usual precautions for the use of electrical equipment are also observed.

Clear Corneal Cataract Procedure

Foldable IOLs and topical anesthetic techniques have been integral with the use of "no stitch" corneal incisions. Patient selection includes the ability to fixate vision on a focal point and cooperate with commands from the surgeon. Tetracaine intraocular drops are used preoperatively and intraoperatively. Additional intraoperative anesthetics include injectable lidocaine without preservatives for infusion into the anterior chamber.

Rehabilitation After Cataract Extraction

Rehabilitation after cataract extraction consists of substitution for the missing part, the lens, so the optical system can function to focus incoming light on the retina. Patients with no optical substitute see only blurred objects of large size. Rehabilitation may be accomplished by spectacles (glasses), contact lenses, or IOL implantation.

Spectacle correction of aphakia, the absence of the lens, provides focusing of light. The spectacle lens is approximately 2 cm in front of the original lens and magnifies images so they are approximately 35% larger than those the patient saw before development and extraction of the cataract. This magnification requires considerable readjustment to judge distances. In addition, peripheral areas are distorted. The spectacle type of replacement is intolerable in patients who have good vision in the unaffected eye because an attempt to fuse the dissimilar images of the two eyes causes double vision.

A contact lens often is used to replace the optical deficiency caused by cataract extraction. This lens rests on the cornea only 2 to 3 mm from the original lens and thus causes only 7% magnification and provides a full, undistorted field of vision. It is difficult for some older adults to handle and care for contact lenses because of a lack of manual dexterity, arthritic hand and finger joints, or visual defects in the opposite eye. For these patients, an implanted IOL is a feasible and popular alternative.

Implantation of Intraocular Lens

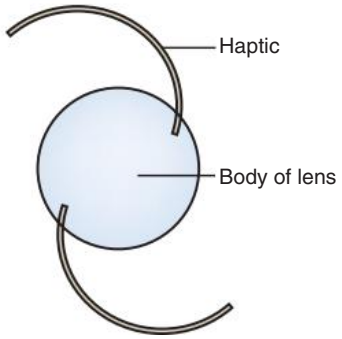
IOL implantation is a microsurgical procedure in which an IOL is implanted in almost the identical position of the original lens and therefore does not change the size of the retinal image. Spatial displacement as seen by the **aphakic** eye and narrowing and distortion of the visual field are eliminated, thereby producing early visual rehabilitation. With spatial displacement, orientation in space is changed—objects are not where they appear to be.

An IOL is intended to remain in situ permanently. The implant is usually inserted through the same incision used to remove the defective, natural lens; this is called *primary insertion.* Some surgeons prefer to implant the lens at a later time; this is referred to as *secondary insertion.* The type of IOL used is contingent on the type of cataract extraction the surgeon chooses. Anterior chamber lenses are inserted in conjunction with ICCE or as secondary implants. Posterior chamber lenses are used after ECCE.

The prescription of the implanted lens (refractive power) involves complex preoperative calculations based on the patient's corneal curvature as determined by keratometer readings, anterior chamber depth, and eyeball axial length. Ultrasonography is helpful in making these determinations preoperatively. The information obtained is fed into a computer that automatically calculates the appropriate refractive power of the IOL.

Numerous IOLs of different shapes and sizes are available. Fig. 39.25 depicts a common type of implantable lens. The optical portion of a hard lens is made of an inert plastic, polymethyl methacrylate (PMMA) with or without an ultraviolet blocker, that has been polished to a microscopic smoothness. Flexible and foldable lenses are made of silicone elastomer and acrylic resin.

The fixation portion has springlike supports or loops, called **haptics**, made of plastic (usually polypropylene). Some lenses are



• **Fig. 39.25** Intraocular lens.

secured with polypropylene sutures. Lenses differ in design and method of fixation, and they can be classified according to placement or method of fixation.

Anterior Chamber (Angle Fixation)

An anterior chamber lens consists of a band of plastic long enough to traverse the anterior chamber from one angle to the other. The optical portion is centrally located in the anterior chamber, in front of the pupil and iris. The pupil remains mobile because iris adhesions are not required for fixation. Although anterior chamber lenses are sometimes inserted primarily, they are popular lenses for secondary insertion.

Posterior Chamber (Capsular or Ciliary Body Fixation)

Posterior chamber lenses are placed behind the iris and pupil, where the patient's own lens used to be. Placement of the IOL in the most normal physiologic position results in stabilization of the iris; less irritation of the uveal tract; a reduced tendency for iritis, secondary glaucoma, and cystoid macular edema; and stabilization of the optics. Posterior lenses permit safe dilation of the pupil if necessary to examine or treat posterior structures of the eye, such as the retina.

With capsular fixation, the lower loop of the haptic is inserted into a pocket or capsule created during extraction of the cataract. The lens does not touch the iris, and the pupil is free to move. With ciliary fixation, the haptics are placed between the iris and the posterior capsule. They rest on the corona (inner rim) of the ciliary body.

Pros and Cons of Intraocular Lens Implantation

The final decision to implant an artificial lens rests with the surgeon, who should exercise good judgment to avoid serious complications.

Indications for implantation are the following:

- Older adult patients with disabling bilateral cataracts and others who cannot adapt to contact lenses
- Patients with occupations having specific visual requirements (e.g., airplane pilots) or a difficult working environment (e.g., ranchers in a dusty area)
- Children with a traumatic cataract, thus preventing amblyopia

Contraindications for implantation are the following:

- Impossibility for follow-up to observe patient for late complications
- Ocular conditions such as poorly controlled glaucoma or previous retinal detachment
- Diabetic proliferative retinopathy
- Poor result in previous implant
- Patient anxiety in regard to the procedure
- Young patients with congenital cataracts
- Endothelial corneal dystrophy
- Cataracts associated with recurrent iritis

Advantages to IOL implantation are the following:

- Superior spatial orientation and binocular vision
- Permanency of device unless complications develop
- Additional option for post–cataract extraction refractive correction
- Unrestricted pupillary dilation if necessary

Complications with IOL implantation are the following:

- Corneal damage or latent edema
- Prolonged inflammation such as iritis or vitritis
- Cystoid macular edema
- Secondary cataract (i.e., opacification of the anterior vitreous) from recurrent iritis
- Corneal opacity (rare with posterior implants)
- Dislocation or malposition of the lens, which can damage the cornea (fortunately rare)

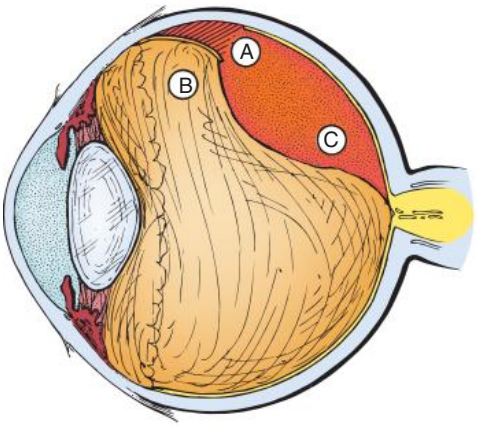
The type of approach used to repair a dislocation depends on the amount of dislocation. With the anterior approach, an anterior vitrectomy is performed to remove the vitreous in front of the lens, followed by removal or repositioning of the lens. With the posterior approach, the vitrector is used to remove the lens and/or vitreous through the pars plana. The IOL can be repositioned or removed.

Retina

Defects in the continuity of the retina can occur after accidental or surgical trauma or as a result of certain degenerative diseases. The dense network of capillary vessels in the retina makes the eyes vulnerable to microvascular disease. Retinopathy is a noninflammatory degenerative disease of the retina.

Retinal changes can occur in patients with diabetes (i.e., diabetic retinopathy). Diabetes can affect every part of the eye, causing lens changes (cataract), palsied extraocular muscles, glaucoma, or corneal problems. A person who has had diabetes for more than 15 years has a significant likelihood of having some form of retinopathy, which generally occurs bilaterally. The severity of retinopathy may differ from one eye to the other. Retinopathy is classified as one of the following:

- *Background or nonproliferative:* With this type of retinopathy, disease is confined to the retinal surface. Bulges or microaneurysms form in retinal capillary walls, eventually permitting leakage and the deposition of exudates. Intraretinal hemorrhages occur and are reabsorbed. Progressive changes in capillary membranes lead to the blockage of capillaries, resulting in retinal ischemia. Deterioration then progresses to the proliferative stage.
- *Proliferative:* In the proliferative stage, new blood vessels emerge from the retina and form in the surrounding tissues in an effort to relieve retinal anoxia (i.e., neovascularization). These fragile vessels may rupture spontaneously, producing hemorrhage into the retina and/or vitreous humor. The eventual result may be partial or complete blindness. Panretinal photocoagulation (PRP) is one method of eliminating abnormal vascularization. PRP consists of the application of hundreds of laser burns to the peripheral retinal tissue to partially destroy it, thereby reducing the retinal metabolic need for oxygen. After neovascularization has occurred, laser therapy is less effective in delaying or stopping the destructive process. Therefore early diagnosis and treatment are crucial. In an effort to



• **Fig. 39.26** Detached retina. **A,** Retinal break. **B,** Vitreous. **C,** Fluid or blood behind the retina. (From Ryan SJ, Wilkinson C, Schachat A, et al, editors: *Retina,* ed 4, vol 3, St. Louis, 2006, Mosby.)

prevent the formation of new vessels, lasers are used to cauterize minute hypoxic areas of tissue before damage occurs.

A laser is used for cauterizing bleeding vessels, for diabetic retinopathy, and for other retinopathies such as central serous retinopathy with swelling of the macula, angiomas and hemangiomas, aneurysms, and small tumors. Laser is absorbed selectively by three pigments in the retina: macular xanthophyll, hemoglobin in the retinal and subretinal blood vessels, and melanin in the retinal pigment epithelium. Laser therapy is not effective in correcting severe retinal damage or detachment.

Repair of Detached Retina

The retina can become separated from its surrounding nourishing layer, the choroid (Fig. 39.26). This detachment may occur in any region of the retina. Primary retinal detachment is characterized by a hole in the retina.

Secondary detachment may result when blood, fluid, or a tumor gets behind and displaces the retina; this type of detachment is not necessarily accompanied by a hole. The seepage of vitreous fluid into the potential space between the retina and the choroid causes the retina to become detached, and a serious visual disturbance results.

Enucleation is usually indicated for tumor-caused detachment.

Reattachment is effected only by surgical intervention. The retinal defect is sealed off, and often the subretinal fluid is drained. The specific procedure used to achieve retinal reattachment is determined by the type and location of the detachment. All or some of the following procedures may be used in combination:

- *Diathermy:* The traditional procedure involves diathermy coagulation to the area of the sclera overlying the region of the retinal defect. The resultant localized inflammation acts to seal off the break. Coagulation is delivered by a specialized short-wave diathermy unit.
- *Cryosurgery:* Some surgeons prefer cryosurgery because of the type of adhesion obtained. The therapeutic applications of cryosurgery are basically similar to those of diathermy, and the tissue reactions superficially resemble each other. Cryosurgery is often used for anterior tears.
- *Scleral buckling:* Internal elevation of the sclera may be increased by the scleral buckling procedure. This technique involves implantation of a wedge of silicone episclerally or intrasclerally. An encircling band of silicone may be used to keep constant external pressure on the buckle. Fig. 39.27 depicts the result of this procedure.
- *Intraocular gas tamponade:* Injection of room air or absorbable inert gas into the vitreous cavity can be used to create an intraocular tamponade. Room air absorbs after 5 days. Inert gases such as short-acting sulfahexafluoride (SF_6), intermediate-acting perfluoroethane (C_2F_6), or long-acting perfluorooctane (C_3F_8) are sometimes used to approximate the retina to the choroid (i.e., flatten the retina against the choroid).

With **pneumoretinopexy**, the patient remains in a seated position for a superior tear or prone for a tear near the macula. This position is maintained for several weeks postoperatively so the gas bubble can successfully rise to close the retinal hole. The position and length of time in that position are determined by the ophthalmologist according to each patient's need. Pneumoretinopexy is less invasive than scleral buckling for securing a retinal detachment (Fig. 39.28).

- *Intraocular fluid tamponade:* Silicone oil has been approved by the FDA for use as a vitreous substitute in securing a retinal detachment that cannot be corrected through conventional surgical intervention. Silicone oil is used for long-term intraocular tamponade. It is removed by the ophthalmologist several months postoperatively.

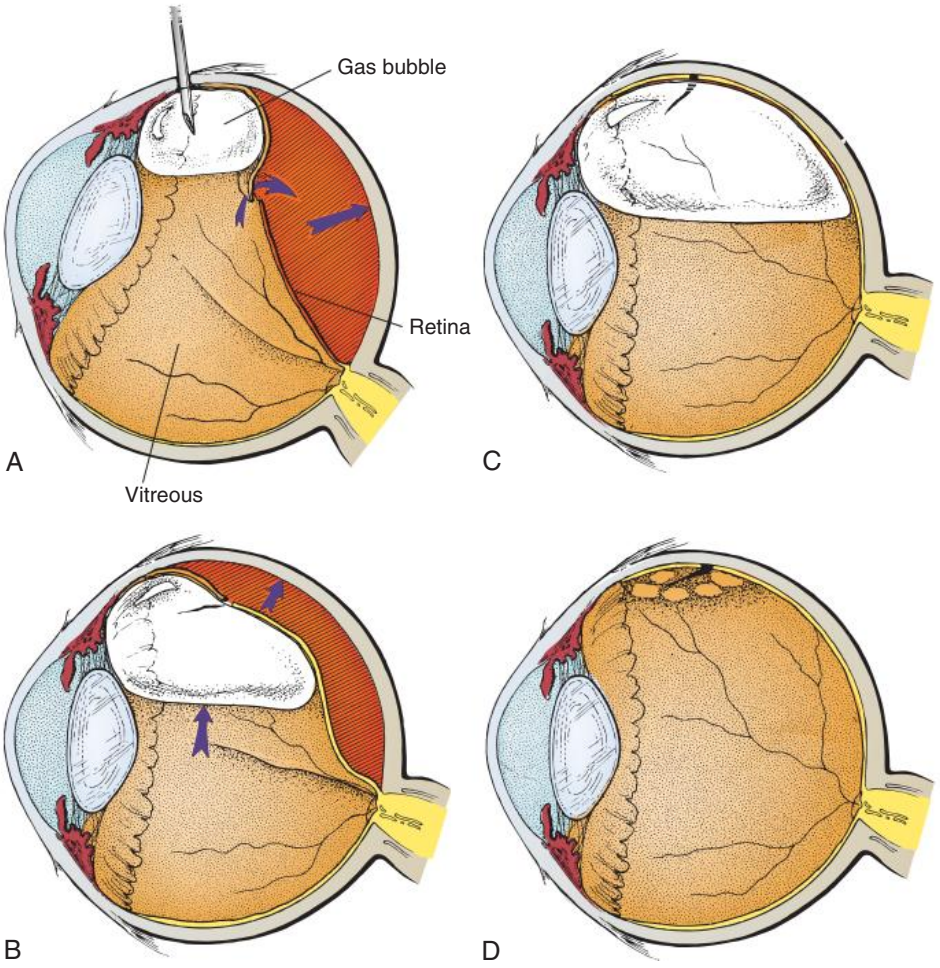
Patients with proliferative vitreoretinopathy with inferior breaks benefit from a blended silicone solution that is heavier than the vitreous. A blend of perfluorohexyloctane and silicone (Densiron) has been shown to effect a repair to the detached lower retina in 90% of patients in clinical trials. The Densiron is removed between 12 and 14 weeks postoperatively.

- *Laser therapy:* Laser therapy can be used to secure the retina, except in severe detachment. A laser is often used to secure small posterior tears. (See the following discussion of laser therapy.)

Glaucoma and infection are potential postoperative complications of retinal reattachment. Glaucoma may be caused by congestion of the uvea by the buckle, increased IOP, or movement of injected gas from the desired site, causing blockage of outflow channels of aqueous humor. Infection is evident by swelling, purulent drainage, and a loss of optical clarity.

Laser Therapy

The laser delivery system uses the binocular microscope of the slit lamp, thus providing stereopsis and greater magnification. The



• **Fig. 39.28** Pneumoretinopexy. **A,** Introduction of gas bubble. **B,** Gas bubble compresses retina. **C,** Tamponade formed by gas bubble. **D,** Gas bubble eventually absorbs. (From Ryan SJ, Wilkinson C, Schachat A, et al, editors: *Retina,* ed 4, vol 3, St. Louis, 2006, Mosby.)

nature of the laser beam permits extremely rapid delivery of radiant energy to produce a sharply defined burn. The small lesion it produces can be placed close to the macula.

Exposure can be as brief as 1/100 second and the treated area as small as 50 mm (less than 2/1000 inch) in diameter. Because of this short exposure time, immobilization of the eye is unnecessary unless the treated area is close to the macula, the central region of the retina with the clearest visual acuity. Accidental injury of the macula may result in a loss of central vision. Pupillary dilation is essential to avoid macular burn.

The argon laser is effective in treating retinal holes or tears and diabetic retinopathy. The krypton laser can be used to treat lesions closer to the macula and to treat retinal bleeding because of its poor absorption of the yellow pigment of the retina. The krypton spectrum is poorly absorbed by the red pigment of hemoglobin. Therefore it may be used effectively to treat retinal bleeding in the presence of blood in the vitreous humor. Under these circumstances the argon blue laser is ineffective because of absorption by even a small amount of blood.

Photocoagulation

A retinal hole not surrounded by any detachment may be prophylactically sealed by xenon or laser photocoagulation. These therapeutic modalities, which are usually performed in an ophthalmic treatment area rather than the OR, were the outgrowth of traumatic retinal burns caused by watching an eclipse of the sun.

The xenon arc photocoagulator uses an intense source of multiwavelength light furnished by a xenon tube. The light is optically focused and concentrated into a delivering device that is basically an indirect ophthalmoscope. The latter can be used both to view the area to be treated and to aim the light beam. The light may be directed to any of the pigmented (light-absorbing) layers of the eye, such as the iris or retina. These darker layers readily absorb the white light of the xenon tube. The optical system of the eye is used in the process of focusing the light beam on the desired area.

The power setting and exposure time are completely controlled by the operating ophthalmologist. The pupil of the eye under therapy is dilated to give maximum visibility to the surgeon. The eye is immobilized by local anesthesia to prevent undesired movement, which could result in a burn to an area other than the one desired. Anesthesia also prevents pain from the intensity of the heat. Vitreous shrinkage that possibly leads to an inoperable detachment can be a complication.

Vitrectomy

Vitrectomy is the deliberate removal of a portion of the vitreous humor, also called *vitreous body,* that fills the space between the lens and the retina. Therapeutically it is performed for vitreal

opacities, vitreal hemorrhage, and certain types of retinal damage or detachment. In addition to other causes, endophthalmitis (i.e., inflammation of the internal tissues of the eyeball) and the presence of an intraocular foreign body may result in vitreal opacity. In general, the candidates for vitrectomy have substantially impaired vision and complicated conditions preoperatively.

Whereas aqueous fluid is a clear liquid, vitreous is normally a transparent, gelatinous, viscid material containing fibrils. The vitreous helps give shape to the eyeball and serves a refractive function. It permits light rays to pass through it to the retina after the rays have traversed the lens. Diagnostically, the removal of a small amount of vitreous provides a sample for microbiologic study in suspected endophthalmitis. The procedure also provides tissue for biopsy to establish the diagnosis of intraocular tumors.

Alterations in the vitreous can have serious consequences. The loss of vitreous during surgical procedures is a dreaded complication, particularly of cataract extraction. Subsequent to retinal hemorrhage, which is common in patients with diabetes, bands of scar tissue may opacify the vitreous as well as adhere to the retina near the original bleeding vessel. Traction on the retina by these bands or further cicatrization (scarring) can lead to retinal tears or detachment. A persistent hemorrhage, lasting more than 1 year, is permanent. It will not absorb spontaneously.

For years the vitreous was considered an inaccessible, inoperable area. Research and the advent of microsurgery have changed this belief. A loss of vitreous from the posterior segment during a cataract procedure is relatively innocuous if the anterior segment is cleared of vitreous. Thus no residual strands are present to cause traction effects or block visual function. In addition, the eye tolerates subtotal vitreal excision in the posterior segment if the vitreous body is proportionately replaced with BSS.

Vitrectomy is a microsurgical procedure that lasts 2 to 3 hours and requires a skilled retinal surgeon. It is performed with a vitreotome (vitrector) such as the MicroVit. These devices, which incorporate a micromotor, terminate in a needlelike tube that contains a cutting mechanism for severing abnormal adhesions and cutting obstructive tissue into small pieces. In addition, the vitreotome has auxiliary connections for the aspiration of vitreous, debris, or blood from the posterior segment.

Vitreous is replaced with BSS via a separate infusion cannula to maintain adequate IOP. A fiberoptic light source or pic is inserted into the vitreous to illuminate the posterior portion of the globe. Various vitrectomy systems are available, but all have cutting, suction, and illumination systems. The machine may have an automatic or hydraulic pole for rapidly regulating the height of the BSS bottle.

The scrub person and circulating nurse should assemble and check equipment before the surgical procedure begins. The vitreotome handpiece is attached to sterile tubing, which is connected to a power console. One person activates the various switches while the other tests the suction vacuum and cutting function. Suction is tested at maximum pressure. The tip is placed in sterile saline and activated until fluid reaches the collection bottle. The pressure is then lowered to the surgeon's preference.

To assess cutting, the switch is activated and the tip is checked visibly and audibly for movement. The infusion catheter is primed with a solution of the surgeon's choice to remove air bubbles that could disturb the view in the posterior segment. The manufacturer's manual should be consulted.

A local anesthetic is administered unless the patient's condition necessitates a general anesthetic. There are two approaches to the vitreous body, as follows:

1. Through the posterior segment via the pars plana (i.e., the anterior attachment of the retina). Because the pars plana has no visual function, entry here is relatively atraumatic and poses minimal risk for retinal detachment. The anterior segment remains intact, and IOP is maintained. This approach is used to incise opacified vitreous, old hemorrhage, or bands of scar tissue, thereby giving a clear view of the retina and restoring visual function.
2. Through the anterior segment via incision at the limbus (i.e., junction of the cornea and sclera). A small opening is made, and the tip of the vitrector is introduced. The vitreous is exposed through the pupillary opening. This approach is used to remove vitreous inadvertently displaced into the anterior chamber during cataract removal to avoid postoperative complications. The vitreous volume is replaced with BSS. Anterior vitrectomy also is used to correct retinal traction in retinopathy in premature infants (retrolental fibroplasia).

Vitrectomy is intricate and requires special equipment. The surgeon may request a bipolar cautery with a Charles clip attachment for actively bleeding intraocular vessels. A bipolar pencil or "eraser" may be used intraocularly. A handheld or "sew-on" contact lens placed onto the cornea enhances the view of the posterior chamber. A metal ring is sewn into place at two points around the limbus, encircling the cornea. Viscous material is placed on the cornea, and the lens of choice is placed down in the ring. Occasionally, a lensectomy is performed during vitrectomy to facilitate the view of the posterior segment.

After the removal of vitreous, before wound closure, and with the retina in clear view, the retina is inspected for defects such as holes or vascular abnormalities. If these are found, treatment is applied by means of endocryotherapy, a freezing application delivered by intraocular probe or by a laser delivered by an intraocular device. These maneuvers may be accompanied by the injection of air or inert gas to push the retina into physiologic position.

Postoperatively, patients may experience considerable pain that requires medication, ice packs, and steroid eyedrops for treatment of inflammation. After vitrectomy, patients will experience aphakia if the lens was removed for visualization of the posterior segment, and they will eventually need optical correction such as that needed after cataract extraction. Vitrectomy can significantly improve vision.

Complications of vitrectomy include iatrogenic retinal damage, vitreous hemorrhage, or cataract formation from damage to the lens. A secondary surgical procedure may be required to repair the retina (e.g., a scleral buckling procedure or intraocular tamponade). No present treatment for retinopathy is free of danger. To save vision, some tissue is destroyed or sacrificed.

Eye Injuries

Various forms and degrees of trauma may occur as a result of injury. All types of injuries require immediate appraisal by an ophthalmologist.[8] A delay in treating even minor injuries may result in a temporary or permanent loss of vision. Complications include hemorrhage, infection, iritis or tears of the iris, retinal tears or detachment, macular edema, and secondary cataract.

Treatment may be immediate or secondary if a delay is necessary because of life-threatening injuries. Improved surgical management, such as vitrectomy and microsurgery, has reduced the

loss of vision in severely injured eyes. An optimum result is especially crucial in patients with bilateral eye injuries. If possible, patients with eye injuries should be kept in the supine position until seen by an ophthalmologist.

Evaluation of the injury may necessitate sedating or anesthetizing the patient to prevent further damage at examination. Pressure to the eye must be avoided because bone fragments may be displaced or the globe contents emptied.

Injuries may be simple and involve only the external layers, or they may be compound and include the inner structures. They may be nonpenetrating (usually caused by a blunt object) or penetrating (caused by a sharp object). The more structures involved, the more difficult it is to salvage the eye.

Treatment is determined by the type or combination of injuries and aims to do the following:

- Promote healing and prevent anatomic distortion by reparative techniques
- Preserve and/or restore maximum vision
- Control pain by medication
- Prevent infection and inflammation through the administration of antibiotics and steroids

Nonpenetrating Injuries

Burns

Burns may be caused by ultraviolet radiation, such as sunlamps or sunlight, or by an electric flash. These types of burns are basically self-limited and are rarely surgical. A chemical burn constitutes an emergency. The initial treatment consists of flooding the cornea with water. Alkali burns may be further neutralized by prompt irrigation of the epithelium-denuded cornea with ethylenediaminetetraacetic acid (EDTA). This is especially important if discrete particles of alkali are superficially embedded within tissue. EDTA deactivates an enzyme (collagenase) and neutralizes soluble alkali such as sodium hydroxide (lye).

Severe burns may be treated with specific amino acids, EDTA, or acetylcysteine (Mucomyst) to inhibit the continued destruction of the cornea by collagenase; however, these burns often progress to corneal opacity and blindness.

Contusions of the Globe

Contusions of the globe may or may not require surgical treatment. If hemorrhage is present, treatment consists of bed rest and antiglaucoma therapy to control IOP. It is not unusual for a secondary hemorrhage to occur on the third or fourth day after injury.

If IOP remains high, blood staining of the cornea and damage to the optic nerve may result. It is then sometimes necessary to perform a paracentesis, in which an incision is made into the anterior chamber to drain the blood. If an organized clot is found, judicious irrigation may supplement the incision.

Penetrating Injuries

Lacerations of the globe may occur with or without a retained foreign body and with or without prolapse of the ocular contents. In injuries to the globe, an ophthalmic surgeon should repair both the eye wound and the tissues adjacent to the eye.

With a penetrating injury there is the possibility of an eventual sympathetic ophthalmia—an inflammation of the uninjured eye. Antitetanus therapy should be included in the treatment of these injuries.

Vitrectomy and lensectomy have rendered salvageable some massive injuries that formerly were inoperable. Such injuries include extensive lacerations with cataract formation, vitreous hemorrhage, and retinal damage.

Without a Foreign Body

Eyelid Laceration

Lacerations are repaired according to anatomic principles. Plastic repair involves approximation of the anatomic layers. Penetrating wounds, such as animal bites, are debrided. If the laceration includes the lacrimal canaliculus (duct for the passage of tears), special probes are used to identify the proximal portions for rejoining. Lacerations of the lacrimal canaliculus may be repaired by suturing over one of two types of stents.

The Quickert-Dryden tubing consists of a length of flexible silicone with a malleable metal lacrimal probe swaged onto each end. One end of the probe is inserted through the upper lid canaliculus, and the other end is inserted into the lower lid canaliculus. Both ends exit via the tear sac and nasolacrimal canal into the nose. The lacerated canaliculus is then sutured over the tubing, which is removed after healing takes place. Some surgeons prefer the rigid Veirs stainless steel rod, which is inserted into the lacerated canaliculus. A suture swaged to one end permits withdrawal of the rod after healing.

Conjunctival Laceration

Conjunctival laceration is usually debrided and, unless large, is permitted to heal without suturing. If the laceration is large and there is a loss of conjunctival tissue, sutures or rotating flaps of conjunctiva may be necessary for repair.

Corneal and Scleral Lacerations

A small corneal laceration may be covered with a protective soft contact lens to seal it and hold the edges together. A larger wound requires accurate appositional sutures that are best placed using the operating microscope. The microscope is especially useful for irregular, complicated, or multiple tears.

Some irregular corneal lacerations not easily closed by direct suturing may be closed and the leak stopped by the application of cyanoacrylate glue. A soft contact lens is usually placed as a bandage over the freshly glued cornea. A conjunctival flap can be placed to achieve a similar seal, but it is used less frequently. A large laceration may require a penetrating keratoplasty as an emergency procedure to ensure the integrity of the eye.

Adequate exploration, particularly of a scleral wound, is necessary to both determine the extent of injury and ensure uncovering of the entire wound for repair. In instances of vitreous fluid presentation or loss, it is preferable to remove the fluid from the wound and the anterior chamber with the vitreotome before proceeding with repair. This is performed to prevent undesirable vitreous adhesions from developing postoperatively.

Posterior Rupture of the Globe

Rupture of the globe usually involves the herniation of retinal and uveal tissue into the orbit. Although such injuries are self-healing, the eye is irreparably damaged. This injury usually results in enucleation. Avulsion (tearing) of the optic nerve produces permanent blindness even though the rest of the globe may be intact.

With a Foreign Body

Extraocular injuries are usually not extensive. An intraocular foreign object is removed very gently under sterile conditions to avoid secondary infection and further trauma. A corneal foreign body is removed with a sharp probe (spud), and the surrounding rust ring is removed with a rotating burr. The type, size, and position

of other intraocular foreign bodies should be determined accurately before removal. Localization is accomplished by the following:

- Direct vision with an ophthalmoscope
- Computed tomography scan
- Berman locator, a small but extremely sensitive version of a metal detector, which may indicate the exact location of a ferrous metallic foreign body
- X-ray study, using a contact lens containing radiopaque landmarks (Sweet's localizer)

Fragments of ferrous metals often can be retrieved by using the attraction of a strong electromagnet. In some cases these foreign bodies can be withdrawn along the path of entry. Nonmagnetic foreign objects present a more serious problem. Often they are secured only by passing a delicate forceps into the globe. Such instrumentation is combined with a partial vitrectomy, thus obtaining satisfactory results.

In summary, traumatic injuries may introduce infection or produce a severe inflammatory reaction to a greater degree than do elective surgical procedures. Proper early treatment is indicated to save vision. Early intervention, before scar formation, may be necessary in some patients.

Ophthalmic Lasers

The use of an ophthalmic laser is often a safe alternative to conventional surgery for ablation of a pathologic condition. The color and wavelength of each laser determine which part of the eye it can best treat. Specific wavelengths destroy disease in tissues whose pigments are capable of discriminating absorption of that wavelength. Conversely, the selected wavelength should be only minimally absorbed by the vital adjacent tissues to be preserved. The ophthalmologist controls the power, intensity, and direction of the laser beam. The beam precisely cauterizes tissue and blood vessels, preventing bleeding. Each laser has selective uses:

- *Blue-green argon:* For a retinal detachment, tear, or hole; diabetic retinopathy; macular neovascular lesions; laser trabeculoplasty, to lower IOP and facilitate aqueous outflow in select patients with open-angle glaucoma; iridotomy, in place of iridectomy by incision; and to create a small opening in the iris that allows aqueous to enter the anterior chamber (angle-closure glaucoma). The use of this laser may reduce the threat of endophthalmitis, a serious postoperative complication.

Adherence of the iris to laser treatment sites (synechiae) is a complication of laser trabeculoplasty. A portable laser is available for intraoperative use. It permits surgeons to work inside rather than through the eye while the patient is under general anesthesia.

- *Red-yellow krypton:* For blood vessel aberrations of the choroid (common to senile macular disease) in which abnormal vessels damage adjacent nerve tissue; for lesions in the perimacular region (the laser beam passes through cloudy vitreous hemorrhage); and for retinal vascular diseases, such as proliferative diabetic retinopathy and retinal detachment.
- *Invisible pulsed Nd:YAG:* For preoperative anterior capsulotomy before extracapsular cataract extraction; posterior capsulotomy (**discission**) after extracapsular cataract extraction to make an opening in an opaque capsule and thus permit light to reach the retina; and lysis or severing of strands of vitreous and/or fibrous bands in the posterior segment that cause cystoid macular edema.

Cloudy areas of tissue interfering with vision are painlessly pushed aside, resulting in immediate improvement in sight. Rather than producing the effect by absorption, energy is released almost entirely at the point of focus. Problems in both anterior and posterior parts of the eye are treatable (e.g., with optical iridectomy and photocoagulation of retinal disorders). Unlike with the visible light lasers, the Nd:YAG laser does not require the target tissue to be pigmented for effectiveness.

- *Visible excimer:* Argon-fluoride in the ultraviolet range. Used for shaping the cornea, as in lamellar keratectomy, to correct refractive disorders.
- *Invisible Ho:YAG:* For sclerostomy to create an opening in the sclera that promotes filtration for glaucoma. It also can be used for corneal sculpting.

The following are advantages of laser therapy:

- Possibility of infection is minimal. Treatment is noninvasive and sterile, which is an advantage to diabetic and susceptible patients.
- Pain is minimal. Only a topical anesthetic is required unless many retinal areas are treated with a high-energy laser.
- It is performed as an ambulatory procedure.
- The appropriate amount of energy is concentrated in a very small area.
- The light is highly flexible, which seems to do little damage to the clear medium it traverses.
- The laser light is selectively absorbed. Ideally, only desired tissue is affected.
- It is useful in a poor-risk surgical patient or one who has had a previous unsuccessful surgical procedure.

40 Plastic and Reconstructive Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify pertinent anatomy of the integumentary system.
- List four primary reasons for plastic surgery.
- Differentiate autografts, allografts, and xenografts.
- Describe the techniques of skin and tissue grafting.
- Discuss the importance of fluid balance in the burn patient.

KEY TERMS AND DEFINITIONS

Aesthetic Pleasing visual form.
Composite graft Tissue graft composed of multiple tissue types. A composite graft can have skin, muscle, bone, and blood vessels in combination.
Debridement Removal of dead tissue from wound edges to reveal vital tissue.
Dermatome Instrument for graft procurement. Can be mechanized or freehand knife style.
Dorsal space The back of the hand.
Eschar Tissue layer that forms over a burn site.
Expander A silicone sac placed beneath the skin and gradually expanded to increase the surface area of the skin to cover a defect.
Flap A multilayer tissue segment used as a surface cover. Can remain attached to a vascularized pedicle or can be a separate segment anastomosed to a new vascular attachment.
Full-thickness skin graft (FTSG) Skin graft that consists of the epidermis and dermis.
Graft A portion of tissue used as a surface cover. Not vascularized.
Mesher A mechanical device used in the sterile field to cut slits into a split skin graft to expand the surface area.
Ptosis Drooping of a part such as an eyelid or breast.
Replantation Reattach a severed part. Involves the anastomosis of vessels, nerves, and compact tissue.
Split-thickness skin graft (STSG) Skin graft that consists of the epidermis and a thin layer of papillary dermis.
"Take" The process of physiologic acceptance and integration of a graft or flap.
Volar space Palm side of the hand.

Special Features of Plastic and Reconstructive Surgery

Plastic surgery has been called the "surgery of millimeters" because of the critical margin between good and poor cosmetic results. Each millimeter lack or excess of tissue can have a psychologic impact on the patient. If the patient thinks his or her appearance has improved, the patient's personality and self-image may improve and others may respond more positively to him or her. The term *plastic* means "to mold or give form."

Plastic surgeons practice their art on virtually any part of the body. They attempt to restore both form (**aesthetic** appearance) and function. Some plastic surgeons limit their practice to specific areas, such as the head and neck, hand, or breast. The surgeon specifically trained in the art of plastic surgery frequently is a member of a multidisciplinary team to assist with the repair of defects and/or restoration of function. The results depend not only on the skill of the plastic surgeon and the team but also on the age, health status, skin texture, bone structure, extent of the defect, and healing capacity of the patient.

Many plastic and reconstructive surgical procedures are performed on an ambulatory basis; many are performed with the patient under local anesthesia with sedation. The surgeon performs the simplest and safest procedure that will provide a realistic outcome.

Scars are inevitable whenever skin is incised or excised. The incision is made along natural skin lines whenever possible. The plastic surgeon attempts to minimize scar formation by meticulous realignment and approximation of underlying tissues and wound edges. Many plastic procedures involve only the

subcuticular tissues and skin. Reconstructive procedures may include manipulation of underlying cartilage, bones, muscles, tendons, nerves, and blood vessels.

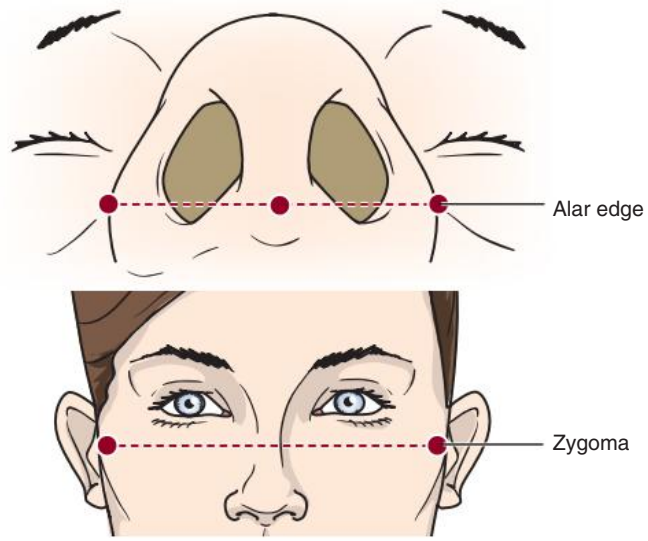
Replacement tissues or other structural substances come from several sources as follows:

- *Autograft:* Use tissue from self
- *Isograft:* Use tissue from genetically identical person
- *Allograft:* Use tissue from same species
- *Xenograft:* Use tissue from different species
- *Bioengineered graft:* **Graft** source from combined biologic and synthetic materials
- *Synthetic graft:* Substance from nonbiologic source

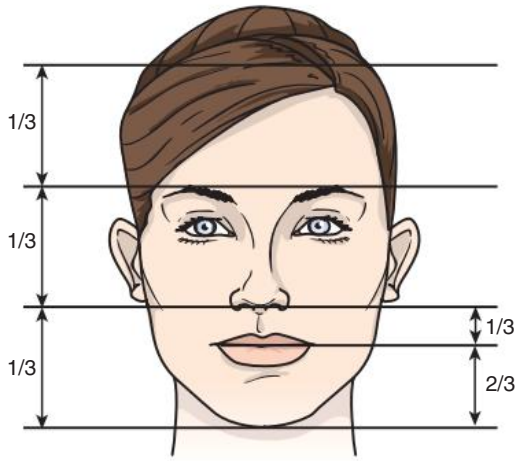
Preoperative instruction to patients include to avoid aspirin and not to smoke for at least 2 weeks before an elective surgical procedure. Aspirin and other substances have an anticoagulant action that can affect bleeding, causing hematoma formation. Medications, herbs, dietary supplements, and other substances may promote postoperative bleeding. Smoking causes vasoconstrictive ischemia that can affect wound healing, causing tissue necrosis. Photographs are commonly taken preoperatively, intraoperatively, and postoperatively for planning, documentation, and teaching purposes.

General Considerations in Plastic Surgery

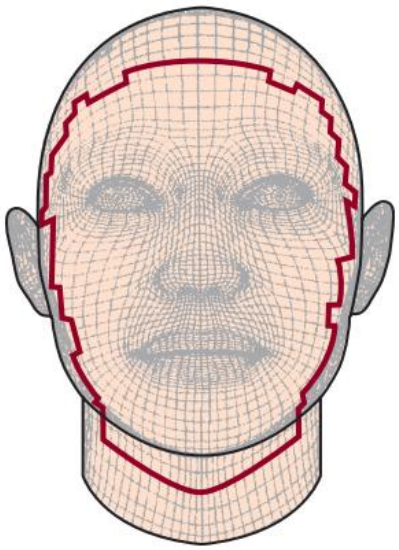
1. Pressure points are protected during prolonged procedures. Microvascular plastic and reconstructive surgical procedures may take several hours to complete. The patient should be positioned on a gel pad mattress. Bony prominences should be well padded to prevent tissue necrosis.
2. Sterile dye, such as methylene blue, indigo carmine, gentian violet, Bonney's blue, or brilliant green, is often used to outline areas for incision. This can be done with a sterile marking pen or stylus before or after the skin is prepped. Some surgeons will use intravenous (IV) indocyanine green or fluorescent dye (Fluorescein) and a black light (Wood's lamp) to confirm vascularity of a **flap**.
3. Exposure of both sides for comparison is usually required for surgical procedures on the breast, face, ears, and neck. Photography is commonly used preoperatively, intraoperatively, and postoperatively. Equalization of tissue manipulation and excision is matched to preoperative measurements written on a full-size image of the body part undergoing the surgical procedure. Fig. 40.1 depicts the areas marked for facial procedures. The nose is measured in comparison to the distance between the zygomatic arches (Fig. 40.2). Contemporary surgeons are using terrain mapping for procedures such as facial allogenous transplantations (Fig. 40.3).
4. Draping often exposes much skin surface, which is unavoidable. A fenestrated sheet frequently cannot be used. The opening does not give adequate exposure, especially for skin grafting. Towels, self-adhering plastic sheeting, and minor and medium sheets under and around the areas according to need are used to drape as much of the patient as possible. Drapes can be secured with nonpiercing towel clips, skin staples, or sutures.
5. Local anesthesia is used for many surgical procedures on adults. Epinephrine may be added to help localize the agent, prolong the anesthetic action, and provide hemostasis by vasoconstriction. Care is taken not to use epinephrine in digits,



• **Fig. 40.2** Nasal measurements are planned in relation to the zygoma for plastic surgery.



• **Fig. 40.1** Facial measurement for plastic surgery.



• **Fig. 40.3** Facial terrain measurements for full face transplantation.

ears, or other areas of terminal blood supply. Short 26 or 30-gauge needles are used for injection.
   a. The surgeon may administer a digital nerve block for procedures of the finger. The patient's hand is placed palm down, and a hypodermic needle is inserted through the webspace closest to the affected digit. The surgeon will aspirate to check clearance of all vessels. Then lidocaine 1% or 0.05% without epinephrine, 1 mL, is injected in the volar space (the region of the palmer surface). As the needle is withdrawn, 1 mL is injected at the level of the dorsal space (the region closest to the dorsum of the hand).
6. No. 15 and 11 scalpel blades are routinely used to cut small structures. Smaller blades, such as Beaver style, may be used.
7. An electrosurgical unit (ESU) pencil may be used to cut or coagulate during incision. Small, handheld battery-operated units are useful for tiny bleeders. Overuse of the ESU can cause devitalization of tissue and delay healing.
8. Instruments must be small for handling delicate tissues. Iris scissors, mosquito hemostats, fine-tipped tissue forceps, and other small-scale cutting, holding, clamping, and exposing instruments are part of the routine plastic surgery setup. Microinstruments are needed for microsurgical techniques.
9. Nerve stimulation may be used to help identify nerves, especially in craniofacial, neck, and hand reconstruction procedures.
10. Bone, cartilage, or skin grafts may be needed. Grafts and tissues can be used from several different sources for surface and subsurface modifications. Graft materials should not be allowed to dry out; these should be placed in a basin with a few drops of saline. Do not place in a folded moist sponge because this could be discarded from the field to the sponge bucket by accident.
11. Prosthetic implants may be used in plastic surgery to reconstruct subsurface soft tissue and cartilage defects. They cannot be used unless there is adequate soft tissue coverage. They cannot be used in an infected area.
12. Suture sizes range from 2-0 through 7-0, depending on the location and tissue, with sizes 8-0 through 11-0 sutures for microsurgery. The material used varies according to the personal preference of the surgeon. Synthetic nonabsorbable and absorbable polymers are used more commonly than are natural materials because they cause less tissue reaction. Barbed suture has become popular because fewer knots are required and less suture material remains in the patient to resorb.
13. Atraumatic swaged-on needles of small diameter with sharp cutting edges minimize trauma to superficial tissues. A needle holder with an appropriately fine tip is used with these delicate, curved needles.
14. Skin staples may be used to close skin or secure skin grafts.
15. Wound closure strips may be used as skin dressings with sutures or to supplement closure with skin staples.
16. Closed-wound suction drainage is frequently used to drain flaps to prevent seroma and hematoma formation.
17. Fine mesh gauze may be used for the contact dressing. This may be impregnated with petrolatum or an oil emulsion, with or without medication, to cover denuded areas. Several types of sterile nonadherent dressings are commercially available. Dry gauze is not used on a denuded area because it adheres and acts as a foreign body, causing granulomas.
18. Pressure dressings may be used after extensive surgical procedures to splint soft tissues and prevent contractures. Even pressure keeps fluid formation in tissues or under a skin graft to a minimum. Commercial compression garments or dressings for various body areas are preferred by some plastic surgeons. Some dressings may be sutured into place. Donor graft sites require bulkier dressings because they have multiple pinpoint bleeders that ooze freely.
19. Stent fixation is a method of obtaining pressure when it is impossible to bandage an area snugly, such as the face or neck. A form-fitting mold may be taped over the nose like a splint. Long suture ends can be tied crisscrossed over a dressing to immobilize it and exert gentle, even pressure.

Tissue may be approximated, supplemented, excised, transferred, or transplanted. Many procedures are done in stages before complete reconstruction and restoration of function are achieved. Tissue flaps and grafts, prosthetic implants, and external prosthetic appliances may be required for functional and cosmetic restoration as a result of ablative surgery or trauma.

Psychologic Support for Patients Undergoing Plastic and Reconstructive Surgery

Physical appearance affects self-image and self-esteem. Patients can develop inferiority complexes and introverted personalities because of congenital or acquired alteration in body structure. The defect may not affect physiologic function but may predispose the person to psychologic crippling if it is not corrected to the individual's satisfaction.

Adults who are dissatisfied with their body image may believe a change in personal appearance will solve their social, marital, sexual, or business problems. The plastic surgeon assesses the patient's psychologic status, motivations, and expectations before scheduling a surgical procedure. Realistic, attainable outcomes are identified. The patient should be emotionally stable and aware of the potential outcomes. The surgeon should carefully obtain informed consent. Psychologic assessment and preparation are advisable preoperatively and are essential before surgical procedures that may result in disfigurement.

Extensive reconstruction for severe congenital deformities is done in stages, often over months or years. These patients require prolonged psychologic support and encouragement.

Plastic and reconstructive surgery, either therapeutic or cosmetic, evokes emotional responses from the patient, family or significant others, and the entire perioperative team. Anticipation of the final outcome, which can be seen by the patient and others, often creates temporary psychosocial reactions such as depression and isolation. Positive reassurance of progress in improvement of physical appearance and during emotional crises is essential throughout the perioperative period. Perhaps the surgeon-nurse-patient-family relationship is closer when a person undergoes alteration of physical appearance than with other types of surgeries.

The patient may be physically healthy but may suffer alterations in self-esteem related to a perception of a defect in appearance. Care must be given in a manner that protects the self-esteem of the patient and respects the family's dignity. This requires communication, understanding, and empathy. Preoperative teaching and discharge planning prepare the patient and the family for postoperative rehabilitation.

Categories of Plastic and Reconstructive Surgery

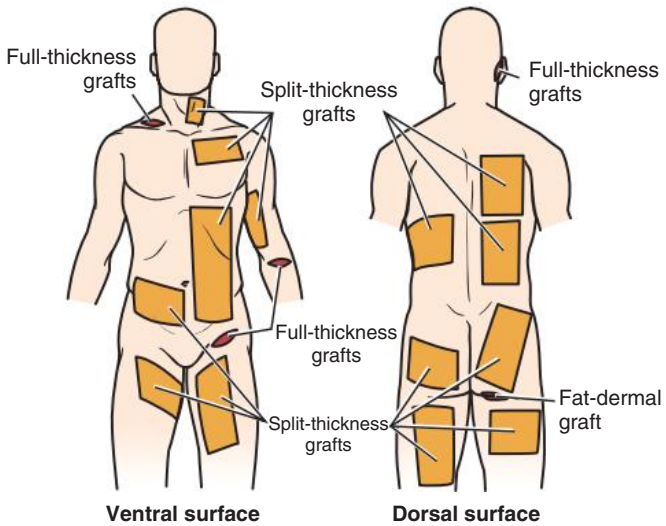
Four main categories of problems are treated by plastic surgeons:
1. *Congenital anomalies,* especially in the structure of the face and hands. Other disciplines may surgically treat genitourinary or orthopedic deformities.

2. *Aesthetic appearance,* especially of the body surface and subsurface, particularly the face and breasts.
3. *Benign and malignant neoplasms,* especially those leaving large soft tissue defects. Resection of extensive tumors other than those involving the skin or head and neck is not usually within the province of the plastic surgeon initially, but the patient may be referred for reconstructive surgery and rehabilitation. Frequently, reconstructive procedures are done in conjunction with another specialty surgeon at the time of tumor resection.
4. *Traumatically acquired disfigurements,* especially facial lacerations, hand injuries, and burns. The objective of the plastic surgeon is to restore function as well as body image.

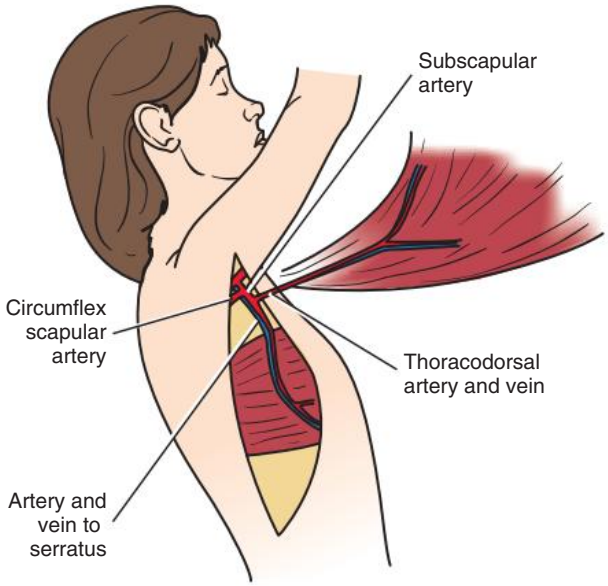
Skin and Tissue Grafting

Denuded areas of the body are resurfaced by transplanting or transferring segments of skin and other tissues from an uninjured area (donor site) to the injured area (recipient site). The plastic surgeon prefers to transfer tissues of compatible color, texture, thickness, and hair-bearing characteristics. Soft tissue autografts are used whenever possible. They are classified as follows according to the source of their vascular supply (which is essential for viability):

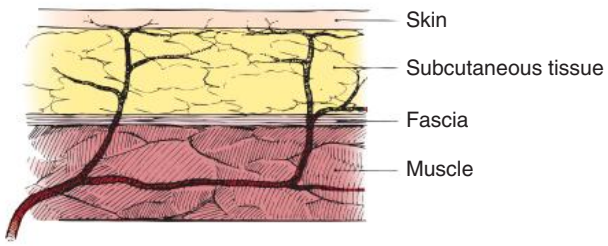
- *Free graft:* Tissue is detached from the donor site and transplanted into the recipient site. It derives its vascular supply from the capillary ingrowth from the recipient site. Fig. 40.4 depicts regions of the body suitable for autologous graft procurement.
- *Pedicle flap:* Tissue remains attached at one or both ends of the donor site during transfer to the recipient site. The vascular supply is maintained from the vessels preserved in the pedicle of the donor site.[1] Advancement flaps, rotational flaps, rhomboid flaps, transverse rectus abdominis myocutaneous (TRAM) flaps, and latissimus dorsi flaps (Fig. 40.5) are forms of pedicle flaps.
- *Free flap:* Tissue, including its vascular bundle, is detached from the donor site and transferred to the recipient site. Composite free flaps may include muscle, bone, and skin. Microvascular anastomoses between arteries and veins in the flap or autograft and recipient site establish the vascularity necessary for viability (Fig. 40.6).



• **Fig. 40.4** Donor sites for autologous grafts.



• **Fig. 40.5** Latissimus dorsi vascularized flap for breast reconstruction.



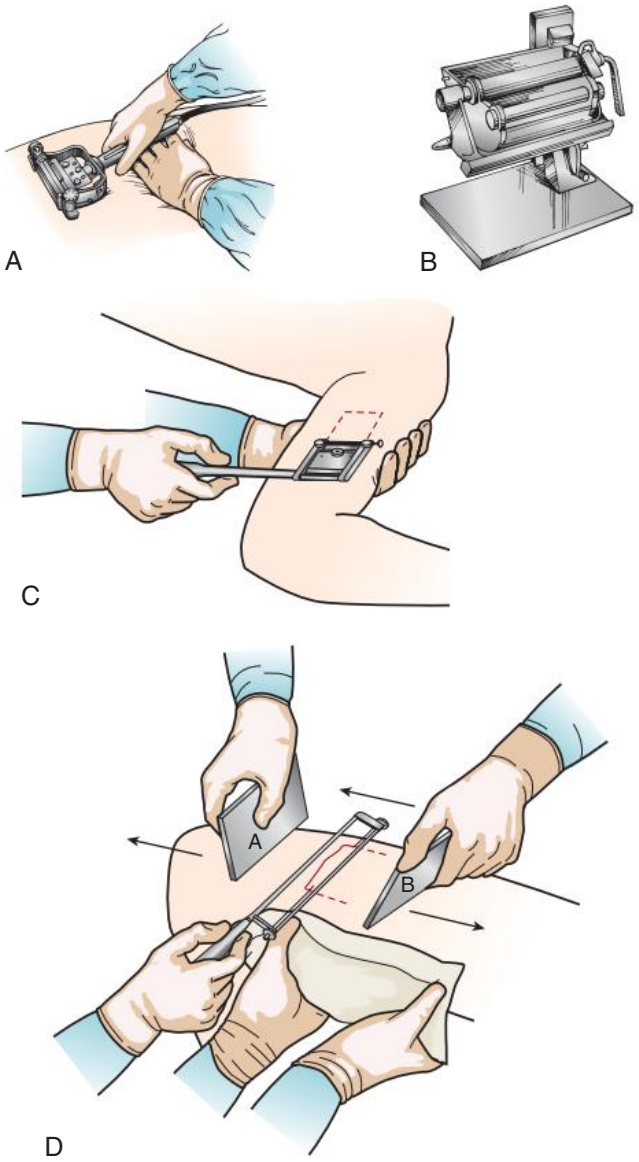
• **Fig. 40.6** Myocutaneous free flap.

Deformities caused by loss of soft tissue substance, such as trauma from accidental injury, tumor resection, or radiation therapy, may require a graft to fill in deficiencies and restore contours or to cover tendons and bones. Free grafts, pedicle flaps, and free flaps may be taken from various areas of the body to reconstruct soft tissue defects.

Grafting from one area of the body to another requires a process referred to as **"take."** The recipient site has to accept the donor tissue for the graft to take, or remain as a permanently viable tissue replacement. The skin graft take occurs in three steps. During the first 48 hours, plasma accumulates at the contact area of the graft. This keeps the tissue vitalized before circulation is established. The second phase is the start of capillary ingrowth. And the last step is the anastomosis of vascular channels. If the graft does not take, it sloughs off and necroses.

Skin Graft Knives and Dermatomes

A **dermatome** is a cutting instrument designed to excise split-thickness skin grafts (STSGs). The thickness of the graft can be calibrated by adjusting the depth gauge. The width of the graft is determined by the width of the cutting blade. Blades are detachable and disposable, which always ensures a sharp new blade for every patient. The cutting depth should always be reset at zero after changing blades. The length, width, and depth of the graft may be limited by the type of dermatome used and the surface from which the graft is procured (Fig. 40.7).



• **Fig. 40.7** Dermatomes. **A,** Powered oscillating blade-type dermatome with depth gauges on each side of blade. **B,** Drum-type dermatome to manually cut skin graft. **C,** DeSilva freehand skin graft knife. **D,** Assistant provides countertraction for use of a manual Watson skin graft knife.

Freehand Skin Graft Knives and Dermatomes

Freehand knife dermatomes are used when the surface can be stabilized for precision cutting. The depth of the cut is determined by the setting on the blade gauge and adjusted by turning screws on the handle. Most styles have disposable blades. American surgeons Vilray Blair (1871–1955) and James Barrett Brown (1899–1971) developed a freehand knife that was modified by later plastic surgeons. The original style was designed like a straight razor but was later modified to include a roller for more accurate depth measurement (see Fig. 40.7, *C, D*).

Drum-Style Skin Graft Dermatomes

Padgett and Reese dermatomes consist of one half of a metal drum, which forms half a circle (see Fig. 40.7, *B*). A metal handle through the center of the drum has an arm on each end. These arms hold the bar that carries the blade. The bar swings around the drum to cut the graft. The size of the graft is limited by the width and length of the drum. An adhesive is placed on both the skin surface and the drum to keep the skin in contact with the drum. The knife blade is moved from side to side as slight tension is exerted on the skin by rotating the drum. The drum-type dermatome is used on flat, open areas because it is bulky. Its use is limited by the body contour and the amount of suitable skin on the donor site.

Dermatome tape is used with the Reese dermatome. Packaged sterile, the tape has an adhesive coating on each side, covered with a paper backing. The backing is removed on one side and applied to the drum, taking care to line up the edges of the tape and the drum. After the backing paper is removed from the other side of the tape, the drum is placed on the skin, which adheres to it.

When a drum-type dermatome is being handled, the blade carrier is always grasped to prevent its swinging around the drum and seriously injuring the hands. The dermatome is left in the sterile rack when not in use or until the blade is removed.

Powered Skin Graft Dermatomes

Oscillating blade-type dermatomes may be electric or air powered with compressed nitrogen or air. The length of the graft is limited only by the donor site. The surgeon checks the adjustable-depth gauge before cutting the graft (see Fig. 40.7, *A*). The oscillating blade, free of vibrations, takes an accurate graft from donor sites that overlie firm structures, such as bone. The oscillating blade-type dermatome generally is not used on the abdominal wall, where underlying support is not firm.

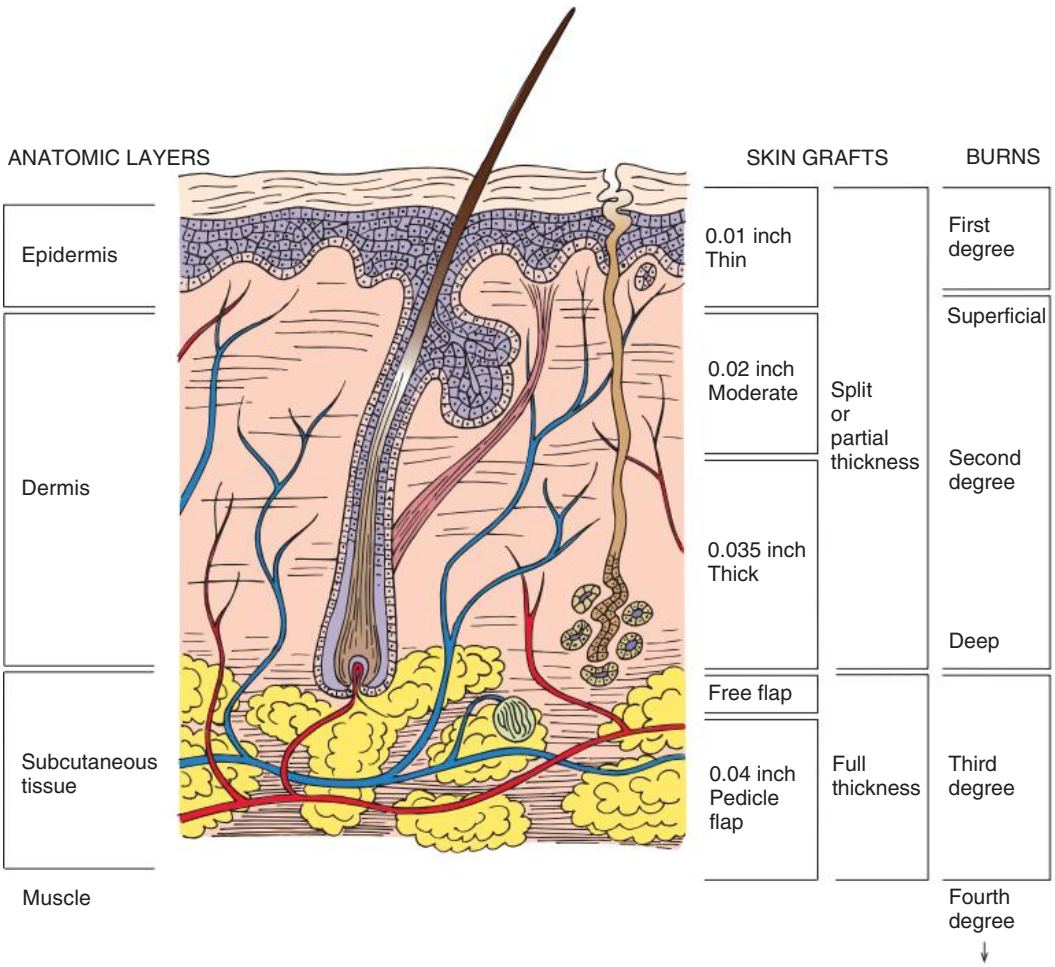
Care is used in handling these precision dermatomes. If the dermatome is electric, the circulator should remove the foot pedal after the graft is taken. If the dermatome is air powered, the scrub person and surgeon should place a thumb under the lever on the handle while preparing the instrument for use. These dermatomes cannot be immersed in water or put in a washer-sterilizer or ultrasonic cleaner. The manufacturer's instructions should be followed for use, care, and sterilization.

Types of Skin and Tissue Grafts

Skin Grafts

The epidermis, including the basal layer of the dermis that generates new skin, is transplanted from a donor site to a recipient site, in which it becomes a part of living tissue in that area. Adherence to healthy underlying tissue and adequate vascularity are necessary for graft take (survival). A fibrin layer forms to bind the graft to the recipient site and to provide nourishment until vascularization is established in the graft. The depth of the graft (Fig. 40.8) varies according to its purpose, as follows:

- **Split-thickness skin graft (STSG):** The epidermis and half of the dermis to a depth of 0.010 to 0.035 inch (0.3 to 1 mm) are removed. The donor site heals uneventfully unless it becomes infected. STSGs are widely used to cover large denuded areas on the back, trunk, and legs and can be meshed to cover larger areas. The donor site can be reused in 2 to 3 weeks after healing.
- **Full-thickness skin graft (FTSG):** The epidermis, dermis, and occasionally subcutaneous fat at a depth greater than 0.035 inch (1 mm) are removed or elevated. FTSGs inhibit wound contraction better than STSGs and generally are preferred on the face, neck, hands, elbows, axillae, knees, and feet. The donor site is either grafted or closed by primary intention. The donor site cannot be used again in the future.



• **Fig. 40.8** Cross-section of skin and subcutaneous tissue, relative thickness of skin grafts, and categorization of burn injury.

- **Composite graft**: This graft includes epidermis, dermis, fat, and other structures such as bone, cartilage, nerve, or tendon.

The desired thickness of a skin graft is determined by the plastic surgeon before the skin is incised. The appropriate cutting instrument is selected to obtain the graft.

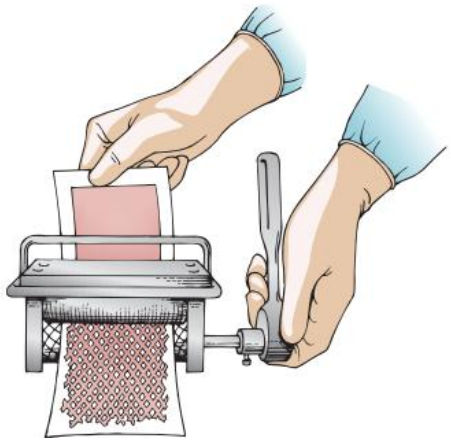
Split-Thickness Thiersch Graft

Removed with a freehand skin graft knife or dermatome, Thiersch grafts are used to cover superficial defects. The surgeon may use sutures or skin staples along the edges of the graft to hold it to underlying subcutaneous tissue. An even-pressure dressing is secured over the top of the graft. This prevents movement and helps obliterate dead space in the recipient site. The skin of the donor site regenerates rapidly, and the same area can be used again in 2 or 3 weeks if necessary. If a thin graft is taken and the site remains free of infection, that donor site may be used again sooner.

Split-Thickness Mesh Graft

A mesh graft makes it possible to obtain a greater area of coverage from a STSG. After removal with a dermatome, the graft is placed on a plastic derma carrier, cut side down on the **mesher** platform. This is a rigid base to keep the graft spread out flat while it is put through a mesh dermatome. This instrument cuts small parallel slits in the graft. When expanded, the slits become diamond-shaped openings (Fig. 40.9). This permits expansion of the graft to cover an area three times as large as the original graft obtained from the donor site.

The mesh graft can be placed over the recipient site with slight tension. The increased edge exposures are conducive to rapid epithelialization. The mesh allows serum to escape through the openings. If a mesh dermatome is not available or is not feasible to use, slits can be made with a knife blade in the donor graft to accomplish the same purposes.



• **Fig. 40.9** Split-thickness skin graft being passed through mesh dermatome. Mesh graft expands to obtain greater coverage of recipient graft area.

Although this method covers a larger area and contours well, much of the wound has to heal by secondary intention, causing scar contracture. The healed area maintains a "cobblestone" appearance.

Full-Thickness Wolfe Graft

The Wolfe graft is cut exactly to the size and shape of the recipient site with a skin graft knife. It is sutured into place under normal skin tension. FTSGs are used on the face, neck, or hands to fill in superficial denuded areas and over joints to prevent contractures. This graft does not become viable readily on granulated surfaces, and the amount that can be transferred is much more limited than with Thiersch grafts.

To ensure viability, the donor graft must be held in apposition to healthy tissue in the underlying recipient site. The surgeon tacks the edges of the graft with sutures or staples. The middle portion may be "quilted" (i.e., affixed) with sutures or staples. The graft is covered with an even-pressure dressing.

Free Composite Grafts

A composite graft usually includes skin, subcutaneous tissue and cartilage, bone, or other tissues. The viability of the graft depends on ingrowth of the vascular system from the recipient site.

Free Omental Grafts

A free graft of omentum can be used to provide contour in a soft tissue defect in the face or neck, to resurface an area such as the scalp, to provide vascular support for bone and skin grafts around prosthetic materials, and to control wound infection, such as in the chest wall. Omentum will localize inflammation and wall off infection.

It will not resorb when grafted. Omentum resected from the peritoneal cavity can be transplanted to an avascular area if sufficient blood vessels are available for microvascular anastomoses to the gastroepiploic artery and vein in the graft. STSGs cover the omental graft.

Pedicle Flaps

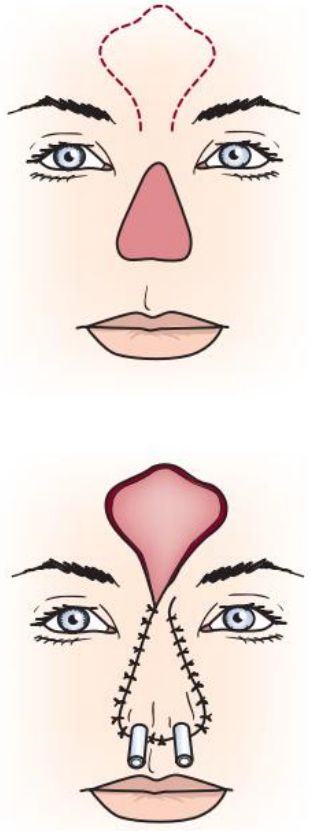
Creation of a pedicle flap may be the procedure of choice to reconstruct deformities of soft tissue loss that will create or that have created an obvious aesthetic or functional disability for the patient. The pedicle, which is the attachment of elevated tissue to the donor site, must contain a vascular bundle to maintain blood supply to the tissue. Pedicle flaps are constructed from several types of tissues and sources of vascular bundles. Nasal reconstruction is commonly done this way (Fig. 40.10).

Flap survival seems to depend on a reduction in vascular resistance or an increase in arterial perfusion pressure, or both. Several techniques are used to monitor circulation in the flap intraoperatively and postoperatively.

Arterialized Tissue Flap

An FTSG contains a vascular bundle within subcutaneous tissue and skin. Arterialized flaps may contain the following:

- Axial vasculature from axial vessels that supply a fairly definite area of skin and subcutaneous tissue. A direct cutaneous artery flows through the length of the flap.
- Random or local vasculature from a subdermal plexus. Random flaps do not have a specific blood vessel within the flap. These are usually small flaps created around the head or neck.
- Both axial and random vasculature. A deltopectoral flap, for example, has axial vessels from the sternal region and random vessels in the deltoid area.



• **Fig. 40.10** Pedicle flap nose reconstruction.

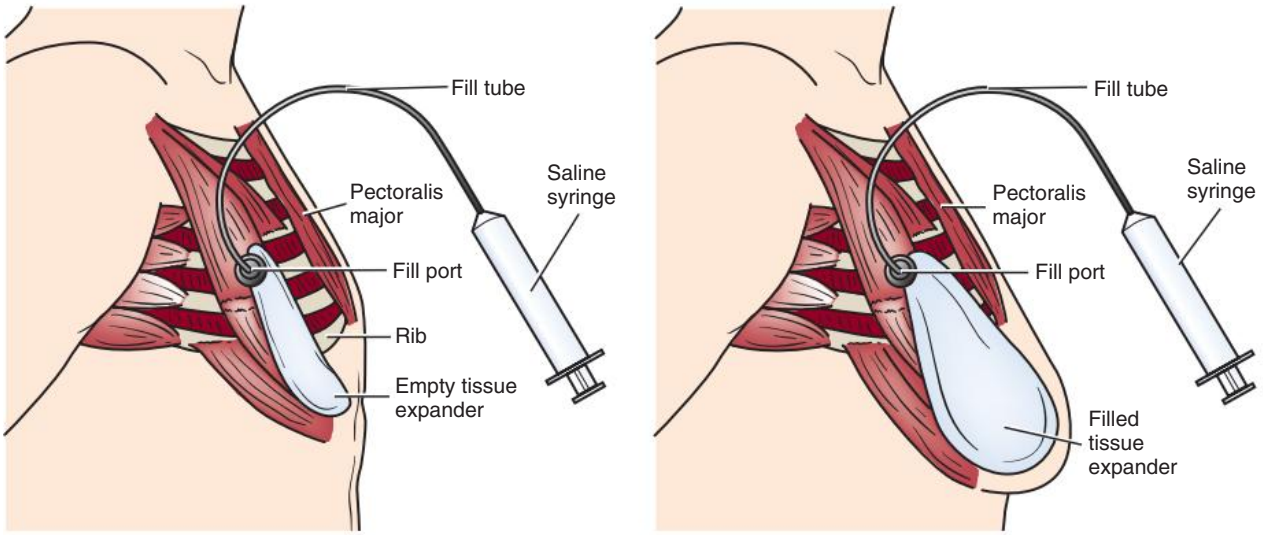
Depending on the proximity of the recipient site to the donor site, the pedicle flap will be one of the types discussed in the next three sections.

Rotational Flap. One end of the flap is rotated and sutured to the recipient site to cover a denuded area. The flap tissue is obtained from an area near the recipient site. Arterialized skin pedicle flaps with axial vasculature are rotated in a one-stage procedure. Random rotational pedicle flaps can be used in the face because vascularity is sufficient in the head and neck.

Cross-Finger Flap. Tissue at the donor site is undermined and rotated to cover a small defect in an adjacent digit.

Tissue Expansion Flap. The surface of the dermal-epidermal layer can be increased by implanting a tissue expansion device subcutaneously, close to the defect (Fig. 40.11). Available in many sizes and shapes, the device has a soft, pliable silicone pouch connected by tubing to a self-sealing inflation reservoir. After insertion under a designated area for creation of the skin flap, the pouch is filled with saline by injecting small amounts into the reservoir. Rapid expansion may be achieved immediately in the head or neck area or gradually over a period of weeks to months in other areas. Natural physiologic skin expansion occurs. The dermis stretches and thins while the epidermis duplicates itself without changing thickness. Tissue will increase to about 1½ times the width of the device.

The vascular network that develops produces more viable tissue than that of other pedicle flaps. The tissue has similar color, texture, and thickness as the recipient site. The expanded tissue is advanced or transferred to cover the defect, helping to minimize scarring and donor site deformity. Tissue expansion flaps are used for scalp and facial defects, breast reconstruction, and other soft



• **Fig. 40.11** Tissue expander under the pectoralis muscle.

tissue defects. They can be used for closure of large donor site defects.

Myocutaneous Flap

Pedicle myocutaneous flaps allow safe and rapid transfer of tissue over long distances to cover large defects and vital structures. They are used, for example, to close soft tissue defects in the lower extremities, to cover pressure sores, and to reconstruct contour after head and neck resection and mastectomy.

A myocutaneous flap incorporates the muscle with its overlying fascia, subcutaneous tissue, and skin. It receives a vigorous blood supply from the vascular pedicle that supplies the underlying muscle (see Fig. 40.6). It may include a neurovascular bundle with nerve fibers to innervate the muscle in the flap. Usually done as a one-stage procedure, myocutaneous flaps can be created from the following and other muscles:

- Trapezius
- Sternocleidomastoid
- Platysma
- Latissimus dorsi
- Pectoralis major
- Rectus abdominis
- Gracilis
- Gluteus maximus
- Tensor fascia lata
- Biceps or quadriceps femoris

Fasciocutaneous Flap

Mobilized fascia, subcutaneous tissue, and skin are transferred as pedicle flaps similarly to the way myocutaneous flaps are transferred. The donor site may need to be covered with an STSG.

Muscle Flap

A divided section of a muscle with its proximal blood supply intact can be rotated over a soft tissue defect, such as an ulcer on the leg or buttock. A vascularized muscle flap may be covered with an STSG.

Neurosensory Flap

Sensory nerves may remain intact in a flap with other tissues or be restored by microneural anastomosis or by nerve grafting. Preservation of nerves in a vascularized flap becomes important when sensation is critical to function, as in the hand or foot.

Omental Flap

Omentum is mobilized from the peritoneal cavity, without compromise of the vascular pedicle, to cover an infected mediastinal wound or a defect in the chest wall, such as after resection for irradiation necrosis or a neoplasm. The vascularity of donor omentum revascularizes the reconstructed chest wall recipient site. STSGs, which may be mesh grafts, cover the omental flap. If additional rigidity is needed to restore the chest wall, polypropylene mesh may be sutured inside the ribcage to supplement the strength of the omental flap.

Microsurgical Free-Flap Transfer

Composite free flaps or grafts of tissue are resected and transplanted from one area of the body to another to cover a denuded area, to restore function, or to restore body contour. Microsurgical techniques allow one-stage transfer of tissues.[2] The main artery and vein supplying donor tissues must be anastomosed to vessels in the recipient site under the operating microscope. Often two teams work simultaneously at donor and recipient sites. These are lengthy, tedious procedures, often taking many hours to complete.

Fasciocutaneous Graft

Free grafts of fascia with overlying skin, with or without underlying muscle, may be transferred. For example, temporalis fascia may be transplanted into another area in the face.

Free Muscle Graft

Free island grafts of functional muscle can be resected and transplanted to replace motor function in another area. Although only a small percentage of the graft survives, significant regeneration of muscle occurs. Free muscle, transferred by microvascular techniques and covered with an STSG, promotes healing of infected wounds.

Vascularized Muscle Pedicle Free Flap

In a multistaged procedure, a myocutaneous flap is raised at the donor site and allowed to develop a new, isolated vascular system

before free transfer to a recipient site. The vascular system in the muscle underlying the skin flap branches out to supply the skin. At the final stage, the newly vascularized muscle pedicle is dissected free from the donor site. The donor site may need to be covered with an STSG.

Under the operating microscope, arteries and veins in the flap are anastomosed to vessels at the recipient site. Two teams may complete the final stage: one prepares and closes the recipient site and the other frees the flap and closes the donor site. The advantage of this type of flap is that the surgeon can select donor skin that will best provide color, texture, bulk, and contour at the recipient site, such as on the face.

Neurovascular Free Flap

Fascicles of nerves must be anastomosed to restore sensation; in addition, microvascular anastomoses of arteries and veins are needed to maintain viability of the donor tissue. A neurovascular free flap, also known as a sensate flap, may be taken from the scapular region. Many surgeons use the scapular flap because it is easy to dissect, has a long vascular pedicle, and creates a minimal donor site deformity. Other donor sites include the medial and lateral thigh and the lateral aspect of the upper arm.

Free Autologous Bone Graft

Vascularized autografts of bone are superior in strength and are less prone to deossification and structural weakness than are conventional bone grafts. Anastomosis of the vascular bundle with a free rib, for example, may increase the chance of survival of the donor bone graft in a poorly vascularized recipient site (Fig. 40.12).

Composite Myoosteocutaneous Free Flap

A composite flap of skin, muscle, and bone provides soft tissue bulk, internal structural support, and external coverage in one-stage reconstruction of compound defects after head and neck resection. The skin and iliac crest on a vascular pedicle from the deep circumflex artery may be preferred. The scapula and tissue from the upper arm provide an alternative donor site. Or the skin, soft tissue, and latissimus dorsi muscle along with a portion of an underlying rib may be dissected free, preserving the thoracodorsal vessels for anastomosis at the recipient site. Other donor sites include the radial forearm and the fibula with the dorsalis pedis muscle.

Digital Transfer

Microneurovascular techniques are used for replantation of traumatically amputated digits. Less common is the toe-to-thumb transfer, called the free wrap-around neurovascular flap, performed when an amputated thumb cannot be salvaged. Skin from the dorsum of the foot, the great toe (including tendons and bone), and the second toe web space are transferred as a sensate flap to the hand.

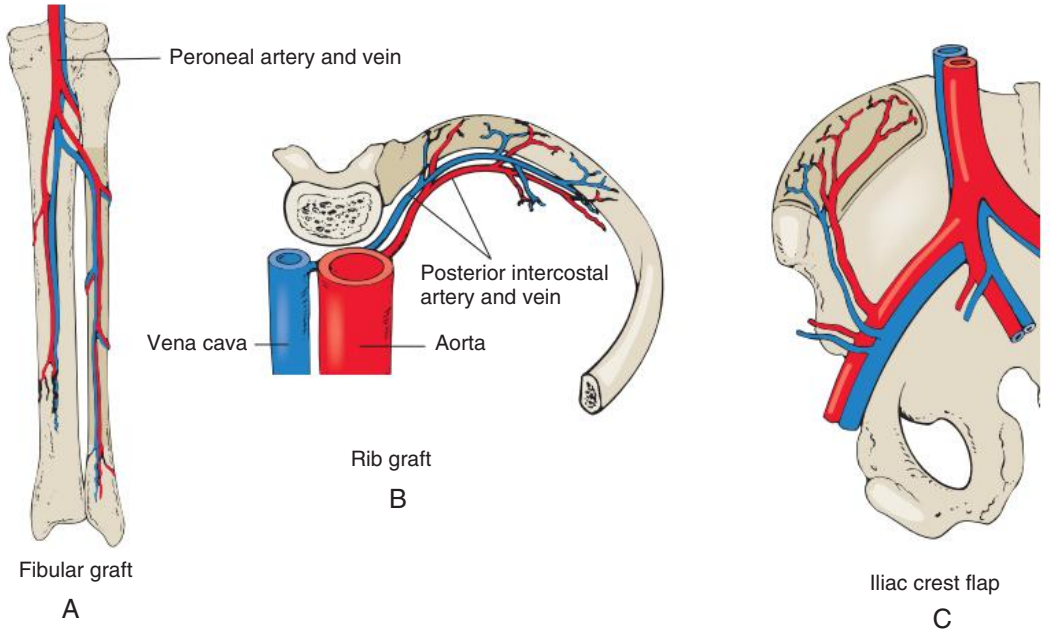
After bone fixation and tendon anastomoses, arterial circulation and venous drainage are established under the microscope. Digital nerves are anastomosed to reinnervate sensation and function. Other toes can be similarly transferred for finger reconstruction.

Replantation of Amputated Parts

Replantation may be attempted to salvage a traumatically amputated digit, hand, or entire upper extremity. A severed foot or lower extremity presents more formidable problems because of the functional necessity for weight bearing. The victim of amputation of the scalp, nose, external ear, or penis also is a candidate for replantation. Using microsurgical techniques, replanted parts can survive with varying degrees of effectiveness.

Functional recovery, up to 80% of normal in some patients, may take up to a year or longer because it takes time for nerves to regenerate (approximately 2 inches [5 cm] per month). A team of specialists in hand surgery or of plastic surgeons with microvascular skill is vital to success in these arduous procedures.

Correct care and preservation of the severed part for transport with the patient is also vital to success. The amputated part should be placed dry into a plastic bag, which is then sealed and immersed in crushed ice inside an insulated container (e.g., Styrofoam) to



• **Fig. 40.12** Common donor sites for vascularized bone grafts. **A,** Fibular graft. **B,** Rib graft. **C,** Iliac crest graft.

retard melting of the ice during travel. The part should not be warmed, frozen, or packed in dry ice. Rapid transport and cooling with ice will buy time.

Initial treatment involves assessment of the total patient. The patient and family should be supported emotionally but not given definitive promises in regard to outcome. The surgeon considers numerous factors when planning for replantation: the need for the part, associated disease and injuries, economic and psychologic factors, and age. The following two criteria are of special significance:

1. The replanted part should have the potential for being useful.
2. There should be no undue risk to the general safety of the patient if the procedure is performed.

Replantation is more successful in young patients than in older patients. Also, incomplete amputations are more successful because they have intact subcutaneous venous circulation in the skin bridges. Restoration is much more difficult in crush injuries than in sharp, clean amputations. Contraindications to replantation include the following:

- Prolonged warm ischemia
- Severe bruising or crushing injury
- Multiple fractures or injury at different levels in the same digit
- Associated injuries that preclude the effort

Supportive therapy after injury includes tetanus toxoid, IV antibiotics, fluid replacement therapy, blood products, and judicious administration of anticoagulants.

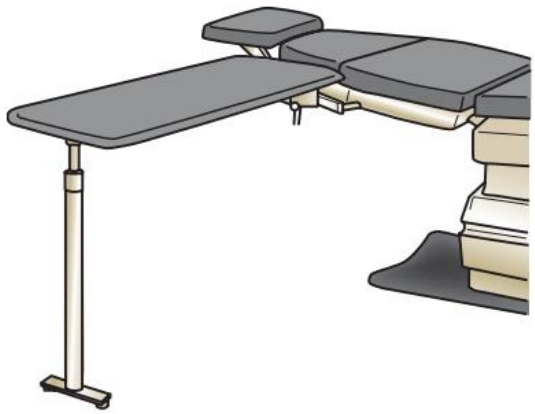
Preoperative patient preparation is in anticipation of a long procedure. The surgical procedure may take from 4 to 16 hours. The patient is placed on a gel-filled mattress. The head, scapulae, sacrum, and heels are padded. A footboard may be used and antiembolic stockings or sequential compression devices applied. An indwelling Foley catheter is inserted if the procedure will take longer than 2 hours.

Most replantations of the hand are done with the patient under moderate sedation and an axillary or supraclavicular block with a long-acting agent, such as bupivacaine (Marcaine, Sensorcaine) without epinephrine. General anesthesia is used for children and may be needed for adults for a long procedure.

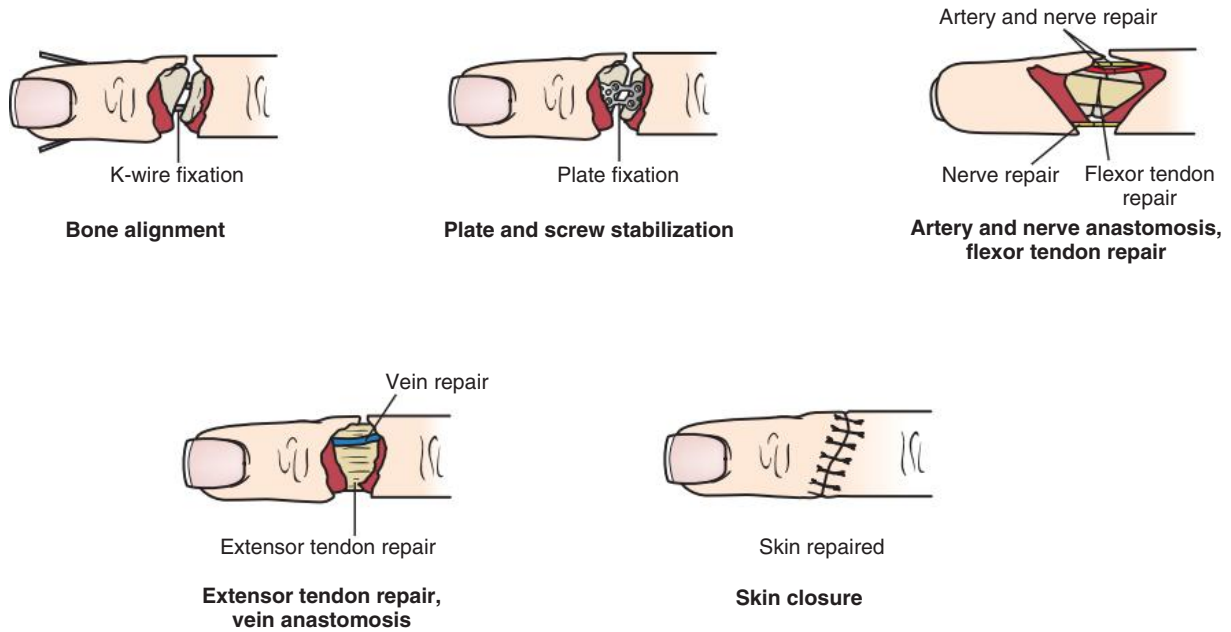
These surgical procedures usually involve a two-team approach: one team prepares the recipient site with the patient's hand and arm positioned on a hand table (Fig. 40.13), and the other prepares the severed or distal part.

In the operating room (OR), the amputated part is cleansed with lactated Ringer's solution or normal saline. **Debridement** of crushed tissue is carried out. Vessels are isolated for repair, and vessel patency is ensured. The basic steps of replantation of digits or extremities include the following (Fig. 40.14):

1. Identify proximal and distal tendons, nerves, and vessels.
2. Shorten bone within an acceptable limit necessary for tension-free repair of blood vessels, nerves, and soft tissues.
3. Stabilize the skeletal structure, such as with internal wire fixation techniques, to maintain joint continuity and fusion in functional position. Small plates and screws may be used.
4. Suture tendons and ligaments, both extensors and flexors, appropriately to lessen the junctional scar process that can inhibit motion.
5. Anastomose arteries and nerves. The vessels may be flushed with heparin solution, and systemic anticoagulants may be given. Antispasmodic agents may be needed.



• **Fig. 40.13** Specialized hand table. The team is seated around the table.



• **Fig. 40.14** Steps in digit replantation.

6. Anastomose veins. A general rule is that more veins are anastomosed than are arteries to provide sufficient venous return and thereby minimize edema. Swelling creates pressure that impedes circulation, leading to necrosis. Leech therapy may be indicated to lessen the effects of diminished venous drainage and swelling.
7. Repair soft tissues and close the skin.
8. Perform a skin graft or tissue flap or transfer if necessary.

Microsurgical techniques are necessary for nerve, artery, and vein repairs of structures that have an external diameter of 1 mm or less.

To avoid constriction, a circumferential bandage is not applied. Instead, a foam bandage is used. The dressing is padded to prevent pressure sores and nerve damage. The original dressing is not changed for 10 days unless indicated.

Postoperative care is extremely important. Dressings must be checked carefully because even slight manipulation can cause great damage.

Checking only the tip of the digit for circulation is not adequate. Circulation is verified by cautiously looking into the dressing to check the capillary refill, color, temperature, and drainage. Doppler imaging and a temperature probe may be used to evaluate arterial circulation. Patients are not permitted to smoke or chew tobacco because nicotine is a vasoconstrictor. Constriction of vessels may reduce circulation and cause devitalization of tissue.

The many hours expended by the OR team initially to achieve a successful repair of all structures can relieve the patient of subsequent procedures. The objective is to obtain maximal return of function by minimizing permanent disability. Physical and occupational therapies are important in rehabilitation.

General Considerations for All Tissue Autografts

1. Hypothermia is avoided. Room temperature should be increased to 75° F to 80° F (24° to 27° C).
2. For long procedures, the patient should be positioned on a gel pad mattress.
3. Skin may be prepped with a colorless antiseptic agent so that the plastic surgeon can see the true skin color and assess the vascularity of the donor graft.
4. Donor and recipient sites are prepped and draped separately but concurrently. Care is taken that cross-contamination does not occur from one site to the other.
5. The recipient site is covered with a sterile drape until the surgeon is ready to apply a free graft or pedicle flap if preparation of the donor site will be the first procedure. If the recipient site must be prepared or debrided to receive the donor graft or flap, the donor site is covered with a sterile towel.
6. A separate sterile instrument table is prepared for the donor site. This includes appropriate instruments for obtaining the graft or flap and dressings for the donor site. Two surgical teams may work simultaneously.

   Place the dermatome on a separate, small sterile table, never on the recipient instrument table. Handle dermatomes carefully so the depth gauge is not disturbed. Care is taken to disconnect the power when loading the blades to prevent accidental activation of the device.
7. Grafts are kept moist by placing them in a basin and covering with normal saline. A free flap should be kept in cool saline until the recipient site is prepared. Ice may damage tissues and should be avoided.
8. The operating microscope and appropriate microinstruments must be in readiness for microvascular and neurologic anastomoses.
9. Tissue viability must be ensured. A sterile device may be needed during the surgical procedure to identify major blood vessels underlying a graft. Assessment of the patency of vessels and perfusion of the flap is possible through several types of monitoring.
   a. *Doppler probe:* A Doppler probe is placed on the recipient site preoperatively to obtain baseline measurements for comparison with postoperative measurements. The device has an audible pulsation sound and a digital readout. Ultrasonic Doppler probes also may be used for monitoring arterial vascularity of a part.
   b. *Photoplethysmographic disc:* A disc applied to the flap surface measures reflected light from pulsatile blood flow changes in tissue. A change in blood volume in tissue produces a corresponding change in the amount of light reflected. These changes are amplified and displayed on an oscilloscope.
   c. *Fluorometer:* A fluorescing dye is injected IV, and fluorescence is measured with a fluorometer to evaluate perfusion of the flap. Fluorescein and an ultraviolet Wood's lamp are used to check patency and perfusion. The room is darkened to see fluorescence. A photomultiplier may be used to amplify skin fluorescent emission.
   d. *Thermocouple probe:* The patency of a microvascular anastomosis can be assessed by the temperature in surrounding tissues.
   e. *Oxygen saturation:* Oxygen saturation of a flap can be monitored postoperatively with a probe similar to a pulse oximeter. Vioptix uses near-infrared spectroscopy to measure oxygen levels in the healing tissues.
10. Hemostasis is obtained during the surgical procedure with the use of warm saline packs, pressure, or thrombin.
11. An ESU is used very sparingly to prevent the devitalization of tissues.
12. Dressings over grafts vary by surgeon preference. Stent fixation to obtain pressure on the grafted area may be preferred. Some plastic surgeons omit pressure dressings and use an exposure technique on grafts so they can watch the graft and drain a hematoma or seroma if necessary.

The graft is kept covered with sterile, moist saline gauze dressings to keep the skin moist until revascularization occurs. Synthetic moisture- and vapor-permeable adhesive dressings are impermeable to liquid and bacteria. Healing under these occlusive dressings may be more rapid and less painful than at donor sites covered with fine mesh gauze. A cast may be applied to immobilize extremities for pedicle flaps.

Head and Neck Plastic and Reconstructive Procedures

Some plastic surgeons specialize in head and neck oncology or reconstruction, or both. Others limit their practice to aesthetic, or cosmetic, surgery.

Soft Tissue Reconstruction

Defects in soft tissues of the face or scalp, usually as a result of trauma, may be reconstructed by advancement of tissue expanded from an adjacent area. This technique ensures consistent skin

color, texture, and hair-bearing characteristics. Other types of grafts or flaps may be necessary or preferred.

Craniofacial Surgical Procedures

The plastic surgeon usually heads the multidisciplinary team that performs the complex craniofacial procedures discussed in Chapter 41. Many of the concepts developed for these procedures are applied in less-complicated surgical procedures. A variety of extracranial osteotomies, with or without bone grafts, reshape the bony framework of the face and skull. The desired aesthetic and functional results can be obtained only by painstakingly careful planning, dissection, and repositioning.

Maxillofacial and Oral Surgical Procedures

Plastic surgeons reconstruct soft tissue defects around and in the mouth that are caused by trauma or surgical resection. Those maxillofacial procedures involving bony structures that may also be performed by plastic surgeons are discussed in Chapter 41. Congenital deformities are discussed in Chapter 8.

Facial Nerve Grafting

Restoration of the quality of facial expressions in a patient with severe facial nerve paralysis can be accomplished by transfacial nerve grafting. Segments of nerve grafts are brought through tunnels across the lips from the normal side of the face to the paralyzed side. These are anastomosed to the distal facial nerve on the normal side and then to the proximal branches of the injured nerve on the paralyzed side.

The overpull of the mouth and lower face toward the normal side is balanced when the nerve graft is anastomosed between fascicles of the intact facial nerve innervating the facial muscles to the same fascicles on the denervated side. If the facial muscle has been paralyzed for a prolonged period, the serratus muscle from the chest wall may be transplanted and innervated by the facial nerve.

Repair of Lacerations of the Lip or Mouth

Wound edges of the lips and/or mucosa in the mouth are carefully sutured to repair lacerations. The borders of the vermilion line are carefully realigned.

Excision of Leukoplakia

Chronic irritation can result in an abnormal whitening of the mucous membrane of the lip and tongue (leukoplakia), a lesion primarily seen in heavy smokers. Sharp dissection or a carbon dioxide (CO_2) laser is used to resect a precancerous lesion.

Excision of a Lip Tumor

Excision of a lip tumor may be minor, with V-wedge excision, or extensive, depending on the stage of malignancy. Extensive lesions require a flap procedure for reconstruction. Closure starts on the vermillion border of the lip.

Lip Reconstruction

Lips can be adequately reconstructed by a variety of techniques to restore sensation and motor function after trauma or surgical resection. Lip cancer is the most common type of cancer in the upper respiratory and digestive tracts. Surgical procedures to reconstruct lips may be classified as follows:

- Repair by primary closure of the remaining lip segments.
- Full-thickness cross-lip flaps from the opposite lip.
- Arterialized or myocutaneous flaps from adjacent cheek or nasolabial tissue.
- Distant flaps. Arterialized and innervated myocutaneous flaps from the forehead or deltopectoral region may be used. These require staged procedures. Free microvascular composite grafts are done in one stage.

The ideal repair yields a lip that is not tight and that has a good vermilion border, an adequate sulcus (philtrum), good sensation, and good muscle tone.

Aesthetic Procedures

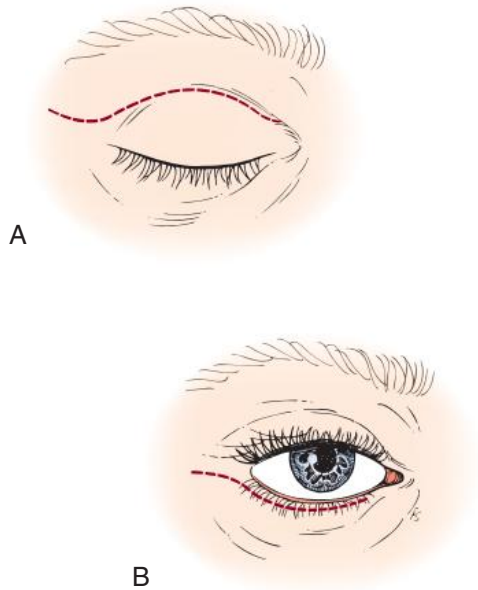
Procedures are not always performed for aesthetic purposes alone. They may restore function as well as correct a facial deformity or defect.

Blepharoplasty

Redundant skin and/or protruding orbital fat is excised to correct deformities of the upper or lower eyelids of one or both eyes. Blepharochalasis (loss of elasticity of the skin of the eyelids) can occur at any age and usually is of unknown cause. Dermatochalasis primarily involves hypertrophy of the skin of the upper lids. Resection of the excessive redundant skin removes the mechanical visual obstruction caused by these two conditions.

Protrusion of intraorbital fat into the lids is the most common eyelid deformity. It is often familial and is sometimes seen in patients as young as 20 years. This fat is removed from the compartments in the upper and/or lower lids to correct the deformity. This may be associated with dermatochalasis. A free graft of cartilage and mucosa from the nasal septum may be necessary to reconstruct lower eyelid defects after excision for tumor. Hypertrophy of the orbicularis muscle appears as a horizontal bulge below the lower lid margin. A skin-muscle flap resection may be performed. A surgical procedure for lifting the eyebrows will secondarily correct a hooding deformity of the upper lids caused by **ptosis** of the eyebrows.

These procedures are usually performed with the patient under local anesthesia. An upper lid incision is made in a natural skinfold; an incision in the lower lid is just under the eyelash line (Fig. 40.15). If the patient wears dentures, he or she should wear



• **Fig. 40.15** Incisions for blepharoplasty. **A,** Upper eyelid. **B,** Lower eyelid.

them to the OR because facial contour is distorted without them. The surgeon could remove too much or too little redundant skin.

Because of the proximity to the eyes, protrusion of periorbital fat may impair vision. Oculoplastic procedures may be performed by an ophthalmologist. Through a conjunctival incision, subconjunctival fat may be removed with a CO_2 laser. An eyelid procedure also may be necessary to protect the eye in a patient with facial nerve paralysis caused by trauma or tumor resection. A gold weight, between 0.05 and 1.2 g, or a spring can be inserted in the upper eyelid with the patient under local anesthesia. This protects the eye by allowing the eyelid to blink.

Otoplasty

Deformities of one or both external ears of an adult are usually the result of burns or traumatic avulsion. A segment of external ear that is partially or completely amputated often can be reattached to the remaining segment and buried beneath a flap of postauricular skin. The area over a completely severed auricular cartilage, which cannot be sutured back in place, is covered with a STSG initially.

Later reconstruction may include insertion of cartilage autograft taken from the patient's ribcage, a cartilage allograft, or a porous polyethylene or silicone prosthetic implant. The porous implant allows vascular and soft tissue ingrowth that reduces the risk for infection and extrusion—potential complications with a silicone implant. The graft or implant is buried beneath a segment of turned-down temporoparietal fascia. Then the area is covered with a STSG from the scalp or a FTSG from the opposite postauricular area.

Rhinoplasty

Reshaping of the nose, although usually performed for cosmetic alteration desired by the patient, may be necessary to correct defects caused by trauma or surgical resection of neoplasms. Subtle changes with limited nasal reduction or augmentation of the nasal tip with the patient's own nasal cartilage can result in an aesthetically attractive and physiologically normal nose in most patients. Through an intranasal incision, the nose can be shortened or narrowed by rearranging, reshaping, and/or removing bone and cartilage. This may be done to relieve breathing problems. Nasal packing and a nasal splint support the structures postoperatively.

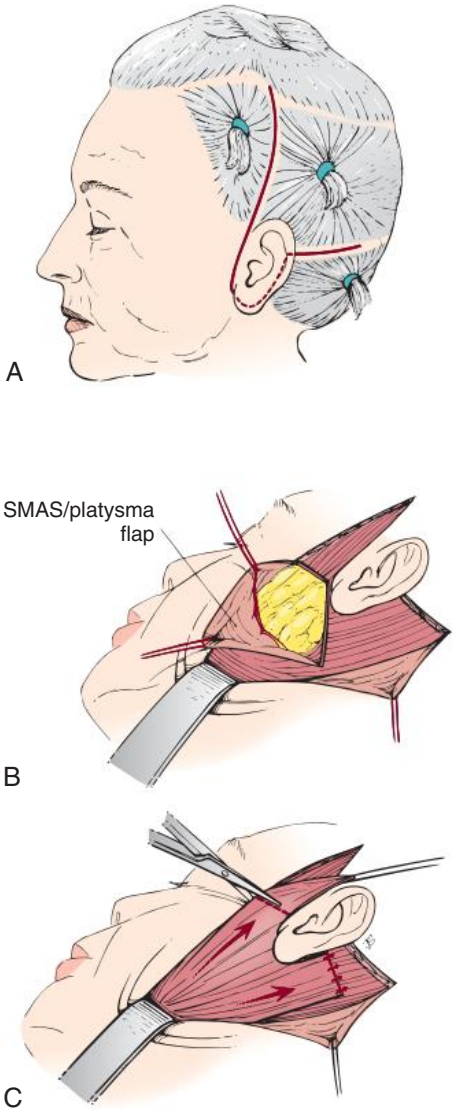
A free composite graft or pedicle flap may be necessary to close a large tissue defect. Bone or cartilage grafts may be needed for skeletal support. Prosthetic reconstruction for partial or total loss of the nose may be the procedure of choice.

Mentoplasty

The shape and size of the chin can be altered for aesthetics and/or functional bite disorders. The mandible can be repositioned forward or backward to change alignment in relation to the maxilla. Sections are removed to reduce size, or osteotomies are made to reshape the chin. An abnormally small jaw (micrognathia) is augmented with bone or cartilage grafts or a silicone implant or by advancing the mandible. Lip incompetence (inability to bring the lips together without tension) may be corrected during the same surgical procedure.

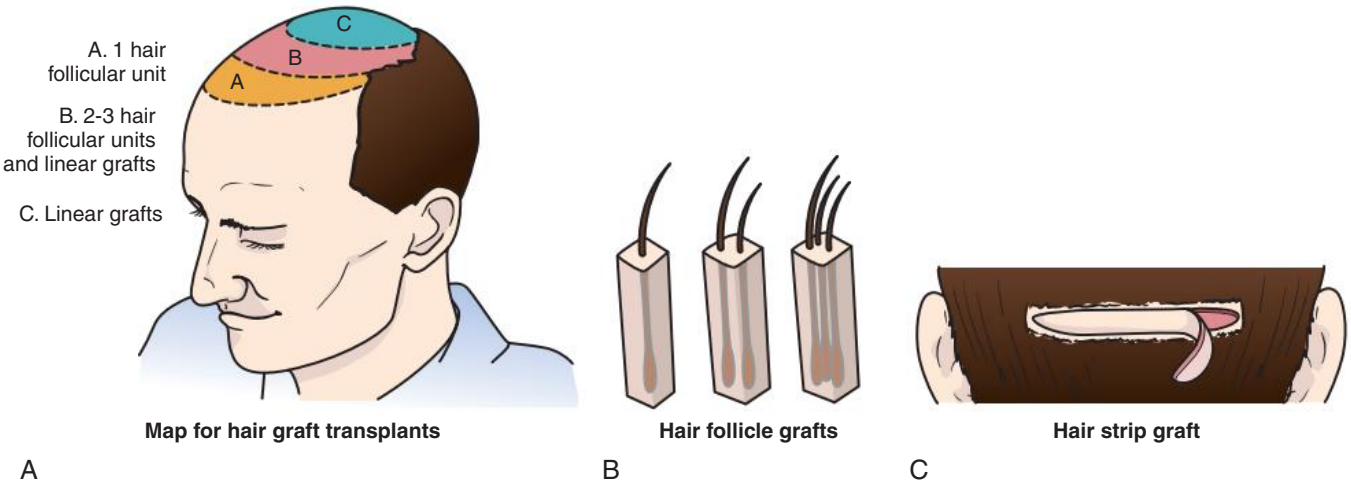
Rhytidoplasty

Commonly referred to as a face lift, rhytidoplasty involves extensive dissection from above the ear, both in front of and behind the pinna, downward along the jaw line and upper neck (Fig. 40.16, *A*). The skin is freed from underlying fascia. Wrinkles and folds caused by the normal aging process smooth out as the skin is lifted up and sutured in place. Dissection beneath the platysma muscle, referred to as the submuscular aponeurotic system (SMAS) procedure, minimizes the amount of skin undermined (see Fig. 40.16, *B*). The platysma is sutured back to the mastoid (see Fig. 40.16, *C*). Redundant skin is trimmed away.



• **Fig. 40.16** Rhytidoplasty (face lift). **A,** Incision from above ear and in front of and behind pinna. **B,** Dissection beneath and elevation of platysma flap (submuscular aponeurotic system [SMAS] procedure). **C,** Platysma muscle is sutured back to mastoid.

A modified lift can be attained by using a clear barbed suture under the skin to lift the bilateral fascial planes. Using this suture is considered minimally invasive. Endoscopic methods can be used to elevate fascial planes. No excess tissue is trimmed away. Patients are advised to minimize the stress over the sutured areas for 3 months by wearing a chin strap at night and avoid traction on the tissues of the face. More discussion of barbed suture is found in Chapter 28 in the discussion of synthetic sutures (barbed polydioxanone: Quill suture, contour thread). This clear synthetic self-anchoring suture is approved for use by the U.S. Food and Drug Administration (FDA). It is used for dermal suturing without the need for knotted ends. The surface of the



• **Fig. 40.17** Hair transplantation.

suture has raised barbs that are angled from the center to the ends in both directions.

Frequently other procedures, such as blepharoplasty or rhinoplasty, accompany this surgical procedure. Meticulous hemostasis is essential to prevent hematoma formation, the foremost complication of rhytidoplasty. Hypotensive anesthesia may be used to help reduce this incidence. Closed-wound suction drainage is frequently used with or without a pressure dressing applied after the surgical procedure.

Face Transplantation

Surgeons in France and China performed successful partial face transplantations in 2006. Full face transplantations were performed in 2010 in Spain and France. The first full face transplantation in the United States was performed in 2011 in Boston. Traumatic injury to the face can cause massive facial tissue loss for which there is no cosmetic or functional replacement. Microvascular anastomosis has made free-flap allogeneic transfer possible, and antirejection drugs offer the promise of long-term take. A face transplant can cause emotional trauma.[3] The patient knows he or she no longer looks the same as before the injury. Long-term success requires monitoring the graft for many years.[4]

Soft Tissue Augmentation

Fat transplantation may be done by mini-liposuction and injection of the patient's own tissue. Fat cells are withdrawn from the lower abdomen, hips, or thighs into a syringe through a hypodermic needle. The fat then is injected into areas around the lips or eyes to smooth wrinkles or into hollow spaces in the cheeks or other facial defects. This procedure may be done in conjunction with a rhytidoplasty. The correction is not permanent because the fat cells will die.

A purified form of bovine dermal collagen can be injected for the same purposes. A series of injections of small amounts of the collagen are deposited to fill small soft tissue defects or to smooth out wrinkles.

Hair Replacement

Hair follicles can be transplanted from the posterior aspect of the scalp to bald or balding areas. Hundreds of micrografts (4 mm) and minigrafts (4.5 mm) are implanted in staged rows over the entire bald area to change the hairline (Fig. 40.17). A new hairline can be initially established with rotational flaps from other parts of the scalp. This may necessitate tissue expansion. If hair loss is not complete, hair follicle grafts complement and thicken the existing hair. Several transplantation sessions may be necessary to achieve the final result the patient is seeking.

Plastic and Reconstructive Procedures of Other Body Areas

Adipose Tissue

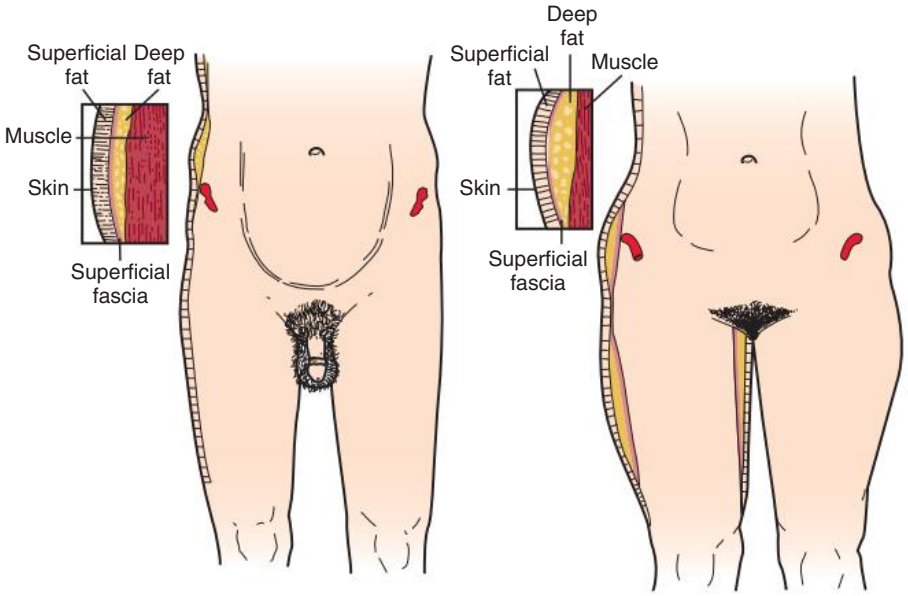
Lipectomy is an excision of excessive fat and redundant skin from the upper arms, abdomen, buttocks, thighs, or other body areas.

Liposuction

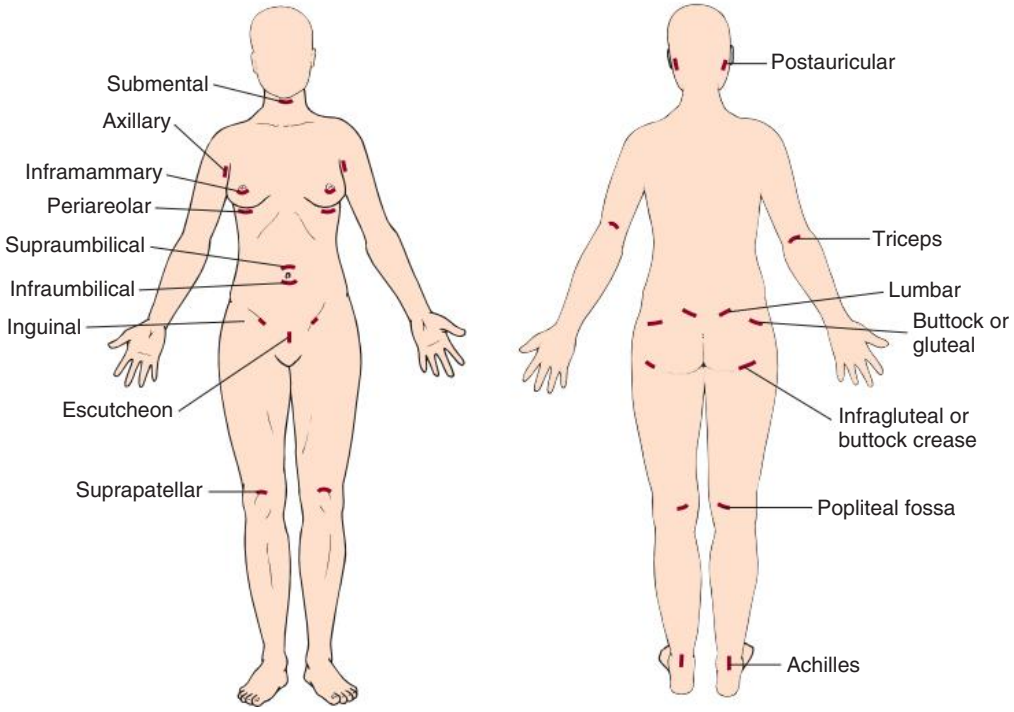
Localized areas of fat deposits are removed by suction-assisted lipectomy, known as liposuction, to alter body contours. Males and females differ in areas of localized fat deposits (Fig. 40.18). Most surgeons prefer to inject target tissue with 1% lidocaine with 1:100,000 epinephrine in saline to create a tumescent effect to plump up the fat and firm the surface. This solution also reduces blood loss during the surgical procedure. The average adult dosage range for tumescent injection should not exceed 7 mg/kg of lidocaine and in general should not total more than 500 mg.

A blunt, hollow, curved or straight metal cannula (Mercedes cannula) measuring 1.5 to 6 mm with multiple openings in the distal shaft connected to a suction machine is inserted through small skin incisions (Fig. 40.19). The cannula is moved back and forth along the axial plane, parallel to the skin surface, to bluntly dissect and aspirate cores of fat in a honeycomb pattern. This pattern allows for uniform tissue contouring. A laser may be used through the cannula to vaporize fat rather than suction it out. The laser diminishes bleeding by coagulating vessels. The patient's hematocrit level decreases by 1% for each 150 mL of fat removed by conventional liposuction.

Suction-assisted lipectomy may be used in conjunction with conventional abdominoplasty. It is also used to remove fat from the neck and chin, upper arms, breasts, flanks, buttocks, thighs, knees, and ankles. It can be used to defat transfer flaps and treat some forms of lymphedema and lipomas. The amount of fat removed should not exceed the ability of the overlying skin to contract and may be between 1500 and 2000 mL.



• **Fig. 40.18** Fat distributions differ between males and females.



• **Fig. 40.19** Incision areas for suction-assisted lipectomy.

If tumescence is used, 2500 to 3000 mL may be removed without complications. Large fluid volume shifts follow lipectomy, so the inflow and suction contents should be monitored closely. The incisions are sutured and reinforced with wound closure strips, and compression garments are worn for 10 days to 2 weeks postoperatively to control edema and help skin remodeling.

Postoperative discharge planning should include advising the patient that each cannula port site will ooze serosanguineous fluid for a few days. Padding the bed at home is recommended. Removing and donning the compression garment can be difficult because of the tightness required for the synthetic elastic to be effective.

The patient can shower with the compression garment on using a liquid antibacterial soap and dry the garment area with a cool hair dryer. If the garment is removed, the reapplication is easier if the patient's body is completely dry and body powder is applied to the skin.

Abdominoplasty

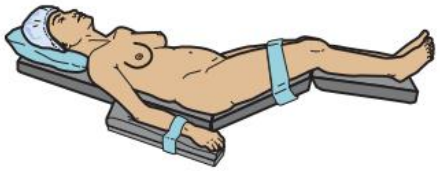
Abdominoplasty includes excising excess, lax abdominal wall skin and adipose tissue, and tightening abdominal wall musculature. This is usually a cosmetic procedure referred to as a "tummy tuck." Physical discomfort or the inability to perform personal

hygiene because of a large pannus that hangs like an apron over the lower abdomen and genital region may be a functional indication for the procedure. Its purpose is not to make an obese person thin. The most suitable patient is of ideal weight and in good health. Causes of the abdominal wall laxity include pregnancy, marked weight loss, and the aging process.

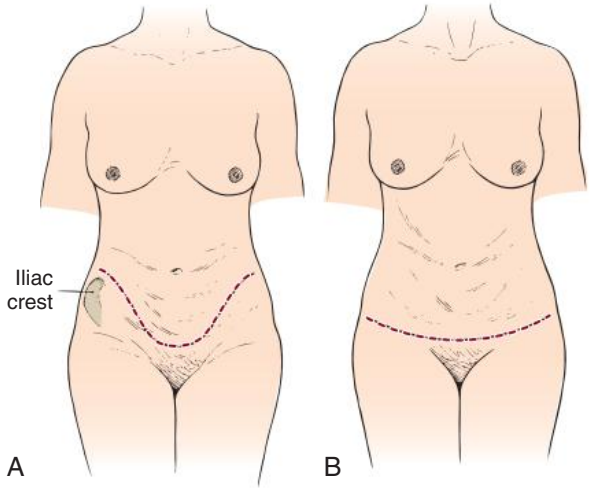
Preoperatively, the primary incision line is marked along a natural skinfold using a marking pen with the patient in a standing position. After the administration of the anesthetic agent, the head and foot of the OR bed are elevated 15 to 20 degrees to anteflex the patient's torso and decrease abdominal tension (Fig. 40.20). The surgeon chooses either a low transverse incision from one anterosuperior iliac crest to the other or a combination transverse secondary vertical incision in a fleur-de-lis pattern (Fig. 40.21). The typical area of dissection extends subcutaneously to the costal margins and xyphoid process superiorly and to the midaxillary to lateral axillary lines laterally.

The umbilicus is preserved on a vascularized stalk and repositioned in the abdominal wall after the rectus muscle is tightened (plicated) and excess skin, subcutaneous tissue, and fat are resected. When wound closure is completed, the abdominal wall should be flat and smooth. Closed-suction drainage, a bulky pressure dressing, and an abdominal binder are used to prevent hematoma formation and eliminate dead space.

Postoperatively the patient is restricted to complete bed rest with the head and foot of the bed flexed for 24 hours and then may ambulate progressively. Some surgeons will have a trapeze bar attached to the postoperative bed so the patient can shift positions easily.



• **Fig. 40.20** Patient positioning for abdominoplasty.



• **Fig. 40.21** Abdominoplasty incisions. **A,** Medial to iliac crest for patient who desires high "French cut" swimsuit. **B,** Natural abdominal skin crease fold below iliac crest.

Breast

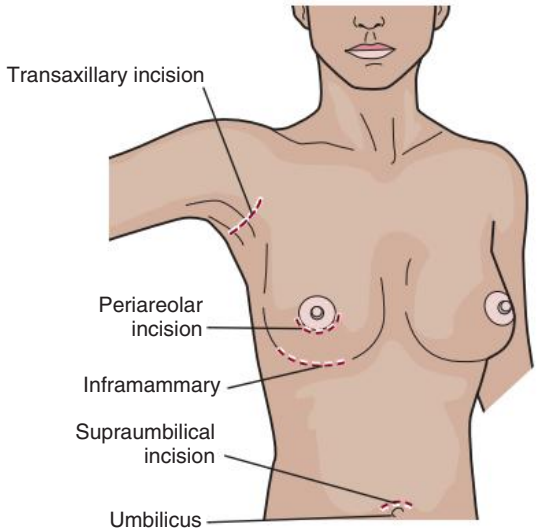
Breasts can be enlarged, reduced, or reconstructed. Unilateral augmentation or reduction is sometimes performed to correct asymmetry of the breasts.

Augmentation Mammoplasty

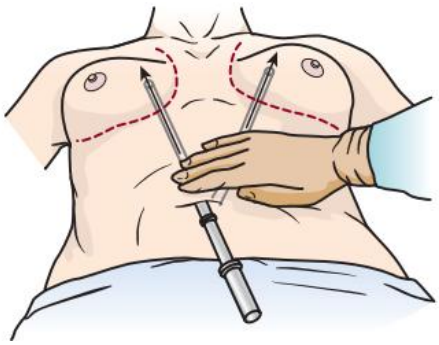
A bilateral mammoplasty usually is performed for aesthetics on a woman who desires larger breasts. Inflatable implants are inserted under breast tissue or the underlying pectoralis muscles and then filled with sterile saline solution through self-sealing valves.

The breast implant can be inserted through a periareolar, transaxillary, inframammary, or supraumbilical endoscopic approach (Figs. 40.22 and 40.23). The periareolar incision, made around the outside border of the lower half of the areola, is the most difficult for insertion of the implant, but it leaves the most inconspicuous scar. The transaxillary incision in the axilla does not scar the breast. The inframammary incision, the most common, is made transversely along the submammary fold. The implant is inserted into a pocket formed between the mammary gland and pectoralis muscle or under the muscle (Fig. 40.24).

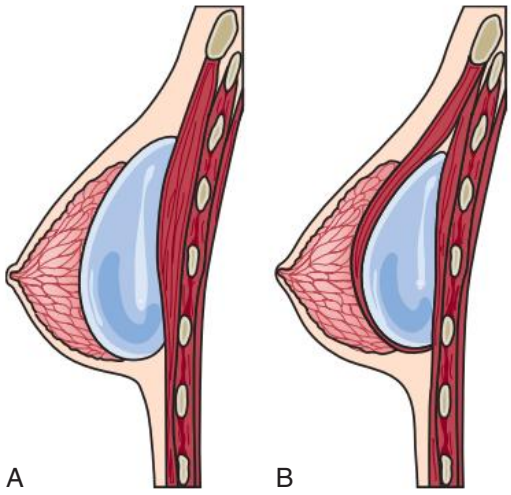
An implant also can be inserted through a supraumbilical endoscopic approach (transumbilical breast augmentation [TUBA]). This technique eliminates an incision into the breast. A single incision is made in the superior border of the inner aspect of the



• **Fig. 40.22** Common incisions for breast implant placement.



• **Fig. 40.23** Transumbilical breast augmentation (TUBA).



• **Fig. 40.24** Placement of breast implants. **A,** Placement of implant under the mammary gland and above the pectoralis muscle. **B,** Placement of implant under the pectoralis muscle.

umbilicus. An endoscope is tunneled between the fascia and subcutaneous tissue up to the breast.

Subpectoral pockets are dissected to accommodate breast implants. The dissection can be performed bluntly or by saline balloon expansion. The endoscope permits visual placement of a deflated **expander** between the breast tissue and the pectoralis muscle. The expander is filled with sterile saline solution, through a fill tube, to create a pocket for the implant. After insertion through the endoscope into the pocket, the deflated implant is inflated with sterile IV saline solution, and the fill tube is removed.

Implants are supplied sterile by the manufacturer. The manufacturer's instructions for sterilization of nonsterile implants must be followed. Sterile packages should not be opened by the circulating nurse until the surgeon selects the appropriate-sized implants. Silastic sizers are frequently used to make this determination. The implant identification card should be put in the patient's chart and each implant's catalog and lot number recorded.

The woman with breast implants is not excluded from routine screening mammography programs. Additional radiologic images may be taken to visualize all of the breast tissue. Ultrasonography may be performed at the same time to confirm the integrity of the implant. Studies have shown that the risk for rupturing the implant is not increased by compression during mammography if performed according to the American College of Radiology standards.

Capsular contraction, hematoma, infection, and skin necrosis are potential complications after prosthetic implantation for breast augmentation performed either unilaterally or bilaterally. Because of reported incidences of rupture and leakage, with the possibility of the development of autoimmune disease, implants containing silicone gel are not used for breast augmentation or reconstruction unless women are enrolled in a controlled clinical study.

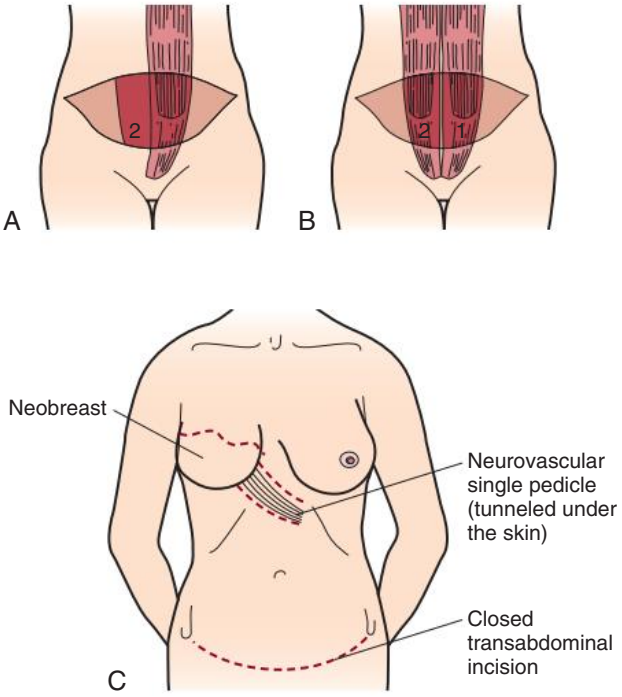
Explantation, or removing a ruptured or leaking silicone implant, frequently is complicated by intracapsular adhesions, also referred to as capsular contractures. Control of bleeding points is critical, to prevent silicone emboli in open blood vessels. This necessitates meticulous capsular dissection and hemostasis during removal of the implant shell, as well as irrigation with copious amounts of sterile saline solution to remove viscous silicone from the wound.

Reconstructive Mammoplasty

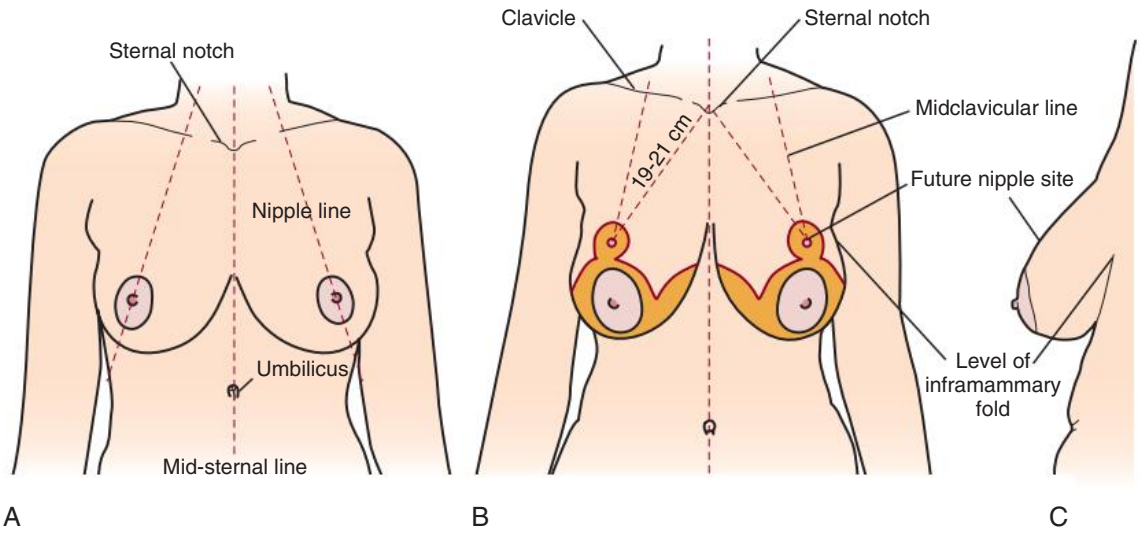
Breast reconstruction after mastectomy psychologically helps the patient cope with an altered body image. The type and timing of reconstruction are influenced by the patient's psychologic response to the mastectomy, the type of mastectomy, and the patient's diagnosis and prognosis.[5] Technical maneuvers of the general surgeon at the time of mastectomy will influence the possibility of an aesthetically acceptable result after breast reconstruction by the plastic surgeon. To reconstruct breast contour, an implant may be inserted beneath the muscle layers at the time of subcutaneous mastectomy in patients having prophylactic mastectomies.

After modified radical or radical mastectomy, the wound should be well healed, the scar mature, and the skin well vascularized before implantation. A prosthesis can be implanted only when reliable skin is available to cover it. Skin flaps should be cut as thickly as is consistent with a curative mastectomy. If sufficient skin flaps are not available, the plastic surgeon may use a tissue expander or transfer a pedicle skin flap from the abdomen or back to the chest wall.[6]

Immediate breast reconstruction, or a delay of only a few days, after a modified radical mastectomy can be psychologically advantageous in women who have small lesions and no metastases. A latissimus dorsi myocutaneous flap may be used with an inflatable implant. A vertical or TRAM island flap with the vascular bundle from the superior epigastric vessels can be used without an implant (Fig. 40.25). These flaps also can be used immediately or weeks to months after mastectomy for reconstruction. Aesthetically, the end result is a semblance of a breast in weight and consistency. The goal is fullness rather than projection from the chest.



• **Fig. 40.25** Transverse rectus abdominis myocutaneous (TRAM) flap. **A,** Single TRAM flap with one rectus muscle used for neobreast. **B,** Both rectus muscles can be dissected for neobreasts if bilateral mastectomy is performed. **C,** Closed abdominal incision spans transversely from iliac crest to iliac crest. The neobreast remains attached to the vascular stalk to preserve viability of the breast mound created by the TRAM flap.



• **Fig. 40.26** Nipple symmetry measurement. **A,** Measurements are taken from the clavicle to the nipple. The midline is marked from the sternal notch to the umbilicus. **B,** The desired placement of the elevated nipple line is measured in a triangulated line based on the midline sternal notch. The average distance is 19 to 21 cm. **C,** The final measurement is taken laterally from the inframammary fold to the central breast anteriorly.

An areola and nipple complex may be constructed in a second-stage surgical procedure. Dermapigmentation (a form of tattooing) may be used to create natural color and shading resembling the nipple-areola complex. The initial tattoo may appear darker, but becomes lighter in color over time.

The techniques described may be contraindicated in markedly obese patients and in some patients who do not have a sufficient amount of autogenous tissue for breast reconstruction. Another option is to place a tissue expander under the pectoralis muscle (see Fig. 40.11). When the desired expansion is achieved, usually slightly larger than the other breast, the expander can be replaced with a permanent prosthesis.

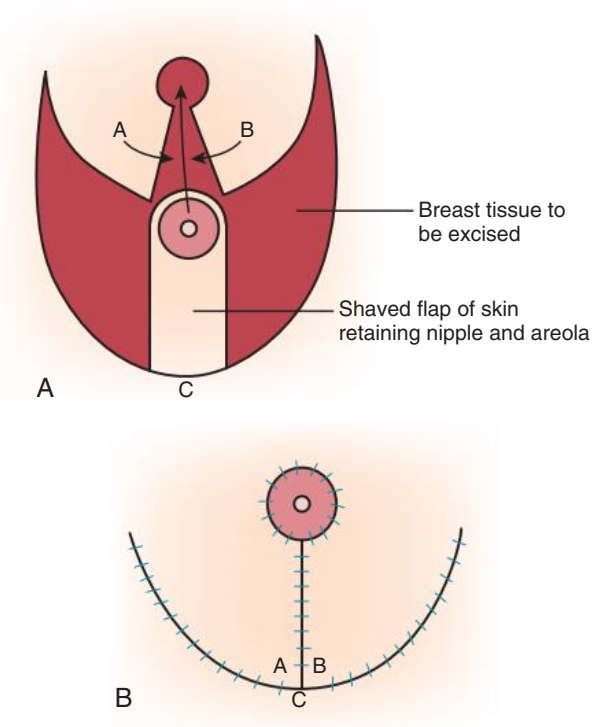
One type of expander/mammary prosthesis has a detachable reservoir and tubing to convert the expander into a permanent prosthesis. If this technique is not an option and the patient does not have adequate tissue in the lower abdomen or back, transfer of a microvascular free flap may be the procedure of choice. The vascular pedicle from a transverse abdominis rectus, superior gluteal, or inferior gluteal myocutaneous free flap may be anastomosed to the axillary or thoracodorsal vessels.

Reduction Mammoplasty

Hyperplasia of the breasts is reduced by resection of skin and glandular tissue. Reduction mammoplasty is usually sought by women for comfort as well as aesthetic improvement of body image. The nipple-areola complexes are mobilized and transferred intact with the underlying breast tissue, maintaining the blood and nerve supply (Fig. 40.26). The excess skin and glandular tissue may be excised with a scalpel, dermatome blade, or laser (Fig. 40.27). Because breast tissue is very vascular, attention to hemostasis is important. The CO_2 laser offers the advantage of coagulating small blood vessels and sealing lymphatics as tissue is incised. A hemostatic scalpel can be used for the same purposes.

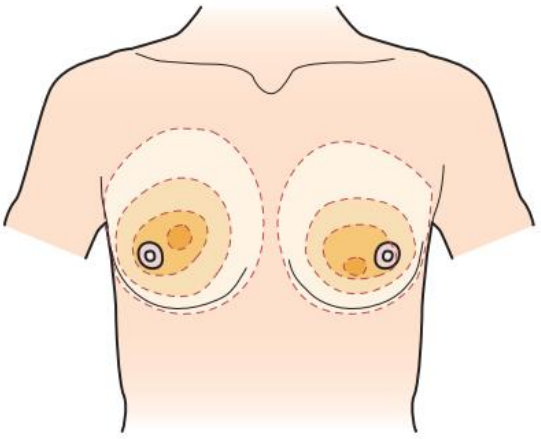
Reduction of the Male Breast

Reduction of the male breast is carried out for gynecomastia, a pathologic condition that consists of bilateral or unilateral



• **Fig. 40.27** Breast reduction. **A,** A keyhole incision is made in the breasts bilaterally. The tissue is deepithelialized, and the nipple is repositioned at the apex of the keyhole. **B,** The nipple is circumferentially sutured in place. The inframammary tissue is approximated vertically, followed by closure of the inframammary fold.

enlargement of the male breast.[7] Gynecomastia occurs primarily after 40 years of age or during puberty and is usually related to alterations in the normal hormonal balance. All subareolar fibroglandular tissue is removed, followed by reconstruction of the resultant defect. Some surgeons perform liposuction-assisted procedures to debulk the male breast (Fig. 40.28). If liposuction is



• **Fig. 40.28** Contours for male breast reduction by liposuction.

used, a compression vest is worn for 4 to 6 weeks postoperatively. Carcinoma can occur in the male breast.

Scars

Scar formation, the body's mechanism for healing wounds, is inevitable whenever skin is incised or injured. The plastic surgeon attempts to make a scar a fine line and as level and smooth as possible at the time of primary wound closure or as a secondary scar revision.

Scar Revision

The plastic surgeon can excise an aesthetically displeasing scar and then realign wound edges and close them with anticipation of a better cosmetic result. The direction of a scar can be changed to be less conspicuous in the natural skin lines. Scars are frequently revised after extensive reconstructive procedures or after a laceration with or without soft tissue trauma, particularly a facial scar. Z-plasty, W-plasty, M-plasty, lazy-S, Y-V-plasty, and other techniques are used to improve the appearance of a hypertrophied or prominent scar (Fig. 40.29).

Keloid formation, an abnormal deposition of collagen in healing skin wounds, presents a particularly difficult problem for the plastic surgeon and a psychologic problem for the patient. Keloids may require excision and grafting. The administration of a lathyrogenic agent and colchicine to inhibit cross-linking of newly synthesized collagen after grafting may prevent the development of recurrent keloid formation. Silicone sheeting sometimes helps reduce the bulkiness. The argon laser also is used in treating keloid scars to reduce the blood supply to the scar and to alter the balance of collagen synthesis and lysis.

Dermabrasion

Dirt and cinders can become embedded in the dermis from a brush burn injury. The plastic surgeon may use a stiff nylon brush to scrub out dirt and irrigate it from the area with warm saline solution. Medical sandpaper sometimes can be used. This procedure is not always satisfactory if many pitted scars are too deep to reach or there are changes in the pigment of scars. Some plastic surgeons prefer to use chemical preparations, such as phenol, trichloroacetic acid, or alpha hydroxy acid, to produce dermal peeling for a skin-smoothing effect in select patients with facial scars or fine wrinkles.

The patient is advised to avoid direct sun exposure for at least 6 months. Patients with fair complexions and thin skin have more favorable results than do patients with dark, oily complexions because the chemicals used decrease melanin in the skin and cause discoloration.

A high-speed dermabrader with rotating tips covered with diamond dust can be used on moderately damaged or tattooed skin. The rotating speed is controlled by regulation of pressure from the compressed nitrogen gas power source. Older dermabraders have narrow bands of waterproof, steam-sterilizable sandpaper mounted on an electric, air-powered, or battery-operated drill. Care is taken by the team to wear appropriate eye protection to shield against splashes and aerosolization of tissue, blood, and fluids.

Facial resurfacing also can be accomplished with the CO_2 laser. The depth of laser penetration is controlled by the focus of the beam. Full-face laser resurfacing promotes continuity of skin color and texture rather than spot removal of facial scars (Table 40.1).

Skin Cancer

Basal cell carcinoma, squamous cell carcinoma, and malignant melanoma are the three most common types of skin cancers.

Because overexposure to ultraviolet (UV) rays in sunlight is the primary cause of skin cancer, most skin cancers occur on exposed areas of the face, neck, and ears. Certain types of nevi are skin lesions that may be precancerous and therefore should be removed.

Non-UV skin cancers such as epidermolysis bullosa (EB) are inherited skin disorders that cause fatal metastatic cancers in young patients. The usual site of EB is chronic wounds that develop into long-term cutaneous scars. Poorly healing burns are frequently sites for EB that develop squamous cell cancers. One

TABLE 40.1 Examples of Lasers Used for Skin Surface Modifications

Type of Laser	Spectrum of Light	Notes
Argon	Blue-green	Used for treatment of superficial vascular lesions, pigmented areas, and some inflammatory lesions; absorbed by hemoglobin
CO_2	Infrared	Has a red aiming beam to make the invisible infrared laser visible; absorbed by water
Tunable dye (Candela)	Yellow	Used to treat port-wine stains and vascular ectasia; very selective vascular destruction; absorbed by pigmented tissues
KTP:YAG	Green	Used to treat tattoos, vascular lesions, and pigmented lesions; good for removal of black, yellow, or blue; works well for dark-skinned patients; articulated arm
Alexandrite	Red	Used to treat tattoos, particularly blue, black, and green; not good for orange or yellow; fiberoptic: flexible arm

From Fortunato NM, McCullough SM: *Plastic and reconstructive surgery*, St. Louis, 1998, Mosby.

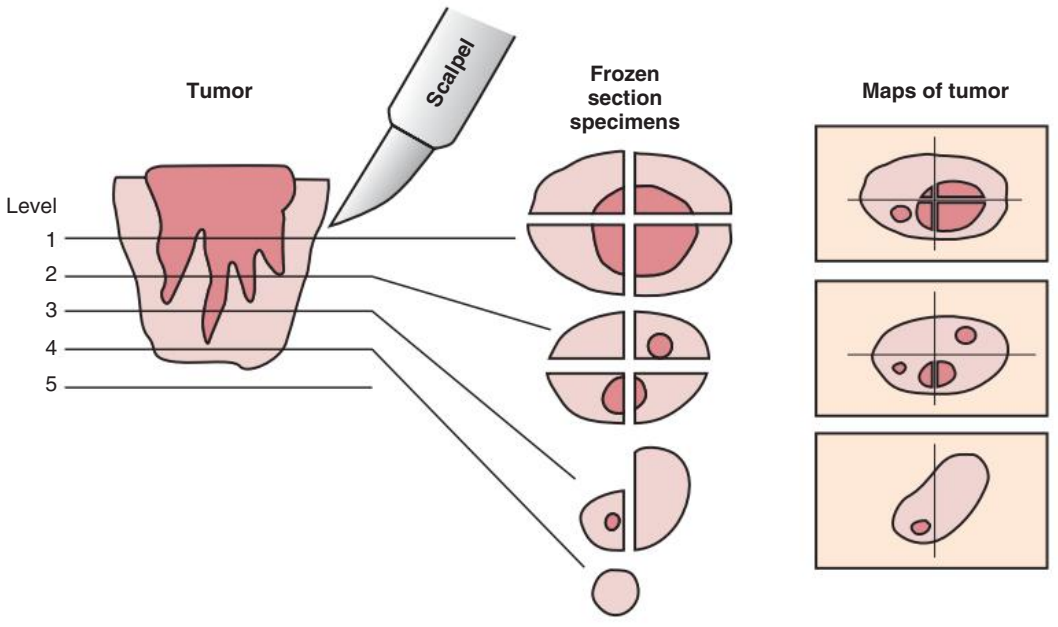
theory suggests that the constant process of healing triggers the cancer in susceptible patients. Surveillance of potential EB in these patients is recommended every 3 to 6 months from the age of 10 years and every 3 months from the age of 16 years. Squamous cell cancers discovered during the examinations are excised widely and full thickness. The extent of excision depends on whether lymphatic involvement can be identified. Treatment can involve chemotherapy, radiation, or amputation.

Suspicious UV and non-UV lesions may be removed by the following methods:

- Excision and closure with sutures, grafts, or flaps
- Punch biopsy with closure by second intention
- Cold-knife excision for frozen section
- Electrosurgical curettage and electrodesiccation
- Cryosurgery
- Laser surgery
- Radiation therapy

Mohs Micrographic Surgery

Mohs micrographic surgery is a technique used to excise advanced, recurrent, or poorly defined basal cell or squamous cell carcinomas of the skin with minimal excision of normal tissue. The bulk of the clinically evident tumor is excised initially. Then the lesion is resected by serial tangential excision (i.e., underlying tissue layers are removed with 1 to 3-mm borders). Each layer is numbered and charted for size and location. A map of the corresponding margins of each layer is drawn. The tissue is frozen, cut into sections, and examined microscopically (Fig. 40.30).



• **Fig. 40.30** Mohs microscopic excisional tissue mapping.

The patient may be allowed to leave the OR and wait in a waiting room for the results. The surgeon removes additional layers of tissue or extends dissection until microscopic examination determines that all cancer cells have been removed. A map of the excisional area is created and then the wound is closed.

Small wounds may be left open to heal by second intention. Others may be sutured or covered with a rotational myocutaneous flap from an adjacent area. Large denuded areas may require a STSG or FTSG. If a cartilage graft is needed, cartilage may be transferred from the auricle (pinna) of the ear to the transplantation site.

Mohs surgery is not used for excision of malignant melanomas. Primary melanomas are treated according to their anatomic site and level of cutaneous penetration. A wide margin of normal tissue is excised around the melanoma. Skin grafts often are required. Regional lymph node dissection may be indicated to control metastatic disease.

Burns

Skin and underlying tissues can be destroyed by thermal, chemical, or electrical injury. Burns are open wounds. As in other injuries, initial treatment is aimed at saving the patient's life. Then the treatment is directed toward preserving or restoring to normal, or as nearly normal as possible, the patient's bodily functions and appearance as rapidly as possible. The depth of the burn will determine how well cell regeneration presents and forms scar tissue. Researchers are working on various cell regenerating processes to grow autografts from the patient's own cells.[8]

Depending on the depth, extent, and location of the burn, reconstruction may extend over long periods, from months to years. The patient must be helped to accept the disfigurement; thus rehabilitation from a psychologic standpoint is important. Psychotherapy, as well as surgery and physiotherapy, may be necessary to promote as early a return to normalcy and usefulness as possible.

Classification of Burns

The severity of the injury is determined by the location and the cause of the burn. The Abbreviated Burn Severity Index (ABSI) is a five-variable scale used to evaluate burn injury severity and the probability of survival. The five variables are sex, age, presence of inhalation injury, presence of full-thickness burn, and percentage of total body surface burned. An ABSI score of 2 to 18 is calculated by the summation of coded values for each variable. Burns are classified by depth and extent as soon after injury as possible. Many burns are a combination of depths. The depth of a burn is classified by the degree of tissue involvement:

- *First-degree superficial burn:* Only the outer layer of the epidermis is involved in a first-degree burn. Superficial erythema, redness of the skin, and tissue destruction occur, but healing takes place rapidly.
- *Second-degree partial-thickness burn:* All of the epidermis and varying depths of the dermis are destroyed in a second-degree burn. This is usually characterized by blister formation, pain, and a moist, mottled red or pink appearance. Hair follicles and sebaceous glands may be destroyed. Reepithelialization can occur provided the deepest layer of the epithelium is viable. Superimposed infection can interfere with healing. Thickened scars form after healing of deep second-degree burns.
- *Third-degree full-thickness burn:* The skin, with all of its epithelial structures and subcutaneous tissue, is destroyed in a third-degree burn. This is characterized by a dry, pearly white or charred-appearing surface void of sensation. The destroyed skin forms a parchment-like **eschar** over the burned area. If removed or left to slough off, eschar leaves a denuded surface that can extend to the fascia. Third-degree burns require skin grafts for healing to occur unless the area is small enough for closure by reepithelialization.
- *Fourth-degree burn:* Sometimes referred to as char burns, fourth-degree burns may damage bones, tendons, muscles, blood vessels, and peripheral nerves. An electrical burn, for example, causes damage much deeper than is apparent on the skin surface. Often, necrotic muscle and bone must be excised.

Estimation of Burn Damage

Two methods are used to estimate the total percentage of body surface burned and the percentage of each degree of burn.

Lund-Browder Chart

The percentage sizes of the head and lower extremities differ in infancy, childhood, and adulthood. According to the guidelines of the Lund-Browder chart (Fig. 40.31), the percentage of burn is estimated on the basis of age in addition to the anatomic location of the burn.

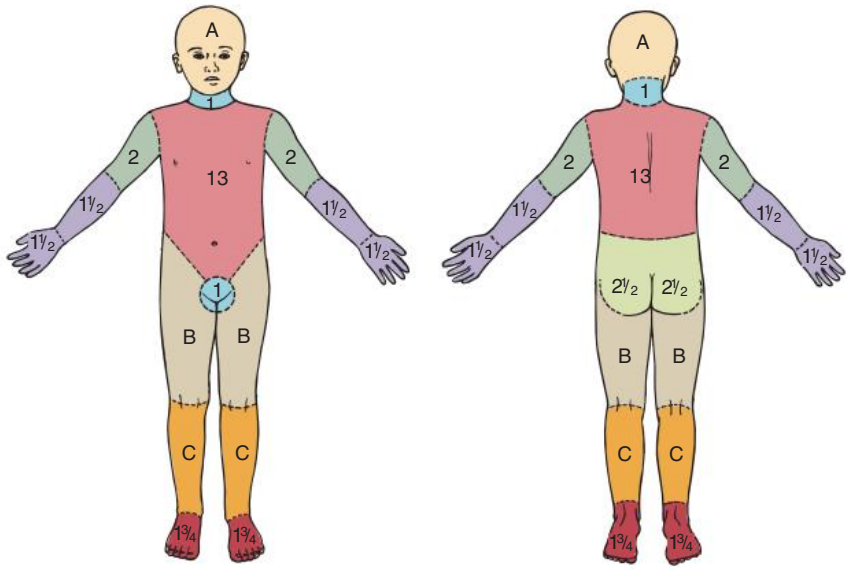
Rule of Nines

The body surface of an adult can be divided into areas equal to multiples of 9% of the total body surface (Fig. 40.32).

Initial Care of the Burn Patient

Patients admitted to the emergency department with obvious burns may have multiple injuries and/or a pretrauma medical history that will complicate treatment. Initial care must include the following measures:

1. *Stop the burning process:* All clothing, jewelry, and metal and synthetic objects in contact with the patient's skin are removed.
2. *Ensure a patent airway:* The respiratory system may be damaged from inhalation of superheated air or toxic gases. Immediate nasotracheal intubation with assisted mechanical ventilation may be necessary. Soft endotracheal tubes are preferred for prolonged intubation. Tracheotomy may be required several days later for prolonged respiratory assistance if the patient cannot be weaned from the ventilator. Bronchoscopy is performed routinely to evaluate the extent of tracheobronchial damage.
3. *Establish IV fluid therapy:* Blood samples are drawn for laboratory analysis and type and crossmatching when a venipuncture, cutdown, or central line initiation is performed to establish an IV route for fluid and nutritional administration. Fluid and electrolyte balance must be restored as quickly as possible. Fluid, electrolytes, and protein are lost through changes in capillary permeability, causing intravascular volume shifts to interstitial tissues (third spacing). Fluid shifts are directly proportional to the depth and extent of the burn. Several formulas for determining fluid replacement have been developed to maintain plasma volume during the first 24 hours (Table 40.2). The calculated fluid replacement time begins at the time of injury, not when the patient arrives in the emergency department. A crystalloid solution of lactated Ringer's solution is infused initially because its hypertonic state decreases fluid loss from the intravascular space. Colloid-containing fluid, fresh frozen plasma, and other nutrients may be infused after the first



Relative percentage of areas affected by growth	Age in Years					
	0	1	5	10	15	Adult
A—½ of head	9½	8½	6½	5½	4½	3½
B—½ of one thigh	2¾	3¼	4	4¼	4½	4¾
C—½ of one leg	2½	2½	2¾	3	3¼	3½
Total percent burned	2°+			3°−

• **Fig. 40.32** Rule of nines chart to estimate burn injury to an adult.

24 hours. The colloids will provide essential proteins to maintain balance in the intravascular compartment.

4. *Insert an indwelling Foley catheter:* Renal function is monitored closely. Urine specimens are sent for analysis. Urine is checked for pH and specific gravity at frequent intervals. The hourly output is recorded. Adequate fluid replacement should maintain an output of at least 30 mL/hr.
5. *Cleanse the wound:* All burns are treated with sterile technique. A mild cleansing agent, such as povidone-iodine, and warm water or saline solution are used to gently remove debris and loose, devitalized tissue. Copious amounts of water, along with appropriate neutralizing agents, are used to cleanse and irrigate chemical burns. After cleansing, wet sheets under and around the patient must be removed and dry, sterile sheets applied. Nonwoven sheets specifically designed for burn care are commercially available.
6. *Estimate the percentage and depth of the burn:* Definitive treatment may be completed in the emergency department, or the patient may be transported to an immersion tank for further cleansing and debridement or to the OR for initiation of further therapy as indicated by assessment of the burn. The burned area is covered with sterile or clean linen for transfer of the patient from the emergency department.
7. *Assess the patient's preexisting medical history and other injuries:* The patient may have a chronic illness, such as diabetes or heart disease, that must be stabilized as part of the treatment regimen. Withdrawal from alcohol or drugs may cause physiologic disturbances. The patient may have suffered other injuries in the accident causing the burn. Abuse may be suspected, particularly in a child or older person. Appropriate interventions must be taken. The burn may not be the first priority if, for example, the patient has a head injury, ruptured internal organs, or fractures.

TABLE 40.2 Fluid Replacement Formulas* for Burn Patients Developed at Major Burn Centers

First 24 Hours	Second 24 Hours
Parkland Hospital	
Crystalloid	
4 mL Ringer's lactate/% burn/kg	Dextrose 5% in water
Half during first 8 hours	Maintenance
Half during next 16 hours	
Colloid	
None	0.5 mL/% burn/kg
Brooke Army Hospital	
Crystalloid	
2 mL Ringer's lactate/% burn/kg	Dextrose 5% in water
Half during first 8 hours	Maintenance
Half during next 16 hours	
Colloid	
None	0.5 mL/% burn/kg
Massachusetts General Hospital	
Crystalloid	
1.5 mL Ringer's lactate/% burn/kg	None specified
Half during first 8 hours	
Half during next 16 hours	
Colloid	
0.5 mL/% burn/kg	None specified
None during first 4 hours	
Half during second 4 hours	
Half during next 16 hours	

*Formula is calculated as percent of total body surface area (% TBSA) × each kilogram (kg) of body weight × milliliters (mL) of fluid.

8. *Prepare the patient for transport:* The patient may go from the emergency department directly to a burn unit, the OR, or some other care area. The attending physician may initiate therapy before referral to a plastic surgeon. If available, hyperbaric oxygen (HBO) therapy may be used. HBO produces marked vasoconstriction, decreasing the loss of serum through the burn surface. This may reduce the need for fluid replacement.

Oxygen in cells around the burn may positively affect burn tissue to regenerate and begin healing. Partial-thickness burns may be prevented from progressing to full-thickness burns.

Methods of Surgical Treatment

Prevention of infection and promotion of healing are of utmost concern in the treatment of burn patients. The probability of infection developing increases in proportion to the percentage of body surface burned. Colonization of microorganisms may begin as early as 24 hours after the burn.

Excisional Debridement

Primary excision of necrotic tissue from deep second-degree and all full-thickness third-degree burned areas, followed immediately by skin grafting, is performed as soon as possible after the injury. Debridement can be accomplished with a scalpel, scissors, or other specialized instrument. The surgeon selects the most appropriate instrument for the particular burned area to be excised. Layers of burned tissue are removed sequentially until capillary bleeding indicates that tissue is viable. Hypotensive anesthesia may help control massive blood loss during extensive excisions.

Wound Bed Cover After Debridement

Areas of denuded tissue lose large amounts of fluid and provide a portal of entry for microorganisms. Skin replacement includes the use of natural and synthetic materials. First-line natural material is the patient's own skin and tissue (autograft). The availability of donor skin on the patient's body depends on the extent of injury and location of the recipient site. Meshed grafts are frequently used to expand coverage with small amounts of autografted skin. The patient's own skin (keratinocytes and fibroblasts) can be cultured and grown for placement over a wound (Epicel). Other techniques include growing autologous cells in a suspension and spraying them over the recipient site. Autologous fibroblasts can be incorporated into a hyaluronic matrix and placed over a wound.[8]

Allogeneic epidermal keratinocytes and dermal cells can serve as a biomaterial wound cover, but are not permanent. The recipient wound bed granulates and eventually rejects the allograft, requiring excision and regrafting with available autograft. Biologic materials used include neonatal skin cells from newborn circumcisions (OrCel) and cadavers. Allograft cells can be used alone (AlloDerm) or grown into porcine or bovine collagen or into synthetic materials such as silicone (TransCyte), polyglactin mesh (Dermagraft), and collagen (Apligraf and StrataGraft). Duration of allograft effectiveness can last for several weeks before rejection.

Xenograft of bovine or porcine collagen is derived from dermis and submucosa (Permacol, EZ Derm, Matriderm, and OASIS). A composite acellular silicone-nylon membrane with a chemically bonded polypeptide of porcine collagen (Biobrane) will adhere to the wound surface to inhibit infection and control fluid loss for 7 to 10 days. Biobrane stimulates granulation tissue and prepares the wound bed for autologous grafting.

Tangential Excision

Burned tissue is excised until normal dermal tissue is reached below the depth of the wound. Tangential excision is usually the procedure of choice for deep partial-thickness burns of the dorsum of the hands or on the arms or legs. It is advantageous to minimize contractures. The wound base, containing some viable dermal structures necessary for regeneration, is covered with a split-thickness autograft. Early tangential excision and grafting in one procedure for body surface burns can reduce mortality and septic complications and shorten hospitalization.

Escharectomy

Full-thickness eschar is excised down to the fascia when viable tissues in more superficial layers are not evident, except on the hands, neck, or face. All denuded areas created by excision are covered with a biologic dressing for 3 to 5 days. They are then grafted with full-thickness autografts. Frequently, split-thickness mesh grafts must be used to spread over large areas and allow seepage of serous fluids. These are not placed on the face and neck or over joints. If sufficient skin is not available for autografting,

allografts or xenografts continue to be used as biologic dressings for short periods. They are changed every 3 to 5 days.

Other Surgical Procedures

During the course of hospitalization, a burn patient may come to the OR for one or many procedures. The patient is compromised and may be given a tetanus shot during treatment.

Escharotomy

Shrinkage of eschar may occur and cause a tourniquet effect in circumferential burns of the extremities or thorax. Bilateral incisions through the eschar, not including the fascia, are made to improve circulation to a lower extremity. Multiple incisions on the chest wall relieve respiratory distress. Sites of incisions avoid major peripheral nerves to prevent irreversible neurologic complications.

Fasciotomy

If adequate decompression does not occur after escharotomy, the incision may be extended into underlying fascia. Compartment syndrome can develop as blood or serum effuses between the fascial layers. The fascia may need to be incised in the body part if compromised circulation is evident. The incised layers will remain open for weeks or months and may need skin grafts to completely heal.

Amputation of Digits

Amputation may be necessary to control infection in the extremity and prevent septicemia if escharotomy is unsuccessful.

Debridement

Debridement of underlying tissues helps prevent extension of tissue loss. Nonviable tendons, cartilage, or bone may be excised, such as from the hand, ear, or skull.

Full-Thickness Skin Grafts

With or without tarsorrhaphy, FTSGs are used to prevent contracture of the eyelids. The cornea must be protected from exposure with corneal shields and lubrication.

Split-Thickness Skin Grafts

Autografts are applied to debrided areas as rapidly as possible. The hands and face are the first priority to restore function; joints and flexion creases are second to prevent contractures; and the extremities and trunk are the lowest priority. Skin from donor sites is cut thin if the site will be used again. Mesh grafts are frequently used to cover very large surfaces or irregular areas such as the perineum. Grafts are held in place with staples or sutures and dressings to achieve apposition and immobilization.

Tissue Expansion

If sufficient normal skin is available, a tissue expander may be placed beneath subcutaneous tissue to broaden the width for future use as a local flap to cover an adjacent burned area after excision of scar tissue or for better closure of the donor site.

Myocutaneous Flaps

Myocutaneous flaps, either on a pedicle or by free microvascular transfer, may be used in the reconstruction of burn wounds.

Biologic Dressing Changes

Instead of leaving a biologic dressing in place until rejection, with attendant inflammatory reaction, a biologic dressing is usually replaced as often as needed until the area is ready for an autograft or skin for an autograft is available. Biologic dressings may be allografts of human skin from a living or cadaver donor, placental or amniotic membranes, or a xenograft of porcine skin. Porcine dressings are applied initially on second-degree burns as a temporary dressing or used in conjunction with extensive excisional therapy. Synthetic skin substitutes may be preferred. A biologic dressing is used for the following several reasons:

- It helps control infection by covering denuded areas.
- It prevents loss of serum.
- It decreases pain.
- It seems to stimulate the formation of epithelium in dermis under it.
- It promotes growth of granulation tissue.

Dressing Changes

Occlusive dressings, if used, must be changed frequently to control infection harboring under them. An antimicrobial or chemotherapeutic agent may be applied as an integral part of the dressing. The following considerations apply:

1. *Silver sulfadiazine (Silvadene 1%) cream* applied directly to the burned area makes removal of a dressing less painful and does not disturb the healing process as it is removed. It is an effective topical antimicrobial and produces no metabolic side effects; some patients have developed neutropenia and delayed wound healing after its use. Some patients may develop a fungal infection.

   Fresh cream is applied after cleansing and debridement. A layer of fine mesh gauze is laid over it (unless the open-exposure method will be used for further healing). Then soft, absorbent material, such as fluffed gauze, and a preformed splint may be used. These are held in place by a cotton elastic bandage. An occlusive dressing may be used to hold a hand, foot, or joint in functional position.

   Silver sulfadiazine is a pregnancy class B drug and is not used if the patient has a sulfa allergy or is pregnant. The use of the cream is contraindicated on a pregnant woman near term because of the risk for kernicterus in the fetus. It should not be used on infants younger than 2 months of age.
2. *Mafenide acetate (Sulfamylon 5%) cream* penetrates intact eschar rapidly and is quite successful in reducing bacterial counts to optimal levels for skin grafting. Application directly on the burned area is painful for the patient after cleansing and debridement. It may cause maceration under the dressing. Absorption may result in metabolic acidosis; thus the acid-base balance must be closely monitored. Prolonged use may lead to renal or pulmonary complications.

   Sulfamylon is available in a topical solution form. It is supplied in a 50-g package that can be added to a 1000-mL bottle of sterile saline or water for irrigation. Once prepared, the solution should be discarded after 48 hours. The solution is used to keep grafted skin dressings moist. Irrigation should not be done longer than 5 days because it can inhibit epithelial regeneration.
3. *Silver nitrate solution 0.5% in sterile distilled water* is used infrequently. After cleansing and debridement, multiple-thickness dressings are applied to the area. These are kept saturated with 0.5% silver nitrate solution and changed every 12 hours. For debridement, sterile distilled water is used for irrigation because saline may cause the precipitation of silver salts. It is ineffective in treating established wound infection because it does not penetrate intact eschar.

   Care is taken to avoid splashing silver nitrate solution onto walls and floors because staining can occur. If disposable drapes and gowns are not used, stained linen must be laundered separately from other linen.

Serial Biopsy Cultures

Through two linear incisions, a biopsy of tissue, including subcutaneous fat, is excised for culturing. This is done every 2 or 3 days, until the eschar begins to separate, to monitor the colonization of microorganisms in the wound. The results of serial biopsy culture enable the surgeon to make decisions specific to the therapeutic needs of the patient. An antimicrobial or chemotherapeutic topical agent is selected or changed according to these results.

Treatment of Curling's Ulcer

Gastrointestinal complications may occur any time from the early postinjury period through rehabilitation. Complaints must be carefully evaluated. The patient who develops massive bleeding from a stress ulcer in the stomach and duodenum (Curling's ulcer) must be operated on. Vagotomy with antrectomy are most frequently performed by a general surgeon.

Treatment of Marjolin Ulcer

An ulceration caused by malignant changes (Marjolin ulcer) can develop in the surface area of a burn scar. As long as 20 years after the burn, a prolonged ulceration can lead to squamous cell carcinoma of the skin. The ulcer should be excised.

Environmental Considerations for Burn Patients

1. Environmental control is perhaps the essence of burn therapy. The environment must protect the wound from further injury and microbial invasion. A burn wound is always potentially contaminated until epithelialization occurs. Open exposure of the wound to room air may be the choice of the plastic surgeon for select patients. Regardless of the method of treatment, the following adjuncts are used, if the equipment is available, in the care of burn patients, in addition to strict adherence to all of the principles of aseptic technique:
   a. Reverse isolation technique may be practiced to protect the patient, whose resistance is low, from infection from personnel. Caps, masks, shoe covers, sterile gowns, and sterile gloves are worn by all personnel attending the patient. This may be referred to as protective isolation.
   b. Laminar, or downward unidirectional, airflow away from the wound helps minimize airborne contamination.
   c. A plastic isolator protects the patient. Personnel do not directly enter this isolation unit. Patient care is given through clear plastic access walls. The environment around the patient inside the isolator is controlled at 90° F (32° C) and 94% relative humidity to conserve heat loss by evaporation.
2. Patients with extensive burns may be placed on a Stryker frame or a CircOlectric bed specially designed to facilitate handling and turning. They are transported to the OR on these frames or beds. Patients must be turned slowly and gently because they are often hypovolemic after the injury.
3. Hypothermia must be prevented. The patient's thermoregulatory mechanism is altered by the destruction of skin that normally acts as an insulator. Heat loss is the greatest single problem the burn patient faces in the OR.
   a. The room temperature should be increased to between 80° F and 90° F (27° and 32° C) with low relative humidity of about 30% to 40%.
   b. The OR must be ready to receive the patient directly from the burn unit. The patient should not wait in a cool holding area or corridor. Concern is for the patient's thermoregulation and potential for infection.
   c. A warm hyperthermia blanket should cover the OR bed. The patient should be exposed as little as possible. Cover with warm blankets.
   d. The patient's temperature should be monitored with a rectal or esophageal probe. Affixing skin probes may be contraindicated when large areas of tissue are damaged.
   e. Solutions should be warmed before irrigation or infusion.
   f. Operating during nighttime hours is advantageous for the patient because the normal schedule for oral intake is not interrupted.
4. Hypnosis and biofeedback techniques can reduce potential postanesthetic complications when many surgical procedures are necessary to achieve acceptable functional and aesthetic results after a burn. The OR environment must be quiet to be conducive to hypnotic suggestions given to the patient.

After the initial assessment of a severely burned patient, a prolonged period of treatment begins. A multidisciplinary team must coordinate the treatment plan to achieve the best possible clinical outcome for the patient. As with all plastic surgery patients, both physiologic support and psychosocial support are essential to successful rehabilitation.

Otorhinolaryngologic and Head and Neck Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify the pertinent anatomy of the ear, nose, and throat.
- Describe the care of the patient having an otorhinolaryngologic procedure.
- List the main types of hearing loss and the treatments.
- Discuss the psychologic effects of head and neck surgery.
- List the precautions of caring for the patient with a tracheostomy.

KEY TERMS AND DEFINITIONS

Anomaly Abnormal development.
Cholesteatoma A mass of cholesterol and epithelial cells in the middle ear.
Cleft A separation of tissue.
Congenital Condition present at birth.
Deglutition Swallowing
Glossoptosis Prolapsed tongue.
Gnathia Jaw structure.
Suture Joint between skull bones that ossifies with age under normal circumstances.

General Considerations in Ear, Nose, and Throat Procedures

Surgical procedures of the structures of the head and neck region are not within the province of any one surgical specialty. Subspecialists from many disciplines, most notably general surgeons, plastic surgeons, otolaryngologists, and dentists, limit their surgical practice to specific types of problems involving areas of the head and/or neck. Training in these subspecialties is included in specialty postgraduate programs.

Otorhinolaryngology has traditionally been concerned with research and surgical treatment of diseases of the ear (oto), nose (rhino), and throat (laryngo). Advances in scientific knowledge, diagnostic capabilities, and technology have broadened the scope of this field, which has led to subspecialization. General otorhinolaryngologists, commonly called ear, nose, and throat (ENT) surgeons, practice within the total scope of this specialty. Other surgeons confine their practice to one of the subspecialties: otology, facial surgery, or head and neck oncology. The certifying body for this specialty is the American Board of Otolaryngology.

Dental and skeletal deformities of alignment and function coexist with aesthetic appearance. These deformities may be congenital, or they may be caused by trauma or disease. They may interfere with breathing, eating, swallowing, speaking, seeing, or hearing. A multidisciplinary team of surgical specialists is often required to reconstruct complex deformities. This team may be all-inclusive with a plastic surgeon, neurosurgeon, oral surgeon, orthodontist or prosthodontist, otolaryngologist, ophthalmologist, radiologist, and general surgeon; or it may be limited to two or three specialists. The team may also include a psychiatrist or psychologist, speech pathologist, and social worker. A team includes all of the specialties needed for complete preoperative assessment, intraoperative care, and postoperative rehabilitation of the individual patient.

Specific considerations include the following:

1. Preoperative explanations and postoperative instructions are vital to the outcome. For example, after ear or nasal procedures the patient must avoid blowing the nose, which would force air up the eustachian tube, potentially causing infection; force air through the incision; or dislodge a graft. To sneeze, both the nose and mouth should be open.
2. Communication is a major problem for patients with loss of hearing or voice. Touch is an effective means of conveying concern and letting the patient know he or she is not abandoned.

Pencil and paper or a Magic Slate can be useful for the patient to communicate.

Anesthesia Considerations

Anesthesia can be local or general. Use of local anesthesia minimizes bleeding and postoperative discomfort in addition to affording the surgeon observation of patient response. It allows patient cooperation. A qualified perioperative nurse may deliver moderate sedation and monitor vital signs, including cardiac function with electrocardiogram (ECG) and oxygenation with a pulse oximeter in the absence of an anesthesia provider. The nurse records the amount of local anesthesia administered and documents the patient's intraoperative responses.

Monitored anesthesia care (MAC) may be used with an anesthesia provider in attendance for more complicated patients who need additional adjunctive medication and monitoring.

General anesthesia requires good control of the airway. The presence of an endotracheal tube in the mouth during general anesthesia can distort features during a surgical procedure in the oral cavity. Nasotracheal intubation may be necessary. Special endotracheal tubes are used if a laser is employed. The use of methylene blue dye in sterile saline for filling the endotracheal tube cuff is recommended. If the cuff is perforated, the dye acts as an indicator.

In complex cases involving large areas of the head and neck, the patient may have a tracheostomy created and sutured in place for the duration of the procedure. The tracheostomy may be permanent or temporary depending on the procedure performed. Great care is exercised when using a surgically created airway. Tissue manipulation can dislodge the tracheostomy tube or serious bleeding can occur. Some anesthesia providers may hyperinflate the cuff on the tube to tamponade areas of bleeding. Hyperinflation of the cuff can cause tissue ischemia and is done with great care.[1] A fiberoptic laryngoscope or lighted bougie should be on hand to monitor the status of the airway when a tracheostomy tube is used during a surgical resection.

The anesthesia provider requires periodic access to the patient's head and neck, as do the surgeon and sterile team. Positioning of the operating room (OR) bed must provide space for the anesthesia machine and other equipment, such as the microscope.[2] The anesthesia machine may be positioned near the patient's side or feet. The endotracheal tube is taped to prevent becoming dislodged during the procedure; all connections must be tight, and tubes must be unkinked. Breathing circuits may need an extension hose if the anesthesia machine is at the foot of the OR bed. The anesthesia provider usually sits alongside the OR bed near the lower half of the patient on the side opposite the surgeon (Fig. 41.1).[2] Provisions are made for the anesthesia provider to have access to the intravenous (IV) line when the patient's arms are tucked in at the sides. Extension IV tubing is used.

Pharmacologic Considerations

Epinephrine in a local anesthetic, such as lidocaine, is frequently used as a vasoconstrictor in ENT procedures. The epinephrine in the local anesthetic can cause cardiac dysrhythmias, and the anesthesia provider should be alerted when it is injected.

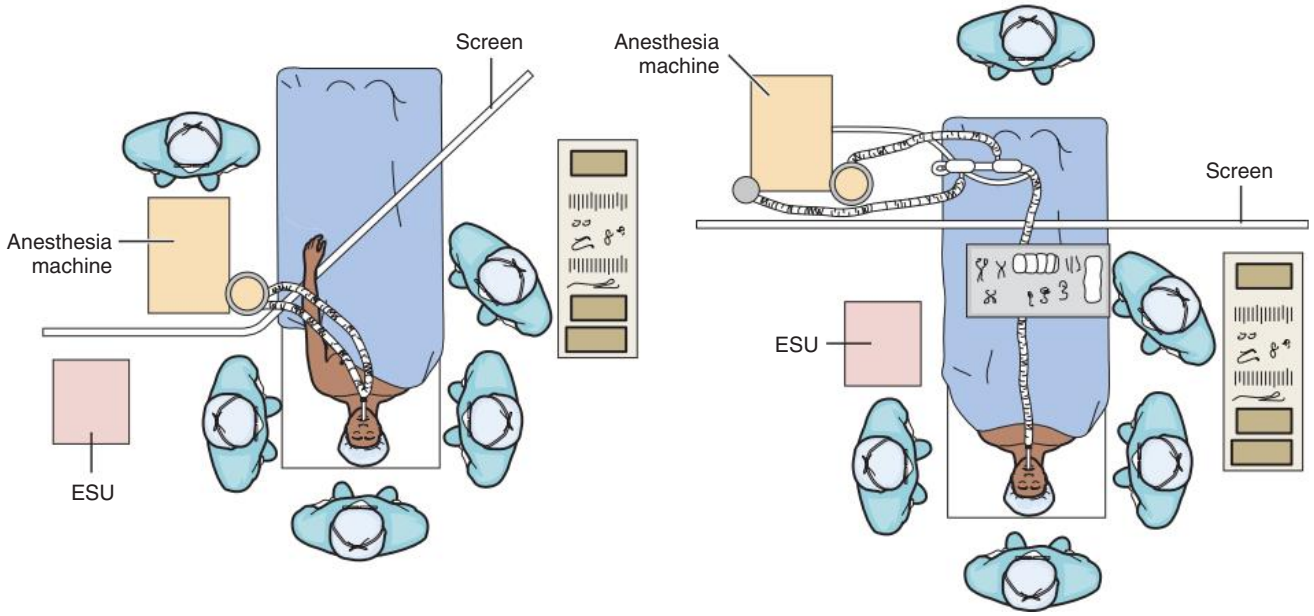
Nitrous oxide diffuses into the middle ear, causing pressure. During ear procedures, such as tympanoplasty, the nitrous oxide is decreased or discontinued once the tympanic graft is placed, to minimize inner ear pressure that could displace the graft.[2]

Neuromuscular blockade affects the nerves of the head and neck. The use of nerve conduction monitoring or nerve stimulators is adversely affected by strong skeletal relaxation drugs.

Positioning, Prepping, and Draping

Although the oral cavity is considered contaminated, sterile equipment and sterile technique are preferred to avoid introducing exogenous bloodborne microorganisms.

The patient is positioned supine. The arms are usually tucked in at the sides or secured over the abdomen. The patient's head is positioned in a donut or horseshoe headrest to prevent movement during the procedure. Many procedures are done with the patient



• **Fig. 41.1** Room setup plan for ear, nose, and throat (ENT) cases. *ESU,* Electrosurgical unit.

in a slight reverse Trendelenburg's position or with a roll under the shoulders to hyperextend the head. Some surgeons prefer to have the patient in a modified beach-chair position. This helps anatomic positioning and controls bleeding.

The patient's eyes should be protected by corneal shields and sterile ophthalmic lubricant. Care is taken not to lean on the patient's draped face during the procedure. Pressure on the patient's eye can cause eye damage and cardiac dysrhythmias.

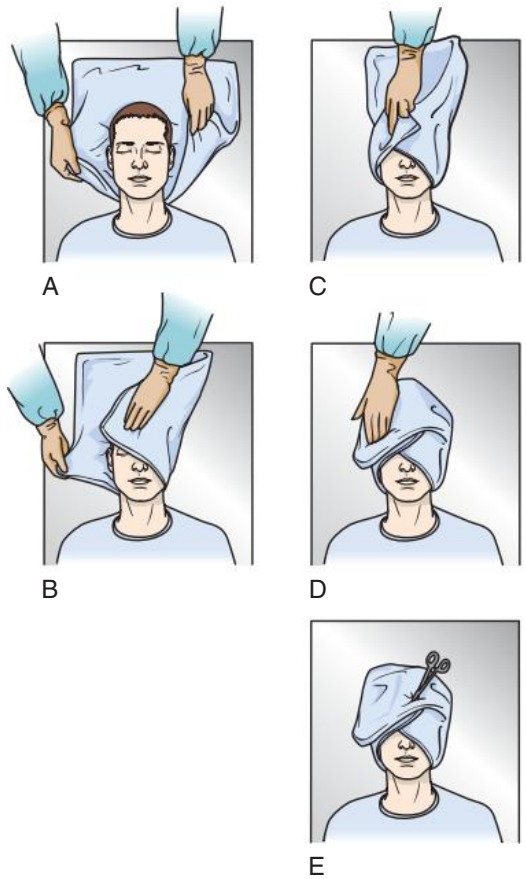
Care with antiseptic solutions during a facial prep is necessary because they are painful and irritating if they are allowed to touch a perforated eardrum or get into the eyes. A cotton or rayon ball can be used to occlude the ear during facial prepping. Cotton fibers can stick inside the ear, causing itching and discomfort postoperatively, and a small nonradiopaque gauze (2 × 2 inches) can be used instead. Some solutions, such as chlorhexidine or hexachlorophene, can cause permanent damage. Consult the manufacturer's recommendations before use.

The awake patient under local anesthesia may experience anxiety with drapes over the head. Oxygen (6 to 8 L/min) administered during the procedure affords relief. A patient with chronic lung disease should be given oxygen at 3 L/min.

Care is taken not to permit the use of cautery in an oxygen-rich environment. Oxygen builds up under the drapes and could create a fire hazard. Oxygen is combustible.

A patient having a procedure longer than 2 hours should have a Foley catheter inserted to monitor urine output. The drainage bag should be positioned in the view of the anesthesia provider.

Some surgeons prefer a turban-style head drape. Fig. 41.2, *A–E* depicts the method used to create a turban from a drape.



• **Fig. 41.2 A-E,** Making a head drape turban.

Patients undergoing local anesthesia may wear pajama-type bottoms or underpants to the OR in some facilities. Patients having general anesthesia should wear only a gown.

Equipment and Instrumentation

Illumination is provided by the overhead spotlight, the operating microscope, the endoscope, or the surgeon's fiberoptic headlight. Some surgeons want the room darkened during endoscopy. Various types of fiberoptic endoscopes with appropriate accessories are used. The diameter of aspirating tubes and forceps is small enough to pass through small lumens, and the length is long enough to extend beyond the end of the scope. The lighting mechanism and all accessories should be checked for working order before the patient is brought to the room.

Suction should be available at all times and should include several patent cannulas. The degree of suction should be variable and usually includes a thumbhole for intermittent release of the vacuum. Cannulas with very fine suction tips should be irrigated frequently to avoid blockage. Fine suction tips are equipped with stylets for clearing the lumens.

Suction irrigators are used with sinus endoscopes. Irrigation equipment and solution at body temperature should be available to remove bone dust, clean burrs, and rinse suction apparatus. Warm solutions would cause vasodilation, with the potential for obscured vision by venous bleeding.

Special care with electrical appliances is indicated. Bipolar and monopolar electrosurgery are used to control bleeding. Many ENT surgeons use coblation technology, which is a form of high-frequency bipolar energy in a conductive medium, usually saline. The target tissue is removed using a lower temperature than traditional electrosurgery devices.

Compressed air or nitrogen drills with a foot-pedal control are used on bone, such as the mastoid area. Only the operator should activate the foot pedal. A number of drills for extremely fine work, such as stapes sculpturing, are powered by small electric motors fitted into a handpiece. The tip of the drill is cooled by small drips of irrigation solution during use.

Instrumentation is varied to suit the area. It includes very delicate, small endoscopic and microsurgical implements in addition to various-sized bone instruments because of the extensive involvement of cartilage and bone in the facial structures and skull. These areas have relatively little soft tissue. Many instruments are angled with small jaws to permit insertion without obscuring visualization.

Lasers may be used. Carbon dioxide (CO_2) lasers are used to vaporize tissue. Argon lasers coagulate tissue by heat generation. Potassium titanyl phosphate (KTP) lasers coagulate to shrink or debulk tissues. Neodymium:yttrium aluminum garnet (Nd:YAG) lasers cut and coagulate to minimize bleeding. Appropriate ebonized or dulled instrumentation and attachments must be available for each type of laser.

Laser surgery is usually done in conjunction with the operating microscope or endoscope. Microsurgical techniques are used because they facilitate distinction between normal and diseased tissue and allow more accurate dissection. All safety precautions are taken to avoid ignition and injury when a laser is used. Team members must wear protective eyewear of the correct optical density for the type of laser in use.

Cryosurgery may be used to destroy tissue in accessible areas, especially those that bleed profusely if incised.

Hemostasis and Drugs on the Sterile Field

One or two drops of blood can obscure a microsurgical field. Hemostatic aids and sponges should be ready at all times. Gelfoam pledgets soaked in 1:1000 epinephrine are commonly used. Soaked pledgets are kept in a labeled Petri dish and passed only with forceps. Press the saturated pledget against the side of the dish to wring out some of the moisture before passing to the surgeon.

Various solutions and medications are on the sterile field, such as lidocaine, and epinephrine. Each container and delivery device should be clearly labeled for distinction between irrigation solutions and drugs.

Sponges and compressed patties are relatively small and are a distinct hazard when blood soaked because they can occlude an airway. All items used in the OR are counted or accounted for in their entirety at the end of the procedure.

Tissue Grafts and Implants

Handle tissue grafts only with forceps, taking care not to crush the tissue. Tissue grafts must be kept from drying out before use. A convenient method is to place the graft on a moist cellulose sponge in a sterile, covered Petri dish. Some surgeons intentionally dry a temporalis fascia graft to facilitate handling. This type of graft, as well as cartilage, may be flattened and thinned in a small sterile press.

Ear

Anatomy of the Ear

The structures of the outer and inner ear (Fig. 41.3, *A* and *B*) are concerned with two functions:

1. Hearing (i.e., receiving sound, amplifying it, and transmitting it to the brain for interpretation)
2. Maintaining body equilibrium

Anatomically, the ear is divided into three parts: external, middle, and inner.

External Ear

The external, or outer, ear consists of the auricle, or pinna, composed of cartilage except for the lobe; the skin; and the external auditory canal. The meatus of the auricle leads, via the ear canal, to the tympanic membrane or eardrum. This membrane separates the external and the middle ear. A color change of the translucent eardrum, visible through a speculum, may be indicative of middle ear disease. The outermost lining of the tympanic membrane is derived from tissue of the ear canal. The inner lining is continuous with the middle ear mucosa. The eardrum protects the middle ear but may be perforated by injury or pressure built up in the middle ear by infection.

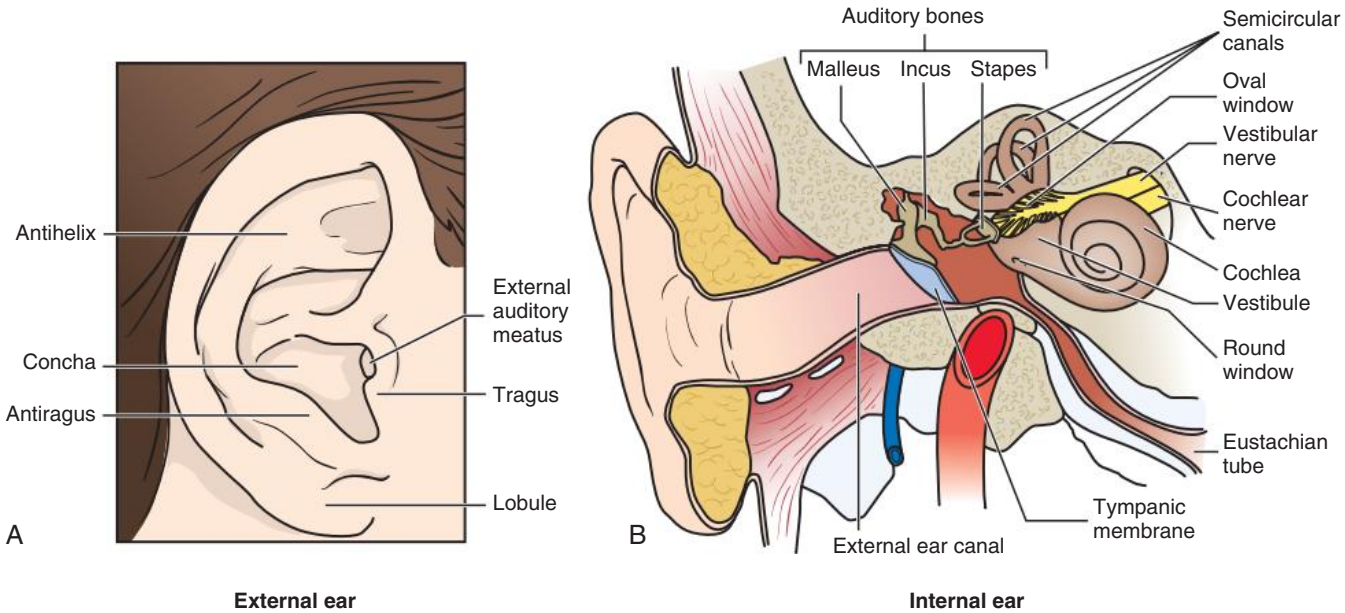
Middle Ear

The middle ear consists of the tympanic cavity, a closed chamber that lies between the tympanic membrane and the inner ear. Within this cavity are the three smallest bones in the body—an ossicular chain comprising the malleus, incus, and stapes. They resemble a hammer, anvil, and stirrups, respectively. The malleus, which is attached to the eardrum, joins the incus, the extremity of which articulates with the stapes, the innermost bone. The footplate of the stapes fits in the oval (vestibular) window, an opening in the wall of the inner ear.

The bones of the ossicular chain must be able to move mechanically to conduct sound from the eardrum to the inner ear. The round (cochlear) window, also between the middle and the inner ear, equalizes pressure that enters through the oval window.

The middle ear opens into the nasopharynx by way of the eustachian tube. Normally closed during swallowing or yawning, the eustachian tube aerates the middle ear cavity. This mechanism is essential for adequate hearing.

Posteriorly the middle ear exits to the mastoid process. This inferior projection of the temporal bone is a honeycomb of air cells lined with mucous membrane. Because the antrum of the mastoid process connects with it, middle ear infection may produce mastoiditis. The middle ear is situated in the tympanic portion of the temporal bone; the inner ear is situated in the petrous portion, which integrates with the base of the skull. The tympanic portion also forms part of the ear canal.



• **Fig. 41.3** **A,** Anatomy of the outer ear. **B,** Anatomy of the inner ear.

Inner Ear

The end organs of hearing and equilibrium are situated in the inner ear. The two main sections—cochlear and vestibular—have distinct, although coordinated, functions. The cochlea, a bony spiral, relates to hearing. The vestibular labyrinth, which is composed of three semicircular canals, relates to equilibrium. These structures house two separate fluids—endolymph and perilymph—which nourish and protect the hearing receptors.

The neuroepithelium of the organ of Corti, the end organ of hearing, holds thousands of minute hair cells, which respond to sound waves that enter the cochlea via the oval window. The neuroepithelium of the vestibular portion also contains hair cells. Rapid head motion produces current in the endolymph that may result in nausea or vertigo. The eighth cranial (vestibulocochlear) nerve governs reflexes to muscles to maintain equilibrium and controls hearing.[3]

Proximal Structures

The middle and the inner ear are adjacent to many important structures. The seventh cranial (facial) nerve is enclosed in a bony canal running through the tympanic cavity and mastoid bone. The meninges of the temporal lobe of the brain are also near the middle ear and the mastoid. Facial paralysis, meningitis, and intracranial infection, such as brain abscess, are potential complications of ear infection.

The major blood vessels are the internal carotid artery and internal jugular vein, as well as the lateral sinus. Thrombosis and infection of the lateral sinus of the dura mater are potentially lethal complications of otitis media, with or without mastoiditis.

Physiology of Hearing

Sound or pressure waves enter the auricle. They pass along the ear canal to the tympanic membrane. The vibration of the waves is transmitted across the middle ear sequentially by the ossicles. Amplification of sound is enhanced to some extent by mechanical action of the ossicles but mainly by aerial ratio. A large volume of sound wave pressure from the tympanic membrane funnels to a small reactive area, the stapedial footplate, intensifying sound. At the stapedial footplate, sound pressure is transferred to the inner ear via the oval window. The hair cells of the organ of Corti are set in motion by disturbance of the inner ear fluids as sound wave pressure moves from the oval to the round window. Mechanical energy is converted to electrical potential, which is delivered to the brain along the eighth cranial nerve. The brain interprets the impulse (sound) as hearing.

Pathology of Hearing

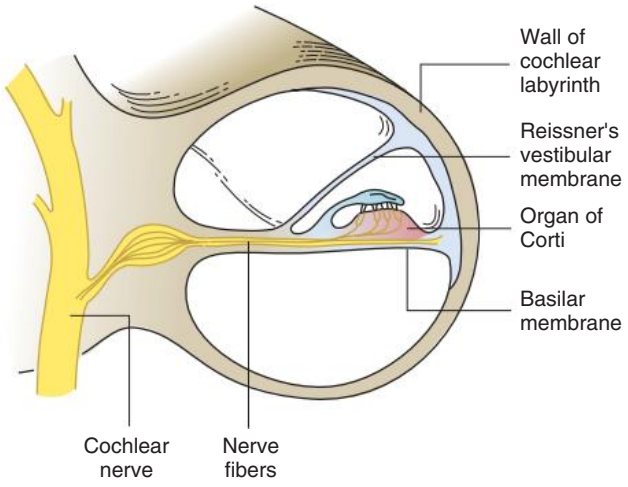
Hearing affects the quality and quantity of interpersonal interactions. It is a major sense for communicating within one's environment. Loss of hearing therefore affects social relationships. The type of deafness or hearing loss in varying degrees may result from the following:

1. *Disease,* such as otosclerosis, in which changes in the bony capsule of the labyrinth occur. Otosclerotic bone invades the stapedial footplate, resulting in its fixation and ultimate inability to vibrate in the oval window. Hearing loss is gradual but progressive. This type of deficiency can be surgically corrected when auditory nerve endings are not destroyed.
2. *Trauma,* such as a perforated eardrum, requiring repair to restore function and aerial ratio.
3. *Infection,* usually controlled by antibiotics. Although it is more common in children, infection may also occur in adults. It may cause accumulation of fluid in the middle ear. Mastoiditis results from extension of otitis media.
   a. Serous otitis media may result from obstruction of the pharyngeal orifice of the eustachian tube. If blocked, for example, by hypertrophied adenoid tissue, infection, or allergic swelling, the eustachian tube is unable to equalize pressure because air cannot enter the middle ear from the pharynx. The vacuum or negative pressure thus created causes serum to be drawn into the tympanic cavity from blood vessels in the middle ear mucosa. Recurrent otitis media may require drainage of purulent exudate if conservative treatment fails.
   b. Acute otitis media may require drainage of purulent exudate if conservative treatment fails.
   c. Chronic otitis media with or without mastoiditis may follow recurrent otitis media with tympanic membrane perforation. It can produce a chronically draining ear.

Differential Diagnosis

Measurements that compare bone conduction with air conduction are important in differential diagnosis. Bone conduction refers to hearing as transmitted through the skull; air conduction refers to transmission of sound waves from the tympanic membrane to the inner ear via air. Hearing loss caused by a defect in the external or middle ear, referred to as conductive loss, is a mechanical obstruction of air conduction that usually can be helped by surgical intervention. When the decrement is in the inner ear, referred to as perceptive or sensorineural loss, damage to nerve tissue and/or sensory paths to the brain is not benefited by a surgical procedure. Cochlear nerve endings are the main component of sensorineural hearing (Fig. 41.4).[3]

Auditory acuity and function are measured by various tests. The audiogram is one measurement tool. Computer-averaged tomography is used to measure and analyze electrical impulses, known as auditory brainstem responses, from the brain and cortical auditory pathway. An acoustic reflex latency test of the stapedius reflex provides information about hearing sensitivity. Auditory brainstem evoked potentials assess the patient's hearing threshold.



• **Fig. 41.4** Cross-section of cochlear labyrinth with sensory neural mechanism.

Surgical Procedures of the Ear

Current techniques, instrumentation, lasers, and the operating microscope have enhanced the capability of otologists.

General Considerations

1. Local anesthesia may be used for a minor procedure on the external ear, but general anesthesia is used to avoid patient movement while the surgeon is manipulating delicate structures in the middle or inner ear.
   a. Inhalation anesthesia may be given by facemask for a short procedure, with the anesthesia provider seated at the head of the OR bed.
   b. The anesthesia provider sits alongside the OR bed with the patient facing him or her when the patient is intubated for a major procedure.
   c. Hypotensive anesthesia may be employed to create a bloodless field, especially during microsurgery.
   d. Nitrous oxide is discontinued before placement of a graft in the middle ear to minimize the risk for increased pressure in the inner ear.
   e. General anesthesia may be supplemented with a local agent in some procedures, often with epinephrine to control bleeding.
2. The patient's head is turned with the affected side up and stabilized in a donut. The pinna on the unaffected side should be protected from pressure.
3. Lint-free drapes are preferred. It is mandatory that gloves be free of powder and lint. The formation of a powder granuloma in the oval window can cause irreversible sensorineural hearing loss.
4. The operating microscope is used for many otologic procedures. The light source must be carefully observed during the procedure. Strong lights from the microscope can cause tissue burns of the external auricle.[2] Placing a moist sponge over the tissue can increase the effect of the heat and is not advised.
   a. The surgeon sits at the head of the OR bed to use the microscope.
   b. Microinstruments should be carefully handled before, during, and after use.
5. Compressed absorbent patties (cottonoids) moistened with normal saline solution, rather than gauze sponges, are frequently used. They must be counted.
6. Hemostasis may be achieved with epinephrine, absorbable hemostatic sponges or oxidized cellulose, laser, and bone wax.
7. Prosthetic devices should be available in an assortment of types and sizes. Tissue allografts may be used.
8. A nerve stimulator may be used to identify facial, acoustic, cochlear, and/or vestibular nerve branches. Evoked potential audiometry also may be used to monitor the seventh and eighth cranial nerves.
9. Bone instruments, including powered drills, are used for opening the temporal bone.
10. CO_2, Nd:YAG, argon, and KTP lasers are used during otologic procedures to control bleeding, divide nerves, and/or vaporize tissues.
11. Pressure dressings are usually applied. Some surgeons place 1 drop of phenylephrine (Neo-Synephrine) in the ear canal postoperatively.

External Ear Procedures

Removal of a Foreign Body

Removing a foreign body from the outer canal is performed most frequently in children. The object is washed out or removed to prevent purulent infection. A plant seed or vegetable foreign body, such as a pea, is not irrigated, because it may swell in the ear and increase the difficulty of removal.

General anesthesia sometimes may be required. Trauma should be minimal during removal of a foreign body to prevent stenosis of the canal or perforation through the eardrum.

Drainage of a Hematoma

Usually a result of injury, a hematoma is drained to avoid infection with subsequent chondritis and deformity of the auricle.

Excision of a Tumor

The extent of the surgical procedure to excise a tumor, either benign or malignant, depends on the size and type of tumor. The skin of the pinna is vulnerable to actinic (chemical) changes caused by radiant energy during exposure to the sun. Basal cell lesions do not metastasize, but squamous cell carcinoma often does. Primary cancer may be excised by a wide or wedge excision with primary closure or a wide excision with a skin graft. If the lesion is extensive, partial or total pinnectomy may be necessary. The area can be skin-grafted and reconstructed cosmetically with a prosthesis. Radical temporal bone resection is indicated if the bone (canal) is involved. Neck dissection may be indicated if nodal metastases are present.

Middle Ear Procedures

Mastoidectomy

Mastoidectomy, the eradication of mastoid air cells, may be indicated to relieve complications of acute or chronic mastoiditis. Mastoidectomy is more commonly performed in conjunction with a reconstructive procedure (see "Tympanomastoid Reconstruction"). A **cholesteatoma** can form after repeated infections (Fig. 41.5).

Simple Mastoidectomy. The mastoid process is opened behind the ear. Air cells are removed by drilling through bone with small burrs, without involving the middle ear or external canal.

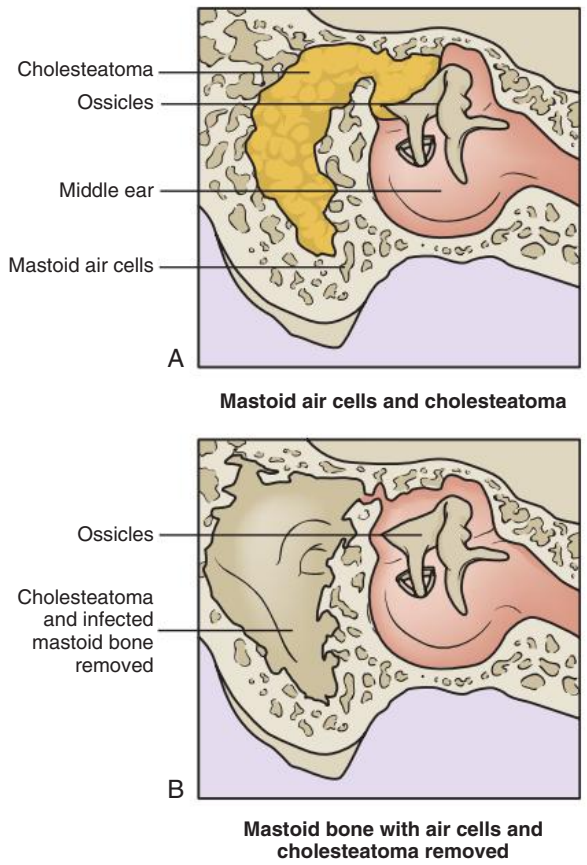
Modified Radical Mastoidectomy. Simple mastoidectomy and removal of the posterior wall of the ear canal provide drainage from the mastoid into the canal. The tympanic membrane and middle ear ossicles are preserved.

Radical Mastoidectomy. A radical mastoidectomy is performed for chronic mastoiditis. The middle ear cavity and mastoid antrum are combined into a single cavity for inspection and cleaning. Mastoid air cells are removed. The ossicles and tympanic membrane are partially removed. The stapes and facial nerve are preserved.

Tympanoplasty

Tympanoplasty, as a general term, refers to any procedure performed to repair defects in the eardrum and/or middle ear structures for the purpose of reconstructing sound conduction paths. The degree of hearing improvement after tympanoplasty is related to the degree of damage. Preferably, the ear should be uninfected at the time of the surgical procedure. If not, infected tissue is debrided. As microsurgical procedures, tympanoplasties are classified into the following five types:

1. *Type I* (myringoplasty) is closure of a perforation in the tympanic membrane caused by infection or trauma. The ossicular chain is normal. Autologous fascia or a vein is used to repair the perforation. A vein graft is taken from the patient's forearm or hand. Fascia, more commonly used as a patch over a perforation, is obtained from the temporalis muscle.



• **Fig. 41.5** **A,** Mastoid air cells and cholesteatoma. **B,** Mastoid bone with air cells and cholesteatoma removed.

2. *Type II* is closure of a perforated tympanic membrane with erosion of the malleus. The graft is placed against the incus or remains of the malleus.
3. *Type III* replaces the tympanic membrane to provide protection for the stapes and round window. The tympanic membrane, malleus, and incus have been destroyed by disease. The stapes is intact and mobile. A homograft of tympanic membrane with attached malleus and incus is placed in contact with the normal stapes, permitting transmission of sound.
4. *Type IV* is similar to type III except that the head, neck, and crura of the stapes are missing. The mobile footplate may be left exposed with the graft placed around it. The air pocket between the graft and the round window provides sound protection for the round window. To conserve the middle ear hearing mechanism, homograft transplantation of tympanic membrane and ossicles may be used to rebuild the chain.
5. *Type V* is similar to type IV except that the stapedial footplate is fixed because of otosclerosis (osteospongiosis). A fenestra (small opening) is made in the horizontal semicircular canal. The homograft seals off the middle ear to provide sound protection for the round window.

Reconstruction of the middle ear may be done with a synthetic bioinert material such as high-density polyethylene sponge (Plasti-Pore). Fibrin glue also is used. Partial and total ossicular replacement prostheses have been developed.

Tympanomastoid Reconstruction

Tympanoplasty may be combined with either simple or radical mastoidectomy. The mastoid is drained and cleaned before reconstruction of the eardrum or middle ear ossicles. After incision behind the auricle, the tympanic membrane and tympanic cavity are inspected. The mastoid antrum is entered by drilling through mastoid bone.

Sometimes in chronic otitis media the mucous membrane of the tympanic cavity is replaced by epithelium from the ear canal as it grows through a perforation in the eardrum. Desquamated skin cells that cannot escape form a ball or cyst, known as a cholesteatoma. If present in the middle ear or mastoid, a cholesteatoma is removed during mastoidectomy and/or tympanoplasty. If left intact, a cholesteatoma can cause permanent hearing loss, balance disturbance, infection, and facial nerve paralysis.

Stapedectomy and Stapedotomy

Conductive hearing loss can result from fixation of the stapes, most often caused by otosclerosis. The surgeon aims to restore vibration from the incus to the mobile oval window membrane to transmit sound. A stapedectomy involves partial or total removal of the stapes.

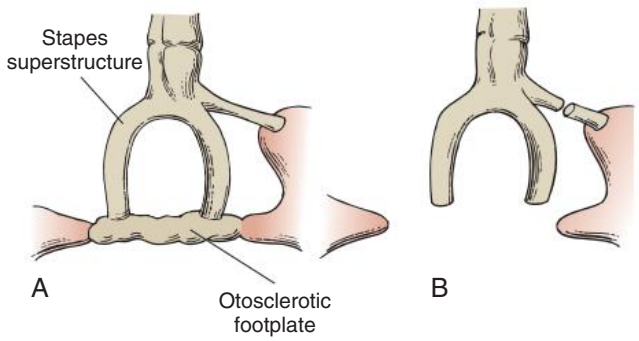
A partial stapedectomy removes only the fixed footplate (Fig. 41.6); a total stapedectomy removes the entire stapes, including the footplate. A stapedotomy (small opening into the footplate) may be the preferred procedure. The opening is made with a handheld perforator, microsurgical power drill, or laser. An argon, CO_2, or KTP laser may be used for this purpose. A low-wattage laser beam avoids thermal damage to the perilymph and inner ear structures. After partial or total stapedectomy or stapedotomy, the remaining superstructure is used to reconstruct the sound-conducting mechanism.

An incision is made deep in the canal near but not in the eardrum. The eardrum is folded over, giving access to the middle ear. The stapes is disconnected from the incus, fractured by fine microinstruments, and removed. The oval window is sealed by a graft of vein, perichondrium, fascia, fat, or an absorbable hemostatic sponge over the oval window. A prosthesis is inserted and connected to the incus and to the graft, thus restoring sound conduction. Prostheses are made of various inert materials such as polyethylene, stainless steel, or tantalum.

By performing the microsurgical procedure with the patient under local anesthesia, the surgeon can reposition the eardrum and use his or her voice to test whether the patient's hearing is improved. Otosclerosis usually involves both ears, but stapedectomy is performed on only one ear at a time.

Stapes Mobilization

The stapes is manipulated at the footplate to restore normal function. A break through an otosclerotic lesion is achieved by means



• **Fig. 41.6** Partial stapedectomy. **A,** Stapes superstructure attached to fixed otosclerotic footplate. **B,** Footplate removed; superstructure remains.

of transcrural pressure or direct application of chisels and picks to the footplate. A mobile, unaffected portion of a functioning stapes remains. Various techniques are used, with or without the use of prosthetic devices. The advantage of the procedure is that the preserved stapedial footplate provides natural protection for the inner ear. The disadvantage is that frequently a continuing otosclerotic process causes the footplate to become refixed. Therefore stapedectomy is more popular because it produces long-lasting results.

Stapes procedures are performed under direct vision with the operating microscope. The procedures do not disturb the integrity or position of the eardrum.

Removal of Middle Ear Vascular Tumors

The argon laser is absorbed by red pigment. Therefore it is suited for removal of small vascular tumors in the middle ear, such as glomus tympanicum tumors. The argon laser acts by photocoagulation.

Inner Ear Procedures

Endolymphatic Sac Shunt

The endolymphatic sac is an appendage of the membranous inner ear located in the posterior fossa, anterior to the lateral sinus and posterior to the semicircular canals. An excessive accumulation of endolymph in this sac causes the episodic vertigo (dizziness), tinnitus (ear ringing), and sensorineural hearing loss of Ménière's disease. Through a simple mastoidectomy approach, the sac is opened and the inner ear is drained into either the subarachnoid space or the mastoid. A shunt tube is inserted to maintain drainage.

Labyrinthectomy

In labyrinthectomy the vestibular labyrinth is removed from the inner ear to correct incapacitating vertigo. This results in loss of vestibular function and hearing.

Vestibular Neurectomy

A middle fossa approach to the internal auditory canal for vestibular neurectomy combines otologic and neurosurgical procedures. Through a temporal bone craniotomy incision, dura of the floor of the middle fossa is elevated to expose structures in the superior portion of the internal auditory canal. The superior and inferior vestibular nerves, which control equilibrium, are sectioned to control intractable vertigo. The cochlear nerve, the hearing portion of the eighth cranial (acoustic) nerve, is not damaged, thus preserving hearing. A graft of temporalis muscle is placed over the exposed internal auditory canal to prevent leakage of cerebrospinal fluid.

Removal of an Acoustic Neuroma

Acoustic neuroma resection may be performed by an otologist and/or a neurosurgeon, depending on its location and the extent of neurologic involvement. An acoustic neuroma is a slow-growing, encapsulated, benign tumor of the eighth cranial nerve. It originates in the neural sheath in the internal auditory canal but grows to involve nerve fibers in the posterior fossa. Initially the patient experiences unilateral hearing loss and disturbances, especially tinnitus, and equilibrium problems such as mild vertigo.

The syndrome may resemble Ménière's disease or an expanding intracranial tumor. Early differential diagnosis is enhanced by brainstem evoked response audiometry, vertebral angiography, and small-volume air-contrast computed tomography (CT).

A small neuroma, confined to the internal auditory canal, may be resected by the otologist using a microsurgical technique through a middle fossa approach to preserve hearing. If a translabyrinthine approach is used to gain access to the internal auditory canal posterior to the inner ear structures, the patient will have total hearing loss after the surgical procedure. Acoustic neuromas extending into the cranial cavity are resected by the neurosurgeon. The CO_2 laser may be used to excise acoustic neuromas through a transmastoid or craniotomy approach. Cerebrospinal fluid leak and meningitis are complications of the craniotomy approach.

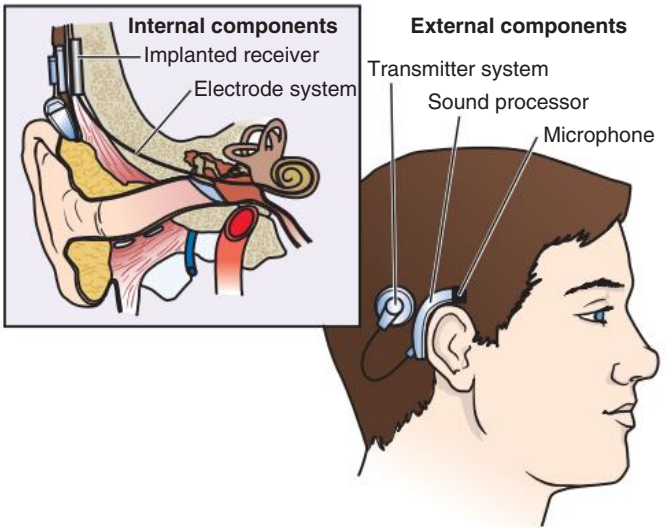
For select patients, stereotactic radiosurgery can be performed on an outpatient basis with local anesthesia. Hearing is preserved in 50% of these patients.

Implantation of a Cochlear Prosthesis

Cochlear implants have been used for adults since the 1980s, but it was not until the 1990s that they were used for children. Children as young as 1 year old can be candidates for implantation. Placement in a young child can assist in speech development when a conventional hearing aid does not provide adequate sound perception.[3] A cochlear implant can restore perception of sound to patients who have profound sensorineural deafness not responsive to external amplification of a hearing aid. They are indicated for use in patients who have intact eighth cranial nerve function.

The implant is an electronic device that converts sound waves into electrical signals to stimulate cochlear nerve fibers in the absence of functioning hair cells. Several devices are available. All of them have external and internal components (Fig. 41.7). The external part, which is attached behind the ear, has a microphone/transmitter and a speech processor/receiver. The internal part has a receiver/stimulator and electrode/channel that is threaded through the cochlea.

The internal electrode attaches to wires permanently implanted in the cochlea. Through a postauricular incision, a simple mastoidectomy is performed. Under the operating microscope, the facial recess between the posterior canal and the facial nerve is enlarged to expose the chorda tympani nerve and the middle ear. The electrode is securely seated in the mastoid cavity and placed through a recess into the middle ear. It is directed through an opening made in the round window into the scala tympani until it meets resistance. Placement is critical. A plug of fascia from the



• **Fig. 41.7** Cochlear implant.

temporalis muscle is placed around the electrode at the round window to prevent perilymph leakage.

The internal electrode stimulates the auditory nerve to interpret sound. The single-channel model stimulates the nerve randomly so the patient can discern environmental sounds but not speech. A multichannel electrode enables the patient to distinguish environmental sounds and some speech by differentiating the frequency, volume, and pitch of sound waves. With a single-channel electrode, a ground wire is placed under the temporalis muscle in the mastoid or middle ear. A multichannel electrode does not have a ground wire. The internal receiver is sutured in position over the temporal bone behind the ear.[3]

Electromagnetic components and/or a titanium enclosure for the receiver may act as an electrical ground device. Only bipolar electrosurgery is used if additional surgery is needed after placement of the receiver. Patients with cochlear implants should avoid magnetic resonance imaging (MRI) because of metal components within the implanted device.

The external microphone/transmitter component of the implant activates the internal receiver/stimulator. Transmission may be percutaneous or transcutaneous. In the percutaneous model, a direct wire to a receiver implanted behind the ear connects the transmitter. In the transcutaneous model, the transmitter converts electrical energy into magnetic currents that pass through intact skin to the receiver. In both models, sound enters the microphone and is transmitted to a speech processor, worn outside the body, where it is encoded into electrical signals or energy and amplified. The coded signals return to the transmitter and are passed to the internal receiver. The patient can adjust amplification of environmental sounds.

Robotic-assisted placement of cochlear implants may be performed using tiny incisions. Precise implant placement and avoiding delicate structures such as the facial nerve is done with CT scans.[3] Research is being done for totally implantable cochlear devices that use vibration sensors implanted into the cochlea. This technology does not have any visible external components.[3]

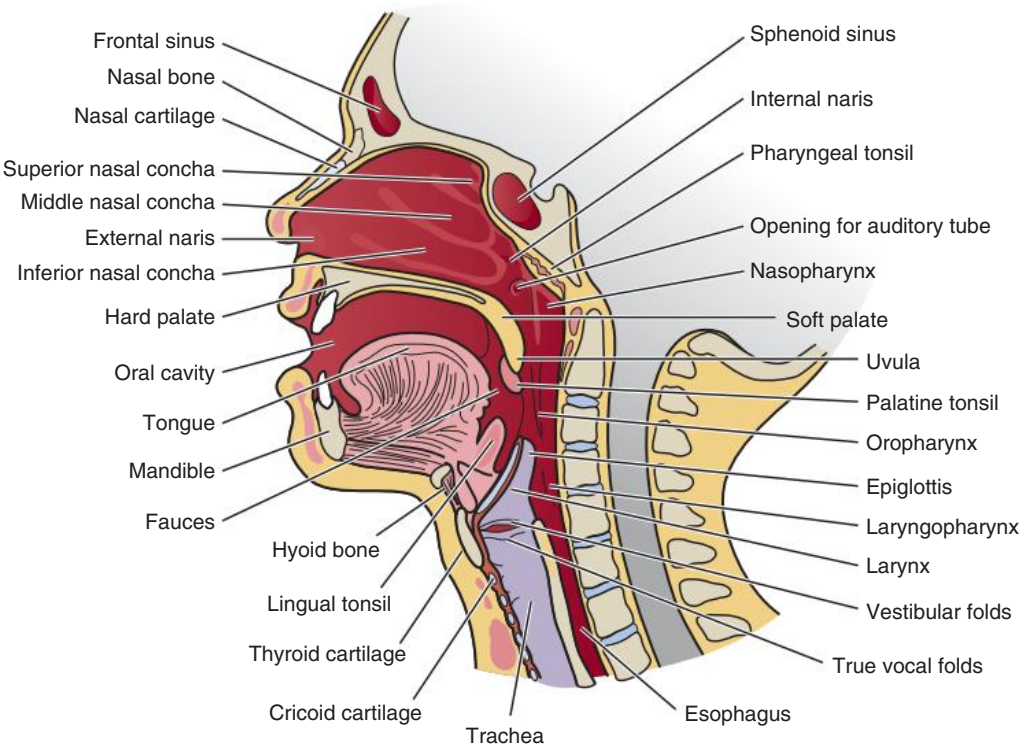
Nose

Anatomy of the Nose

The supporting structures of the nose consist of two nasal bones and the nasal processes of the maxillary bones superiorly, the lateral cartilages and connective tissue inferiorly, and the septum. The septum, composed of bone posteriorly and cartilage anteriorly, divides the nose into two chambers lined by mucous membrane. The anterior portion, or vestibule, holds the nasal hairs. The external anterior orifices are called nares.

The internal portion of the nose, the nasal cavity (Fig. 41.8), extends to the nasopharynx, the space behind the choanae (funnel-like posterior nasal orifices). The nose communicates with the ear via the eustachian tube. The hard and soft palates divide the nasal and oral cavities. The ethmoid bone separates the nasal and cranial cavities.

The paranasal sinuses are the frontal, maxillary, ethmoid, and sphenoid. Ostia (openings from the sinuses and nasolacrimal ducts) are located in the nasal lateral walls. The ostia provide a drainage system for the sinuses, as well as aerate them. Three turbinate bones (superior, middle, and inferior) are also situated in the lateral walls. These bones are covered with a vascular mucosa. Beneath each turbinate is a corresponding meatus. Tears drain into the nose through the nasolacrimal duct that enters the inferior meatus. Drainage from the paranasal sinuses is passed to the nose through the middle and superior meatus.



• **Fig. 41.8** Regions of the head and neck.

External and internal carotid arteries and their branches supply blood to the nasal region. Because of the extensive vascularity, lymphatic supply, and proximity to the brain, infections on or about the face are potentially very dangerous. Microorganisms may readily be carried to the cavernous sinus, or thrombi may form in the cavernous sinus. The sense of smell is derived from the first cranial (olfactory) nerve. The sensory nerve supply of the nasal area is associated with the trigeminal or fifth cranial nerve.

Physiology of the Nose

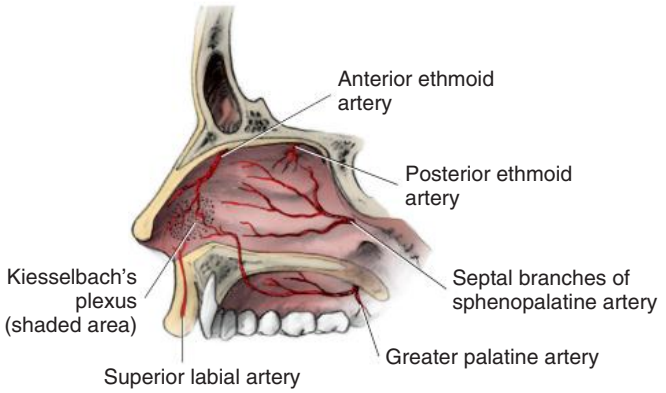
- It provides filtered air to the respiratory system. Fine cilia in the mucous membranes propel mucus toward the nasopharynx. Air is warmed and moistened as it passes to the trachea and lower respiratory tract.
- It contains the end organs for smell in the olfactory epithelium, which differs from other nasal epithelia. When nasal obstruction blocks off the olfactory epithelium, loss of smell (anosmia) results. The senses of smell and taste are closely related.

Surgical Procedures of the Nose

Nasal procedures are concerned with two factors: adequate ventilation to accessory spaces and adequate drainage from them. Abnormalities in structure, congenital or traumatic, and disease processes hinder function. Corrective procedures are done to relieve obstruction, to ensure drainage, to resect tumors, or to control bleeding (epistaxis).

General Considerations

1. CT and rhinoscopy are often performed preoperatively to diagnose the nature and extent of pathologic conditions, especially in the paranasal sinuses.
2. Many nasal procedures are performed with the patient under local anesthesia with or without IV sedation.
   a. Topical anesthetic agents may be sprayed on the nasal mucosa or applied with soaked, compressed, absorbent patties (cottonoids) or sponges put in the nostrils. The used patties must be accounted for at the end of the procedure.
   b. A local agent, often lidocaine hydrochloride, 1% or 2%, is injected into the middle meatus. Epinephrine usually is used for vasoconstriction to control bleeding.
   c. When general anesthesia is indicated, a pack is placed in the pharynx to prevent aspiration of blood after the patient is intubated. Reconciliation of the count and removal of the pack at the end of surgery is critical for prevention of retained foreign objects.
3. Paranasal sinuses and tissues underlying the mucosa are considered sterile. Therefore instrumentation must be sterile, although the nasal cavity is considered a contaminated area because the instrumentation is entering a vascular bed. Venous drainage could easily carry microorganisms to the cavernous sinus, causing an intracranial infection.
4. CO_2, Nd:YAG, and KTP lasers may be used. Endoscopes also are used. All equipment and accessories should be checked for working order.
5. Nasal packing is inserted at the end of most procedures except endoscopic sinus and laser procedures. A mustache dressing may be placed under the nose to act as a drip pad. Postoperatively the patient should be positioned in a head-up position to minimize edema and bleeding. Ice is placed over the nasal bridge for the first 48 hours in 20-minute intervals.



• **Fig. 41.9** Blood supply to nasal cavity.

Nasal Cavity Procedures

The supporting structures surrounding nasal air passages can be injured or displaced. Acute or chronic disease processes can cause dysfunction or obstruction.

Epistaxis

Most nosebleeds are caused by trauma, usually at Kiesselbach's plexus of arteries and veins (also known as Little's area) in the anterior part of the nasal septum (Fig. 41.9). Dehumidified air may cause changes in the mucosa and splitting of tiny vessels. Bleeding may be spontaneous, as in patients with arteriosclerosis, hypertension, or blood dyscrasia. Epistaxis is usually anterior and unilateral. In people with systemic disease, such as leukemia, or with severe fracture, the bleeding is frequently posterior and more severe. Management involves locating the precise bleeding site and promptly instituting appropriate therapy. Severe hemorrhage places the patient in a precarious condition. Hypovolemia should be corrected preoperatively.

Anterior Pack. Local vasoconstriction and pressure on the side of the nose will control most nosebleeds. Electrocoagulation or silver nitrate is used to provide hemostasis at the bleeding point as needed. When bleeding is from the anterior ethmoid artery, inaccessible to cautery, packing is applied to the area of depression between the septum and the middle turbinate.

Posterior Pack. A posterior pack may be necessary for constant pressure when bleeding is severe in the posterior part of the nose. The pack consists of rolled gauze securely tied to the middle of a length of narrow tape or strong string; commercial packs are available. To control infection and odor, gauze is lubricated with antibiotic ointment before insertion.

After a catheter is passed into the mouth via the nose, one end of the tape is tied to the oral end of the catheter. The catheter and attached tape are then drawn back through the mouth and out one nostril, thereby pulling the pack up into the nasopharynx. Thus one end of the tape comes out of the nose, the other end out of the mouth. These ends are secured to the patient's cheek with adhesive tape. The nasal end is taped to prevent the pack from slipping into the throat; the oral end facilitates removal of the pack. Some oozing may persist despite packing. The pack is left in place until bleeding is arrested, usually for at least 48 hours, but prolonged use can lead to otitis media or paranasal sinusitis.

Patients with postnasal packs are often apprehensive and uncomfortable. They must breathe through the mouth. Posterior packs tend to reduce arterial oxygen tension. All patients, especially geriatric patients and those with marginal pulmonary

function, should be observed carefully for respiratory problems that may result from the pack dropping into the hypopharynx.

Artery Ligation. A microsurgical procedure is performed to control persistent nasal hemorrhage by reducing the blood supply to the posterior portion of the nose. Some surgeons prefer artery ligation to packing, or it may be performed with a pack in place. Through an incision in the oral mucosa, removal of the posterior wall exposes the maxillary sinus for transantral ligation. Terminal branches of the internal maxillary artery, a branch of the external carotid artery, are exposed, identified, and ligated with metallic clips. Electrocoagulation is employed to control intraoperative bleeding, but if bleeding is excessive, creation of a nasoantral window establishes drainage. The replaced posterior mucosal flap is covered with an absorbable gelatin sponge, and the incision is closed.

Through an incision along the left side of the nose, ligation of the anterior and posterior ethmoidal arteries is helpful in controlling bleeding in the superior aspect of the nose.

The argon or KTP laser may be used to control severe epistaxis. If a laser is used to control bleeding, nasal packing usually is unnecessary.

Turbinectomy

Chronic engorgement of the middle and/or inferior turbinate causes nasal congestion and rhinorrhea. Rhinitis is frequently an allergic reaction. A KTP laser shrinks turbinates without removing normal mucosa. A CO_2 or Nd:YAG contact laser vaporizes the superficial layer of mucosa without injuring the turbinate or ablating the turbinate. The KTP or CO_2 laser fiber handpiece is directed through a nasal endoscope. Because bleeding is minimal, nasal packing is unnecessary. Electrocoagulation and cryosurgery also have been used to treat soft tissue obstruction and refractory allergic rhinitis.

Nasal Obstruction

Surgical intervention can provide relief for certain types of nasal obstructions. For example, after the mucosa is shrunk with a vasoconstrictor and secretions are suctioned, a foreign body is removed with a forceps. An abscess or hematoma may need to be drained to relieve pressure. Accumulation of pus or blood separates the perichondrium, the connective tissue, from underlying cartilage. This may cause necrosis of cartilage with resultant deformity. Infection must be eradicated to avoid extension to the brain.

Polypectomy. Polyps (soft, edematous masses) projecting from the nasal or sinus mucosa can obstruct the posterior choanae. Polyps usually are bilateral, but they may be unilateral, may be single or multiple, and frequently are infected. In addition to obstructing ventilation, they may obstruct the sense of smell if the olfactory epithelium is blocked.

Some polyps may be excised with a wire-loop snare through a nasal speculum or with forceps through an endoscope. Packing is inserted to control bleeding. The KTP laser coagulates the base to debulk multiple large polyps. The laser fiber can be directed through a straight or angled handpiece. A CO_2 laser can vaporize polyps. The laser is less invasive than other techniques.

Nasal Deformity

Surgical intervention can restore contour and/or improve function after an injury. A deformity in nasal structure also may be corrected to improve cosmetic appearance.

Reduction of a Nasal Fracture. Fracture of the septum or nasal bones often accompanies other trauma to the head. Intranasal manipulation is required to elevate depressed bone or cartilage that may be pushed into the paranasal sinuses. This should be performed as soon as possible to bring the parts into apposition. A delay of 7 to 10 days to permit edema to subside will not affect the outcome. Bleeding from a laceration must be immediately controlled and drained. Intranasal structure compatible with air passage must be preserved.

Septoplasty, Septal Reconstruction, and Submucous Resection. The terms *septoplasty, septal reconstruction,* and *submucous resection* are used interchangeably to describe correction of a deviated nasal septum. Often the result of injury, the condition interferes with breathing and drainage. With the patient under local anesthesia, one side of the septum is incised its entire length. Membranous coverings are detached from cartilage and bone. The deformed part of the septum is removed or straightened and replaced. Bilateral nasal packing is inserted to hold tissues in place and prevent bleeding. The procedure creates a patent airway and straight septal line, thereby reducing sinus disease and polyp formation.

Rhinoplasty. Rhinoplasty, a procedure to correct deformity of the nose, may be performed by a rhinologist or a plastic surgeon. It is a major procedure involving reconstruction and molding of the bones and cartilages. Septoplasty and rhinoplasty may be performed together; septorhinoplasty restores both function and cosmetic appearance. Local anesthesia and a vasoconstrictor are usually used.

Some surgeons prefer to use a nasal spray 30 minutes preoperatively. Both drugs decrease the risk for hypertension during the procedure, which could cause excessive bleeding. The skin is taped postoperatively to maintain the nasal structures in alignment. A rigid shield is applied for protection. This is not removed without a specific order from the surgeon. Temporary ecchymosis from surgical trauma surrounds the eyes postoperatively.

Repair of a Perforated Septum. Perforations occur most often in the anterior cartilage. If bleeding and crusting are severe, the perforation may be covered by rotated mucoperichondrial flaps or the mucosa of adjacent intact septum may be denuded and a skin graft applied to cover the perforation. Nasal packing is inserted.

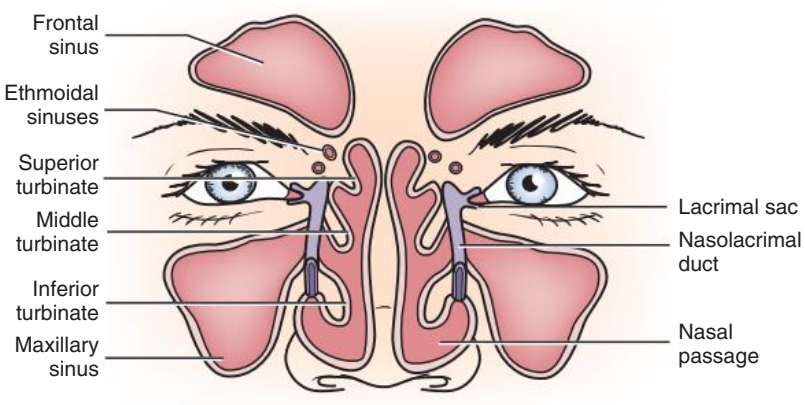
Paranasal Sinus Procedures

The paranasal sinuses are air-filled spaces in the skull (Fig. 41.10). Because the sinus mucous membrane lining is continuous with the mucous membrane lining of the nose, nasal infection may readily spread to the sinuses. Various procedures provide drainage for patients with chronic sinusitis that may result from allergies or repeated nasopharyngeal infection. Swelling of the nasal mucosa can trap microorganisms within a sinus cavity. Ostial occlusion and abnormalities in the walls of the nasal cavity interfere with breathing, drainage, and smell. Sinus procedures are executed through an external or an intranasal approach or through an endoscope.

Maxillary Sinus Procedure

The maxillary sinuses are located bilaterally between the upper teeth and the eyes.

Caldwell-Luc Procedure (Antrostomy). The maxillary sinus contents are approached through an incision of the oral mucous membrane above the canine teeth. The flap is retracted. A section of maxillary bone is cut out to create a large nasoantral window for aeration and permanent drainage by gravity into the nasal fossa under the inferior turbinate. Polyps and diseased tissue are removed, along with eradication of mucosa. At the completion of



• **Fig. 41.10** Paranasal sinuses.

the surgical procedure, the sinus is packed with gauze impregnated with antibiotic ointment. One end of the gauze is brought through the window and into the nose. The incision under the upper lip is sutured. The packing is eventually removed through the nose. Antrostomy is usually limited to adults because of unerupted teeth in children. A Caldwell-Luc incision is also used for removal of a tumor in the maxillary sinus.

Ethmoid Sinus Procedures

The ethmoid sinus cells lie bilaterally between the nose and the orbits. The maxillary sinuses are below the ethmoid bones, and the frontal sinuses are above them.

Ethmoidectomy. Diseased tissue is removed from the ethmoid labyrinth, middle turbinate, and meatus. A large cavity is formed to facilitate aeration and drainage. Severe ethmoiditis can cause orbital abscess requiring drainage through an intranasal or external (Lynch) incision that extends from the inner half of the eyebrow down alongside the nose.

Turbinectomy. Removal of portions of the inferior and middle turbinates increases aeration and drainage. The cavity is packed at completion of the surgical procedure.

Frontal Sinus Procedures

The frontal sinuses are situated above the eyes. They are usually approached through the external incision described for ethmoidectomy, or a coronal incision may be made for exposure across the scalp from ear to ear.

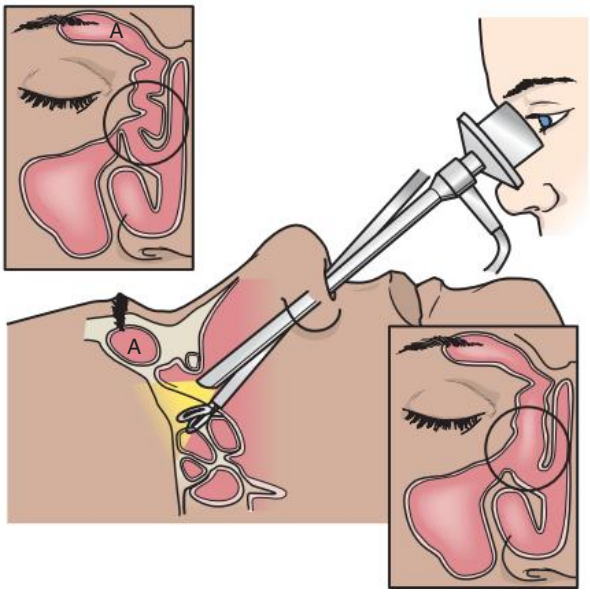
Osteoplastic Flap Procedure. The bone covering the frontal sinus is exposed and incised. The contents of the sinus, such as a mucocele (a cyst lined with mucus-secreting glands), are extracted. The lining of the mucocele sac is removed and the cavity packed with fat (from the abdominal wall) to obliterate the sinus with fibrous tissue that fills in the cavity. The incised bone flap is then repositioned, and the incision is sutured.

Killian Procedure. A frontal sinus cavity is reached by removal of the floor or anterior wall of the sinus through an external incision above the eye. A large communication and drainage channel into the nose is formed.

Sphenoid Sinus Procedure

The sphenoid sinus is deep—almost in the center of the skull. It may be approached intranasally or via the external ethmoidectomy incision through the eyebrow.

Sphenoidotomy. Sphenoidotomy involves the creation of an opening into the sphenoid sinus for drainage.



• **Fig. 41.11** Sinusoscopy.

Endoscopic Sinus Surgery

Sinuscopes permit direct visualization of the paranasal sinuses and the anatomy of lateral nasal walls. The site of diseased mucosa or obstructive tissue, such as polyps, can be localized for removal, with preservation of some mucosa and restoration of drainage (Fig. 41.11). The mucosa of each sinus has cilia that move air in waveforms. With an endoscopic approach, some ciliary motion may be retained for aeration.

The basic principle of endoscopic sinus surgery is that most sinus mucosal disease will resolve if aeration and drainage are reestablished. The extent of the procedure depends on the location of diseased mucosa and the resection necessary to establish drainage. Septal deformities or inferior turbinates causing nasal obstruction may be concurrently corrected (i.e., septoplasty and turbinoplasty). Minor procedures limited to removal of disease from maxillary or ethmoid sinuses usually can be done with topical and local anesthesia. IV sedation or general anesthesia is needed for more extensive procedures, such as ethmoidectomy or sphenoethmoidectomy.

The telescopes of sinuscopes are 2.7 and 4 mm in diameter with 0, 25 or 30, 70, and 120 degree viewing angles. The quartz rod telescope has a solid quartz optical cone in the lightpost that

attaches to a halogen light source. This system provides optimal light transmission through the fiberoptics of the miniaturized scope. An attached suction/irrigation device permits unobstructed viewing. The telescope is inserted intranasally and advanced into the frontal, ethmoid, or sphenoid sinus. It is inserted through a cannula in the canine fossa to reach the maxillary sinus.

Many accessory grasping and cutting instruments, including the KTP laser, are used to remove mucosa, lamina, osteum, and cells. Hemostasis is controlled with epinephrine and cautery or laser. Nasal packing usually is not required.

Functional Endoscopic Sinus Procedure. The functional endoscopic sinus procedure (FESS) is also known as the Messerklinger technique. The surgeon begins at the ethmoid and works anteriorly to the frontal and maxillary sinuses to clear ethmoidal compartments of disease. If a minimal opening of the narrow osteomeatal tract at the anterior ethmoidal sinus will not achieve adequate drainage from other paranasal sinuses, a posterior ethmoidectomy and sphenoidotomy are included in the procedure.

Exenteration. Known as the Wigand procedure, total sphenoethmoidectomy and partial middle turbinate resection are performed, beginning with a sphenoidotomy and working anteriorly to the frontal sinus. This creates a broad opening of the sphenoidal, ethmoidal, frontal, and maxillary sinuses. To avoid the optic nerve, dissection does not extend beyond the lateral wall of the sphenoid. Visual evoked potentials monitor optic nerve function; the eyes are uncovered. The endoscopic procedure may be done bilaterally.

Resection of Tumors

Osteoma, a benign tumor, can arise from bones around the paranasal sinuses. Although rare, primary carcinoma and sarcoma do occur in the frontal, ethmoid, sphenoid, and maxillary sinuses. Most originate in the maxillary sinus. The incidence increases with age. The sinuses are proximal to the orbits, oral cavity, and base of the skull. A tumor in the maxillary sinus may be associated with oral or nasal symptoms, such as loosening of the upper teeth, bleeding from the nose, or asymmetry of the face. A malignant lesion in the ethmoid sinus may be accompanied by displacement of the eye, disturbance of smell, and nasal obstruction. Chronic sinusitis is thought to play an etiologic role because of an associated replacement of respiratory epithelium by stratified squamous cells.

Most sinus tumors are squamous cell carcinomas. Often the bony walls are invaded and destroyed by the time symptoms appear because the tumor tends to extend in all directions. Exploratory surgery by a Caldwell-Luc incision provides the best chance of early diagnosis. Radical craniofacial resection may be indicated.

Oral Cavity and Throat

Anatomy and Physiology of the Oral Cavity and Throat

The oral cavity is lined with thick mucous membrane. This squamous mucosa connects with the nasopharynx superiorly and the hypopharynx below. The hard palate, part of the maxillary bone, forms the floor of the nasal cavity and the anterior part of the roof of the mouth. The soft palate, a musculomembranous structure posterior to the hard palate, occludes the nasal cavity during speech and swallowing. These functions are aided by the uvula, a small conical appendage (tongue-like structure) that projects from the posterior free margin of the soft palate. It contains the uvular muscle covered by mucous membrane. The tongue, occupying much of the oral cavity, joins the soft palate and pharynx posteriorly by folds of mucous membrane.

The throat refers to space surrounded by the soft palate, the palatoglossal and palatopharyngeal arches, the base of the tongue, and the pharynx. The funnel-shaped pharynx is subdivided into the nasopharynx (above), oropharynx (middle), and hypopharynx (below). The nasopharynx communicates with the nasal cavity through the posterior choanae. The oropharynx includes the base of the tongue anteriorly, the tonsillar fossae laterally, and the oropharyngeal walls of the throat posteriorly. The hypopharynx leads from the oropharynx to the larynx, trachea, and esophagus. The pharynx, posterior to the larynx and the nasal and oral cavities, consists of constrictor muscles essential to swallowing. The proximity of food and air passages and the joint function of the pharynx in their passage contribute to the hazard of aspiration.

The nasopharynx and oropharynx contain masses of lymphoid tissue. The adenoids (pharyngeal tonsils) hang from the nasopharyngeal roof; the lingual tonsils are in mucosal crypts. The palatine tonsils lie on either side of the oropharynx. These, referred to as the tonsils, are supported in the tonsillar fossae by anterior and posterior pillars. A fibrous capsule adheres to each laterally.

The salivary glands are located in the soft tissue walls of the oral cavity. The six major paired glands are the submandibular, sublingual, and parotid glands. The parotid glands are the largest. The ducts of these major glands, in addition to lesser glands, secrete saliva into the mouth. Saliva functions to moisten and lubricate food to aid in swallowing, to dissolve some substances and enzymatically digest starches, and to facilitate tasting.

Surgical Procedures of the Oral Cavity and Throat

Pathologic conditions may affect the lips, tongue, floor of the mouth, palates, salivary glands, or pharynx. The oral region is one of the most vascular areas of the body. Hemostasis may be achieved with an electrosurgical unit (ESU), hemostatic scalpel, argon beam coagulator, or laser. Lasers are used to vaporize both benign and malignant superficial and subepithelial lesions.

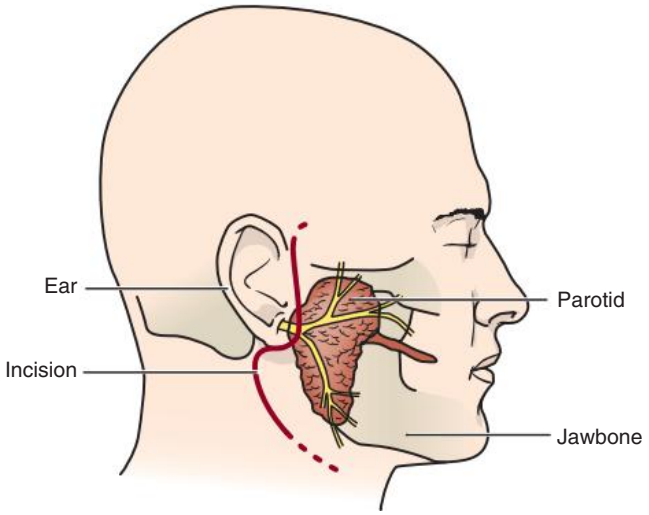
Abnormalities result from congenital malformation, improper occlusion or jaggedness of teeth, and infection, but most commonly they result from trauma and neoplasms. Adequate reconstruction restores the lining, internal structural support, soft tissue, and external coverage. Many of the craniofacial, maxillofacial, and dentofacial procedures previously described in this chapter are performed through intraoral incisions. Plastic surgeons, oral surgeons, laryngologists, or a multidisciplinary team may perform the following procedures through intraoral or extraoral incisions.

Excision of Salivary Gland Tumors

Benign mixed tumors of the salivary glands are more common than are malignant tumors and most frequently are located in a parotid gland. Most tumors can be removed by dissection, and some can be removed by cryosurgery. The incision is of adequate size to expose the entire gland and the facial nerve. A nerve stimulator is used to identify the nerve and its branches. Injury to the nerve results in postoperative facial paralysis.

Parotidectomy

Parotidectomy, excision of a parotid gland, is performed through an incision in the neck below the angle of the mandible and extending upward to one or both sides of the ear (Fig. 41.12). A swelling beneath the skin in the area in front of or below the ear



• **Fig. 41.12** Parotidectomy.

is almost invariably within the substance of the parotid gland. This may be a benign, mixed, or malignant tumor. Benign lesions localized superficially may be excised by superficial subtotal parotidectomy. Lesions deep within the gland, extending under the mandible, frequently displace the soft palate in the oral cavity.

Radical neck dissection or hemimandibulectomy may be indicated to remove a highly invasive malignant tumor. For most parotid tumors the facial nerve can be isolated and preserved during total parotidectomy, unless the nerve is inextricably involved by the tumor. If the facial nerve is to be sacrificed, the nerve may be primarily grafted, with the great auricular nerve as a graft, to prevent total facial nerve paralysis.

Excision of Oral Carcinoma

Primary malignant lesions may occur in the lower lip, tongue, or floor of the mouth. Because of the proximity of cervical lymph nodes, metastasis occurs early. A painful bleeding ulcer is considered a suspicious symptom. Oral cancer in its earliest stages may be asymptomatic and painless. The human papillomavirus is a common cause. Small tumors may be treated with only irradiation, local excision with primary closure, or vaporization with a laser beam. Larger lesions compel more extensive procedures.

Subtotal Glossectomy or Hemiglossectomy

In subtotal glossectomy or hemiglossectomy, part (subtotal) or half (hemi-) of the tongue is removed (glossectomy). The extent of the resection will determine the type of reconstruction to resurface the oral cavity. Innervated free flaps may be used to maintain bulk and tone.

Total Glossectomy

All of the tongue and often the floor of the mouth are resected. A pectoralis major myocutaneous island flap is more advantageous than are the cervical, pectoral, or forehead flaps also used to restore the intraoral lining. Respiratory embarrassment and chronic aspiration are significant problems after glossectomy.

Cricopharyngeal myotomy may be performed to facilitate swallowing and reduce aspiration. The tip of the epiglottis is often sutured to the pharyngeal wall (epiglottopexy) to decrease aspiration. Unless it is involved directly with tumor, the larynx is preserved. Laryngeal suspension, achieved by placing a heavy suture around the mandibular ramus, holds the larynx laterally. Extension into the larynx and cervical metastases are indications for unilateral or bilateral neck dissection, usually with laryngectomy. A tracheotomy is always performed with a total glossectomy to maintain an airway.[3] For postoperative alimentation, a nasogastric tube is inserted before closing the pharynx.

Procedures of the Nasopharynx

Uvulopalatopharyngoplasty

Increasing the air space in the oropharynx corrects obstructive sleep apnea (OSA) caused by anatomic relationships in some patients. OSA can cause oxygen desaturation during apneic episodes that occur during sleep. This can lead to life-threatening pulmonary and systemic hypertension, cardiac dysrhythmias, and neurologic dysfunction if untreated. Upper airway obstruction may be caused by nasal obstruction, a deviated nasal septum, hypertrophied adenoids and/or tonsils, or mandibular retrognathism (overbite), which may be surgically corrected.

To diagnose OSA in patients who do not have obvious abnormalities, airway obstruction can be viewed during sleep with fiberoptic nasopharyngoscopy and fluoroscopy. Obstruction of the air passage for more than 10 seconds is diagnostic. Oxygen saturation of the blood is 85% in moderate cases and less than 60% in severe obstructive cases. Some of the oropharyngeal muscles may become atonic and collapse inward, and the soft palate may drop down. Patients who have a large, drooping soft palate and at least moderately redundant lateral pharyngeal walls or large tonsils are good candidates for uvulopalatopharyngoplasty. These patients have moderate apnea but do not have severe cardiac dysrhythmias.

The patient is continuously monitored during induction of anesthesia. The surgeon is present, and an emergency tracheotomy tray is available in case the patient's airway becomes obstructed.[4]

The full thickness of mucosa is resected from the posterior margin of the soft palate, including the uvula, and most of the anterior tonsillar pillar. The lesser palatine artery is ligated. The tonsils or mucosa of the tonsillar fossae is resected. The remaining posterior tonsillar pillar is sutured to the resected anterior pillar.[5] The palate is closed laterally. The extent of tissue removal varies according to the width and depth of the patient's oropharyngeal space.

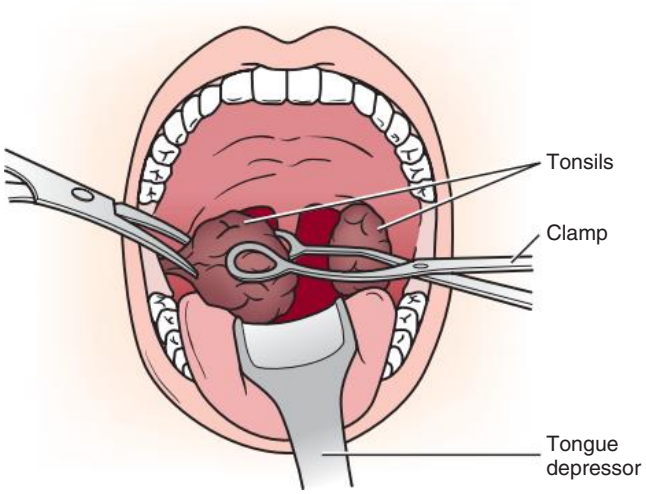
Hypoglossal Nerve Stimulation

In 2019 the U.S. Food and Drug Administration (FDA) approved a nerve stimulator for use in patients with obstructive sleep apnea. A small generator, similar to a pacemaker, is implanted in the upper chest. An electrode is placed around the hypoglossal nerve and a sensor is implanted in the intercostal space. A lead from each is tunneled and connected to the generator. The generator can be programmed to stimulate the hypoglossal nerve during inspiration, preventing airway obstruction.[6]

Adenoidectomy

Adenoidectomy, the removal of hypertrophied adenoid tissue from the nasopharynx and behind the posterior choanae, may be performed in adults to relieve upper airway obstruction. This is more commonly performed in children, often to prevent recurrent otitis media. Adenoid tissue usually atrophies after adolescence.

The patient is supine. General anesthesia is administered, and the patient is intubated. Adenoids can be resected with an adenotome and curette or vaporized with a CO_2 laser. Bleeding is more easily controlled with the laser. Electrosurgery and/or gauze sponges soaked in epinephrine may be used after sharp dissection. Occasionally a posterior nasal pack is needed.



• **Fig. 41.13** Tonsillectomy.

Procedures of the Oropharynx

Tonsillectomy

Chronically infected or hypertrophied tonsils are most frequently removed in childhood (Fig. 41.13). Even slightly enlarged tonsils can obstruct airflow to the lungs during sleep in an adult. Tonsillectomy may significantly improve symptoms of sleep apnea, with or without uvulopalatopharyngoplasty.

A CO_2, Nd:YAG, argon, or KTP laser may be used to excise tonsils from the tonsillar fossae.

The patient is supine. General anesthesia is administered. The endotracheal tube and cuff must be protected, and other laser precautions must be taken around the oral cavity. A smoke evacuator should be available with a CO_2 laser. A handheld laser may be used, or a beam may be directed through the microscope.

Local anesthesia is sometimes used for adult tonsillectomy. The patient is in the semi-Fowler's or sitting position on the OR bed or sits in a specially designed chair. The throat is anesthetized with a topical agent and local infiltration. With sharp and blunt dissection, each tonsil is separated from the pillars and capsule and removed from the fossa with a tonsil snare.

Attention is given to hemostasis to prevent aspiration; suture ligatures, free ties, and/or absorbable ligating clips may be used. Bleeding can be difficult to control and can occur postoperatively with this technique. Less intraoperative bleeding occurs with laser tonsillectomy.

Incision and Drainage of a Peritonsillar Abscess

Less common since the advent of antibiotics, incision into the anterior tonsillar pillar may be necessary to drain purulent material posterior to the tonsillar capsule after acute tonsillitis.

Resection of a Tonsillar Tumor

A localized squamous cell carcinoma of the tonsil may be resected by dissection or with cryosurgery. An en bloc resection includes the primary tumor and nodes. Metastatic nodes are common. Superior progression of the tumor may reach the supratonsillar fossa, soft and hard palates, and uvula. Inferiorly the tumor may spread to the posterior and lateral walls of the larynx, base of the tongue, and pyriform sinus. Neck dissection may be indicated for regional disease. Surgery may be combined with preoperative or postoperative radiation therapy. The most common complications are fistula formation and delayed healing.

Pharyngeal Diverticulectomy (Zenker's Diverticulum)

Pharyngeal diverticulectomy, or removal of sacs or outpouching of lower pharyngeal mucous membrane in which food collects, may be performed in extreme cases in which regurgitation presents a hazard of aspiration. The neck of the sac is dissected from the posterior pharyngeal wall and ligated. The stump of the excised sac is inverted into the pharyngeal wall. Diverticula may be removed endoscopically.

Dental Procedures

Just as the scope of many medical-surgical specialties, such as otolaryngology and head and neck surgery, has broadened, so has dentistry. Likewise, subspecialization within dentistry, through extensive specialized postgraduate education, has given OR practice privileges to dentists who perform surgical procedures in and around the oral cavity. Among these are the following:

- *Oral surgeon:* Oral surgery may be limited to exodontia (extraction of teeth) and minor surgery in the oral cavity. It may also include correction of dentofacial deformities (i.e., oral and maxillofacial surgery). A qualified oral surgeon is competent to complete a history and physical examination and thus determine the patient's ability to undergo the proposed surgical procedure.
- *Orthodontist:* Orthodontics focuses on irregularities of the teeth, malocclusion, and associated facial problems.
- *Prosthodontist:* Prosthodontics is concerned with artificial restoration of intraoral and external facial structures.
- *Periodontist:* Periodontics is the treatment and prevention of disease in the gingiva (gum), underlying soft tissues, and alveoli surrounding the teeth.

Patients with medical problems admitted to the hospital by oral surgeons and all patients admitted for dental care have an admission history, physical examination, and evaluation of their overall medical risk by a physician preoperatively. This physician is responsible for the care of a preexisting condition and any medical problem that arises during hospitalization.

Just as physicians from various specialties function as members of a multidisciplinary team, so do oral surgeons and dentists, each contributing to the dental health of the patient. Frequently they also function as collegial members of the teams involved in craniofacial or maxillofacial surgery. They assist with reconstruction of the face, correction of jaw deformities, and establishment of optimal dental occlusion. For example, the orthodontist may move teeth before a maxillofacial or oral surgeon repositions the jaws to correct malocclusion. Many patients undergo both preoperative and postoperative orthodontia. Prosthodontics may be necessary to replace missing teeth. Prosthodontists also may fit an artificial nose postoperatively after rhinectomy for a tumor or trauma.

Patients seeking dentofacial treatment usually have functional problems. These may include difficulty with mastication (chewing) and **deglutition** (swallowing), speech problems, abnormal tongue posture, or lip incompetence. A dental surgical procedure is defined as any manipulation, cutting, or removal of oral or perioral tissues and tooth structures where bleeding occurs. Oral surgeons and periodontists perform these procedures.

Periodontics

Diseases that affect the gingiva, bone, and supporting structures such as periodontal ligaments can occur at any age. Periodontal disease is the primary cause of tooth loss in adults older than

35 years. Treatment usually takes place in the periodontist's office. Patients who have medical problems, such as hemophilia or some other blood dyscrasia, severe diabetes, or heart disease, are admitted to the hospital. Periodontal plastic surgery encompasses resective, regenerative, and reconstructive techniques.

Gingivectomy

Portions of the gingiva, mucous membrane, and underlying soft tissue that covers the alveolar process and surrounds the teeth are excised to remove deep pockets of plaque, calculus, and inflamed soft tissue. The CO_2 laser may be used for this procedure.

Mucogingivoplasty

Plastic surgery around the teeth and gums is done primarily to reduce inflammation, prevent accumulation of bacteria, and stop sensitivity. Another indication is to rebuild bone and soft tissue destroyed by disease or trauma. Excessive gum tissue is excised to contour or reshape the gingiva for improved physiologic form or aesthetics. The alveoli may be reconstructed to change their shape and height. Gingival margins may be reshaped for the site of a false tooth or fixed bridge.

Gingival grafting or augmentation done before or during orthodontic treatment may reduce the risk for recession of gum tissue from around the roots of the teeth. Autologous mucogingival free grafts from the hard palate or pedicle flaps from adjacent tissues may be used to cover receded alveolar mucosa or an exposed tooth root. Flaps or grafts are used to augment inadequate zones of masticatory gingiva. Gingival onlay grafts are also used to enhance ridges where trauma or extraction has resulted in a reduced ridge, thus correcting an aesthetic defect.

Alveolar Ridge Reconstruction

The alveolar ridge is the bony remains of the alveolar process of the maxilla or mandible that formerly contained the teeth. Some edentulous patients have atrophic maxillae and/or mandibles or bony defects caused by trauma or tumor resection that will not support artificial dentures. The alveolar ridges can be augmented or reconstructed.

Inlay Bone Grafts

Bone grafts are used for augmentation of the maxillae and/or mandible. A prevascularized autologous rib graft may be transplanted into a maxillary defect; microvascular anastomoses revascularize the graft. Composite grafts of freeze-dried cadaver rib with autologous particulate cancellous bone and marrow may be preferred in the maxilla. Iliac bone used to augment the mandible calvaria may be harvested from the frontal, parietal, or occipital cranial bones for maxillofacial bone grafts. Calvarial bone undergoes less resorption than rib and iliac bone because of its dense blood supply; graft tissue revascularizes rapidly. Titanium osseointegration fixtures may be used to secure calvarial bone grafts in place.

Dental Implant

Fixtures are implanted into the gingiva and attached to bone to replace or augment lost dentition. Dental implants may replace a single tooth or missing teeth. They are made of biocompatible metals, most commonly titanium, and may be coated with ceramic, carbon, or sapphire. Several types are used:

- *Endosteal implant:* A threaded screw, cylinder, or flat blade is implanted in an alveolus in the maxilla or mandible. The number of implants placed depends on availability of bone and the number of teeth to be replaced. The fixture is covered with soft tissue. By the process of osseointegration, a perimucosal seal and bond develop between the gingiva and the surface of the implant. Some implants have small holes that allow bone to grow through them to secure the implant. After a minimum of 3 (for the mandible) to 6 (for the maxilla) months, a second-stage procedure is performed to connect a solid post to the implanted fixture. This extends slightly above the gingiva. The artificial tooth is attached to this post with tiny screws. Osseointegration provides firm, immobile support and distributes the stress of chewing evenly within the jaw.
- *Subperiosteal implant:* The implant is placed beneath the periosteum directly onto the alveolar bone. This type of implant is used when bone is insufficient to support an endosteal implant.
- *Transosteal implant:* A bone plate with retaining posts, similar to the mandibular staple (see following), is used when the patient has severe mandibular alveolar ridge atrophy.

Mandibular Staple

The staple fastener prosthesis is implanted as an alternative to bone grafting to restore the ability of the mandible to support a denture. The titanium alloy (Tivanium) device has two transosteal pins with a set of fasteners and lock nuts between them on the curved cross-arch connecting plate. The staple is inserted with a drill guide and twist drills specifically designed for it. The staple is evenly seated in the holes drilled in the mandible to the point of contact with the inferior border.

A scratch or bend may weaken the staple and may result in a fracture of the device. A deformed staple will not fit into the drill holes properly. The prosthesis is carefully protected and is handled very little before implantation.

Neck

Anatomy and Physiology of the Neck

The neck connects the head and trunk of the body. It is supported by the cervical vertebrae posteriorly and muscles anteriorly and laterally. The larynx, leading to the trachea, and the proximal end of the esophagus pass within the muscular structure. The vascular, nervous, and lymphatic systems leading to and from the head also pass through the neck. The thyroid and parathyroid glands lie along the trachea on the anterior aspect at the base of the neck.

Larynx

The larynx, situated anteriorly between the hypopharynx superiorly and the trachea inferiorly, consists of three major cartilages supported by ligaments and muscles: the thyroid cartilage, which protects the soft inner structures; the cricoid cartilage directly beneath it; and the paired arytenoid cartilages posterior to the thyroid and joined to the cricoid. The thyroid cartilage is incomplete posteriorly, but the cricoid is a complete ring. The cricothyroid space lies between the thyroid and cricoid cartilages.

The larynx functions as an organ for speech and for closure of the glottis during swallowing to protect the respiratory passage and prevent aspiration. The epiglottis, an elastic cartilage covered with mucous membrane at the root of the tongue in the hypopharynx, covers the superior opening of the larynx during swallowing.

Extrinsic muscles open and close the glottis, the space between the true vocal cords. Intrinsic muscles regulate vocal cord tension.

Movement of the paired arytenoid cartilages opens and closes the glottis. Folds of mucous membrane covering muscle line the larynx. The two upper folds are the false cords; the two lower folds are the true vocal cords. The true vocal cords attach to the arytenoid cartilages posteriorly and to the thyroid cartilage anteriorly. The cords are an integral part of phonation. They vibrate to produce sounds by rhythmically moving air particles. Production of vocal sound involves coordination of the musculature of the lips, tongue, soft palate, pharynx, and larynx. The mouth and pharynx are the resonating cavities.

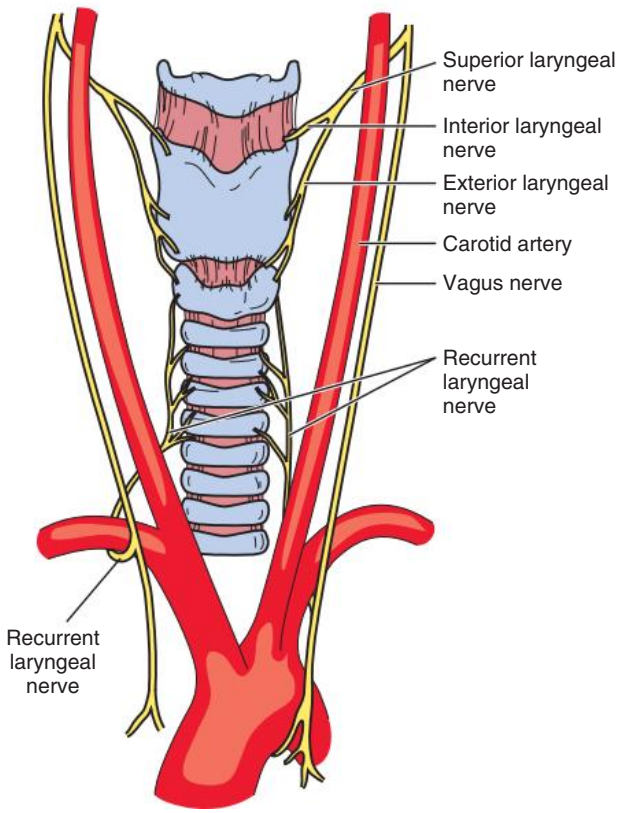
The tenth cranial (vagus) nerve innervates the larynx. Its major branch to the larynx is the recurrent laryngeal nerve (Fig. 41.14). Trauma to the nerve can result in laryngeal paralysis, which is devastating if both nerves are paralyzed.[7]

Trachea

The trachea is a 10 to 11-cm tube composed of rings of cartilage anteriorly and membrane posteriorly. This membrane also forms the anterior wall of the esophagus (the musculomembranous canal between the pharynx and the stomach). The trachea extends from the lower larynx to the carina in the chest, where it bifurcates to form the right and left main bronchi, leading to the lungs.

Surgical Procedures of the Larynx

Trauma or disease involving laryngeal cartilages, mucous membrane, or the vocal cords can obstruct respiration and/or speech. Surgical procedures are directed toward diagnosis of the cause and elimination of obstruction to maintain the larynx's dual functions in respiration and phonation.



• **Fig. 41.14** Anatomy of the superior laryngeal and recurrent laryngeal nerves.

Laryngoscopy

Laryngoscopy is a visual examination of the mucous membrane lining of the larynx and vocal cords with a lighted instrument, with or without the adjunct magnification of the operating microscope. Laryngoscopy is performed for diagnosis, biopsy, and/or treatment of laryngeal lesions, including the following:

- Foreign body, such as a coin, watch battery, or small toy.
- Papilloma of the vocal cords, which prevents accurate cord approximation and a normal voice.
- Laryngeal polyps, with stripping of polypoid mucosa to alleviate recurrence.
- Juvenile papilloma (multiple growths on the larynx, epiglottis, vocal cords, and trachea). These may be treated by cryosurgery or a laser in lieu of excision.
- Leukoplakia (a white thickening on the vocal cords, causing hoarseness). The lesion is examined histologically for differentiation from carcinoma.
- Laryngeal web (adherence of the anterior aspects of the vocal cords as a result of removal of mucous membrane or after inflammation). After excision, a metal or plastic plate may be placed between the cords until normal mucous membrane regenerates. The plate is then removed.

Preoperative preparation and endoscopic technique are similar for laryngoscopy, esophagoscopy, and bronchoscopy. General anesthesia usually is used, but local topical anesthesia may be preferred for some patients. The patient is supine with the neck hyperextended and head supported. As after any anesthetization of the throat, postoperative orders include nothing by mouth (NPO) status for a specific number of hours until throat reflexes have returned, to prevent aspiration.

Indirect Laryngoscopy

In indirect laryngoscopy, a laryngeal mirror is inserted through the mouth to the base of the tongue. With the patient in a sitting position, light is reflected to the area by the surgeon's headlamp. During this simple diagnostic procedure, a biopsy or polypectomy can be performed.

Direct Laryngoscopy

In direct laryngoscopy, a rigid, hollow, tubular laryngoscope is inserted into the larynx for direct visualization. Suction tubes and grasping forceps are maneuvered through the handheld laryngoscope. Fiberoptic light carriers are connected to a light source. Endoscopic principles as discussed in Chapter 32 are applicable.

Suspension Microlaryngoscopy

For microlaryngoscopy, the laryngoscope becomes self-retaining by suspension in a special appliance placed over the patient's chest. This gives the surgeon bimanual freedom in use of the operating microscope. The microscope provides binocular vision and magnification in critical inaccessible areas or areas difficult to visualize by direct laryngoscopy. A standard operating microscope with a 400-mm lens is used. Microlaryngeal instruments are added to the basic setup for direct laryngoscopy. Suspension microlaryngoscopy is used for most intralaryngeal procedures.

Laser Microlaryngoscopy

The CO_2 laser was introduced in laryngology by Jako and Strong in 1971. It was initially used for removal of recurrent laryngeal papillomas. Now CO_2 and other lasers are used to remove a variety of benign and malignant lesions in the respiratory tract,

particularly in the larynx. For example, the argon laser may be used for treatment of hereditary hemorrhagic telangiectasia (dilated groups of capillaries) in the larynx.

A micromanipulator, used to direct the laser, is coupled to the operating microscope. The microscope lens focuses the beam. Reflecting mirrors defocus the beam to reach into otherwise inaccessible areas. Microlaryngeal instruments are used in addition to specific laser instruments. For example, anterior commissure vocal cord retractors with suction attachments are used to clear the smoke of tissue vaporization for visibility.

Laser Safety. The laser is a safe instrument when used around the oral cavity and neck only when the following safety precautions are taken:

1. The patient's eyelids should be taped shut and covered with moistened sponges to prevent injury from inadvertent reflection of the laser beam from a metal surface.
2. The patient's face should be covered with a moist towel so that only the oral cavity is exposed.
3. The patient's teeth should be protected from the pressure of the laryngoscope and from the laser beam.
4. Only noncombustible anesthetic gases are used. Anesthetic gases can be ignited by the laser. Nitrous oxide should not be used. Oxygen concentration may be decreased to between 21% and 30% during the lasing phase of the procedure.
5. A stainless steel or laminated aluminum and silicone endotracheal tube or a ventilating bronchoscope avoids the danger of ignition. Polyvinyl chloride and latex endotracheal tubes cannot be used because they are heat labile. Red rubber and silicone tubes may be wrapped with reflecting aluminum tape, but the tip is not always sufficiently protected if exposed to the laser beam. Ignition of endotracheal tubes has occurred. Moist gauze or compressed patties, attached to strings, are placed through the suspended laryngoscope to protect the balloon in the cuff of the tube from rupture by stray or reflected laser light. The balloon should be filled with sterile normal saline solution, which may be tinted with methylene blue dye, so the balloon will not ignite if ruptured. If a cuff does rupture, the blue dye will be immediately apparent. Rapid replacement of the endotracheal tube is necessary. A tracheotomy tray should be available for emergency use.
6. Combustible materials, such as sponges and drapes, are kept moist. Water effectively inhibits penetration of laser energy into surrounding tissue and materials.
7. Division of a blood vessel larger than 0.5 mm requires ligation or electrocoagulation.
8. All other precautions for laser surgery are taken.

Laryngeal Injuries

Patients with abnormal laryngeal conditions bear close watching for respiratory distress. The anterior, unprotected location of the larynx predisposes it to trauma, such as a crush injury. Treatment is concerned primarily with maintenance of the airway, which may be occluded by edema, hematoma, torn mucosa, or cartilaginous fragments.

Cricothyrotomy (emergency incision into the larynx) and/or tracheotomy (incision into the trachea) may be necessary to open the airway or to prevent asphyxia.[8] An intraluminal stent inserted into the larynx superior to the tracheostomy tube and fixed to it for stabilization may be worn for several months until the laryngeal laceration heals and an intralaryngeal airway reforms. The stent is used to mold the tissues.

Preservation of the voice is also a major concern. Severe laryngeal injury may result in permanent voice impairment. In unilateral vocal cord paralysis, because of muscle atrophy and muscle imbalance, a weak, hoarse ("air-spilling") voice is present. Inadequate glottic closure can be treated by injection of Teflon (Polytef) paste into the affected cord to augment its size and thus help to bring the two cords into apposition. The injected material becomes firm and retains its shape. A functioning cord and marked improvement in voice quality result. This modality is used commonly when the recurrent laryngeal nerve is affected. It is not indicated for acute glottic incompetence. A suspension of Gelfoam powder in saline can be used for temporary augmentation until compensation or the need for permanent augmentation occurs.

Procedures for Carcinoma of the Larynx

Procedures vary depending on the size and location of the lesion, extent of invasion, and presence of regional or distant metastasis, as well as the patient's age, general condition, and rehabilitative capacity. Classification of malignant lesions by location includes glottic (true cords), supraglottic (above true cords), and infraglottic (below true cords) lesions.

In the early stages, cancer of the larynx is one of the most curable of all malignant tumors because of the sparse lymphatic supply in the region of the vocal cords. Radiologic study of the lesion by various methods, such as contrast laryngography, is a valuable adjunct in selecting an appropriate therapeutic modality. Laryngograms can identify mucosal irregularity, vocal cord thickening, or a tumor and can outline the lesion as well as portray functional alteration of laryngeal structures.

Symptoms vary as well. Hoarseness for more than 2 weeks' duration often is a result of cord fixation by a malignant glottic lesion. Dysphagia is suggestive of a tumor at the esophageal opening. Dyspnea from airway obstruction is a late manifestation.

Whenever possible, the surgeon will perform a conservative laryngectomy to retain some natural voice. These procedures yield the same rate of cure of selected cancers as a radical procedure—total laryngectomy—without sacrificing phonation, deglutition, or respiratory function. A neck stoma is usually necessary for breathing.

Laryngofissure with Partial Laryngectomy

Laryngofissure (division of or opening into the larynx) may be necessary to remove a foreign body or tumor. Laryngofissure with partial laryngectomy through an incision in the thyroid cartilage is performed to remove a large tumor confined to one vocal cord. A tracheotomy is performed to maintain the airway. Postoperative hoarseness may diminish as scar tissue forms to replace excised vocal cord.

Supraglottic Laryngectomy

The epiglottis, false cords, and hyoid bone are removed in a supraglottic laryngectomy when a tumor is located in the epiglottis (i.e., is supraglottic). A horizontal incision is made above the true vocal cords, thus preserving voice and a normal airway. Neck dissection may be done simultaneously. A temporary tracheotomy is always part of the procedure because of the danger of aspiration and postoperative edema. With the epiglottis removed, liquids in particular can easily spill into the trachea. A cuffed tracheostomy tube is a necessary precaution postoperatively.

Vertical Hemilaryngectomy

In hemilaryngectomy through a vertical incision, one true cord, false cord, arytenoid, and half of the thyroid cartilage are removed. The epiglottis, cricoid, and opposing cords are preserved. After healing, scar tissue fills in the surgical defect, almost approximating the remaining vocal cord. Thus the patient has a usable although hoarse voice and satisfactory airway and can eat normally. Sometimes a muscle flap is used for glottic reconstruction to improve voice quality. A prophylactic tracheotomy usually is done to protect the airway. Subcutaneous emphysema (i.e., infiltration of air under the skin) is a potential complication.

Total Laryngectomy

A radical procedure, total laryngectomy is performed for advanced lesions involving the larynx and/or hypopharyngeal area, with or without neck dissection. The entire larynx, hyoid bone, cricoid cartilage, two or three tracheal rings, and strap muscles are removed. This resection destroys the connection between the pharynx and the trachea. Pharyngeal walls and the lower trachea are preserved. The pharyngeal opening to the trachea is closed, leaving the pharynx open only to the esophagus.

The patient breathes and expels bronchial secretions through a permanent stoma at the base of the anterior neck postoperatively. This is created by suturing the tracheal stump to the skin (tracheostomy). The size of the stoma should be recorded on the patient's record in the event of emergency need for a tube at a later time. In patients with a permanent stoma, resuscitation is always via the stoma.

The nose no longer humidifies the air to the lungs. The sense of smell is also lost because the nasal olfactory epithelium is not stimulated by inhalation.[7] Acclimatization to air intake through the neck constitutes a major adjustment for the patient.

A nasogastric tube is inserted during the surgical procedure for temporary feeding. Although the patient no longer has a normal voice, normal eating is resumed after healing takes place.

The formation of a salivary fistula is one complication of laryngectomy. Swallowed saliva leaks out through a weakness in the pharyngeal suture line and through the skin. Rupture of the carotid artery, especially in preirradiated patients, is another complication. This may occur if radical neck dissection was also performed, which places the artery in the surgical area.

Rehabilitation should begin preoperatively at the time of diagnosis and include the family. It incorporates input from many professional disciplines because major disability results from the surgical procedure. In working with a speech pathologist, some patients develop esophageal speech.[7] By intake of a bolus of air into the esophagus and vibration by cricopharyngeal muscles, sound is produced to articulate speech. Patients unable to perfect the technique may use an artificial larynx—an electronic device that includes pitch and volume.

Many patients are unable to acquire usable esophageal speech, with or without the artificial larynx. Some of these patients have undergone surgical procedures to rebuild a functioning glottis or create a permanent tracheoesophageal fistula to shunt pulmonary airflow to the pharynx for phonation.[7] Aspiration pneumonia caused by leakage of saliva and food is a major problem after these procedures.

In addition, pharyngeal constrictor muscle spasms or stenosis may inhibit speech rehabilitation. Voice restoration for these aphonic patients may be enhanced by a valved prosthesis. This is inserted through a tracheoesophageal fistula to allow free flow of air into the esophagus for phonation, to prevent aspiration, and to maintain patency of the fistula. Three types of one-way valve voice prostheses are used:

- The Blom-Singer duckbill prosthesis, so named from the shape of the slit valve, is a silicone tube with retention flanges (collar-like projections). The fistula for the prosthesis is created through an esophagoscope inserted into the cervical esophagus. A needle is introduced to puncture the posterior tracheal wall and anterior esophagus at the superior aspect of the laryngectomy stoma. A rubber catheter stent is inserted through the puncture to maintain patency during healing. When the prosthesis is fitted, the flanges are taped to the peristomal skin. The patient occludes the stoma to produce a voice.
- The Blom-Singer tracheostoma valve and low-pressure prosthesis has a diaphragm that opens during normal respiration and closes in response to expiratory airflow for speech. The circular valve is recessed slightly into the tracheostoma, with the housing fixed to the peristomal skin with a hypoallergenic adhesive. The patient does not manually occlude the stoma during speech.
- The Panje voice prosthesis, commonly known as the voice button, is a biflanged silicone valve inserted into a simple tracheoesophageal stab wound. An insertion guide is used to place the prosthesis through the tracheostoma into the created fistula. The patient occludes the stoma to speak.

Practical help and moral support are offered to the newly laryngectomized patient by others who are members of support groups, such as the International Association of Laryngectomees and the Lost Chord Club. The American Cancer Society is also a resource for assistance.

Laryngeal Transplantation

In January of 1998, Marshall Strom, formerly of the Cleveland Clinic Foundation, transplanted a larynx and a portion of a trachea into a 40-year-old man whose larynx was crushed in a motor vehicle accident 19 years previously. He was able to speak a few words within 12 hours of the procedure. The full extent of recovery will not be known for years; however, the patient, Timothy Heidler, has since become a motivational speaker and has joined the church choir.

The second successful larynx recipient was Brenda Charett Jensen in 2010 by Gregory Farwell at the University of California–Davis Medical Center. The surgical procedure took over 18 hours. She also received part of the donor's trachea and thyroid gland. After her surgery she was able to smell for the first time since her initial laryngeal injury. Jensen had a kidney-pancreas transplant in 2006.

Both patients have to take antirejection drugs for the rest of their lives. The earliest documented previous attempt to transplant a larynx was in 1969 in Belgium.

Surgical Procedures of the Esophagus

Esophageal disorders may be acquired or congenital. Abnormalities result from trauma, inflammation, neoplasm, or dysgenesis. A gastroenterologist and/or laryngologist may study them.

Esophagoscopy

Endoscopic direct visualization of the interior of the esophagus is performed to remove foreign bodies; to obtain biopsy, brush cytologic, or secretion specimens for diagnosis; and to examine the

esophagus and esophageal orifice of the stomach for organic disease. Inspection is made for diverticula, varices, strictures, lesions, or a hiatal hernia, which may manifest as symptoms of obstruction, regurgitation, or bleeding.

Esophagoscopes are either rigid, hollow metal tubes or the flexible fiberoptic type of scope that reduces discomfort and trauma. Accessory instruments, such as aspiration tubes and biopsy forceps, are similar for all endoscopes. Removal of an obstructing mass, such as a steak bolus in the esophagus, is better accomplished with the rigid metal scope. Various sizes of scopes are available to suit the individual patient's situation.

The patient is positioned with the shoulders even with, or a little over, the edge of the body section of the OR bed. The head section is lowered. An assistant holds the patient's head. The patient is encouraged to relax by breathing deeply if the procedure is done with local topical anesthesia. The head is raised or lowered slowly, at the direction of the endoscopist as the esophagoscope is passed, until the neck is hyperextended. The esophagoscope is passed through the mouth and cricopharyngeal lumen to the cardiac sphincter at the esophagogastric junction. The entire area is carefully scrutinized. The esophagus may be distended by insufflation of air to assist in viewing in the presence of stenosis, or a lumen finder may be necessary. The scrub person introduces tips of aspirating tubes, grasping forceps, bougies, and other long accessories into a rigid esophagoscope for the endoscopist.

Removal of Foreign Bodies

Removal of foreign bodies from the pharynx and/or esophagus is relatively common. People who wear upper dentures are especially prone to swallowing sharp bones that cannot be felt against the covered palate. Pieces of meat or dental bridgework may lodge or become impacted in the food passage, occluding the airway by pressure. This is an emergency situation necessitating provision of a patent airway by endotracheal intubation or tracheotomy and endoscopic removal of the bolus or foreign object. Acute esophageal obstruction increases salivation, creating the danger of tracheopulmonary aspiration.

Children frequently swallow objects, such as watch batteries, coins, buttons, parts of toys, or safety pins that may remain in the throat. Metallic objects are visible on x-ray, but many others are not.

It is dangerous to attempt to push an object toward the stomach because esophageal perforation can result. Esophagoscopy is the method of choice for removal, although the procedure is often difficult and painstaking. All effort is made to prevent trauma with resultant mediastinitis. Sometimes a small Foley catheter can be passed into the passage beyond the obstruction and the balloon inflated. This can aid in delivering oxygen to the patient and prevent the object from moving deeper into the passage.

Dilation of a Stricture

The esophageal lumen can narrow because of the formation of scar tissue resulting from inflammation or a burn at any level. Treatment consists of regular dilation with bougies of graduated sizes. Steroid administration is adjunctive therapy.

When an individual suffers a severe burn, such as from swallowing a caustic material, gastrostomy may be indicated to bypass the esophagus until it heals. Dilation of such strictures uses retrograde fusiform bougies with spindle-shaped shafts that are linked together. They are carried through the gastrostomy, up the esophagus, and out the mouth. The treatment is continued for an extended period.

Dilation of a stricture at the cardioesophageal junction may be necessary in patients with cardiospasm (achalasia). Gross dilation above the stricture, often a result of muscular atrophy, leads to regurgitation. Diagnosis is made by x-ray, esophagoscopy, or gastroscopy. If dilation is unsuccessful, a myotomy at the esophagogastric junction (Heller procedure) is performed to enlarge the opening into the stomach. Severe, unyielding strictures may necessitate stent placement, resection, or esophageal replacement.

Neoplasms of the Esophagus

Most often malignant, neoplasms of the esophagus are treated by resection, photodynamic therapy, or irradiation. Dysphagia or obstruction demands immediate investigation. Surgical procedures of the esophagus fall under the classification of gastrointestinal surgery and may involve a thoracoabdominal incision.

Cervical Esophageal Reconstruction

Restoration of continuity of the alimentary tract is a major challenge after ablative surgery of the neck, particularly after cervical esophagectomy or circumferential pharyngectomy. The location of the primary tumor and its extension and the extent of resection are contributing factors in determining the most satisfactory reconstruction. A pectoralis major myocutaneous flap or a free revascularized intestinal autograft will satisfactorily restore continuity in some situations.

Transposition of the mobilized stomach, jejunum, or colon into the neck may be performed when the entire esophagus is resected. Two teams working simultaneously perform this pull-up procedure. The team of general surgeons performs the abdominal dissection to mobilize the stomach or intestine while the other team resects the primary tumor in the neck. The tumor may arise from the hypopharynx, cervical esophagus, or thyroid gland. Radical neck dissection is carried out for extension into the cervical lymph nodes. Anastomosis of the stomach or intestine to an esophageal remnant may be accomplished with a circular intraluminal stapler if the primary esophageal tumor is above the level of the thoracic inlet. Primary pharyngogastric anastomosis may be required for high transection of the pharynx.

Surgical Procedures of the Trachea

Upper respiratory tract obstruction and ventilatory failure may require surgical intervention when the need for intubation or positive pressure ventilation would be long term or of indefinite duration or when severe laryngeal obstruction is present. The obstruction is bypassed or resected.

Historically, opening the trachea was recorded in Egypt in 36 BC. Legends report that Alexander the Great (356–323 BC) opened the neck of one of his choking soldiers with the tip of his sword. Contemporary tracheostomy involving an artificial airway tube was not common until the twentieth century. One of the treatments for polio in 1930 used a tracheostomy for clearing the bronchial tree in paralyzed patients.

Tracheotomy and Tracheostomy

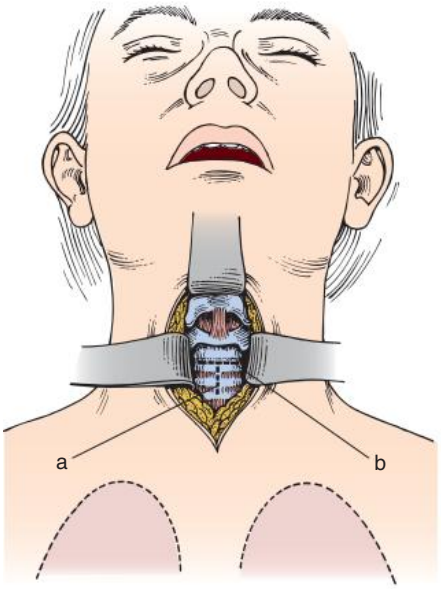
Tracheotomy is an incision into the trachea below the larynx. Tracheostomy is the formation of an opening into the trachea in which a tube is inserted to help the patient breathe. Performed in any age-group to improve or maintain patency of the airway or relieve obstruction, the opening in the trachea provides easy accessibility for suctioning secretions from the tracheobronchial tree or administering anesthetic to patients with facial trauma or burns.

A tracheotomy is commonly a controlled prophylactic procedure but can be an acute emergency. An endotracheal tube may provide temporary airway relief before and during the tracheotomy. Indications for tracheotomy include severe trauma to the hypopharynx or larynx, acute laryngotracheal bronchitis or epiglottitis in infants and children, laryngeal edema, prolonged intubation, or any other condition that obstructs respiration.

Tracheotomy is often done with the patient under local anesthesia. The patient is supine with support under the shoulders to hyperextend the neck. A transverse incision is made, producing a better cosmetic result, or a midline vertical incision is made between the cricoid cartilage and the suprasternal notch. The overlying isthmus of the thyroid gland is retracted or divided, and the exposed third and fourth tracheal rings are incised through a midline vertical incision (Fig. 41.15). Use of cautery is avoided near the open trachea because the oxygen-rich environment supports combustion.[4]

After tracheal suctioning to remove blood and secretions, a tracheostomy tube is inserted with the obturator in place. Immediately after insertion of the tube, the obturator is removed to open the airway. (This remains with the patient constantly in case of future need to reposition the tube.) The outer cannula is fixed in place, and the inner cannula can be suctioned or removed for cleaning. The wound is closed with a few sutures, or the superficial edges of the area above the tube may be sutured and the area below left with natural tissue approximation to facilitate drainage. A smooth-edged dressing split around the tube protects the skin. Commercial tracheostomy dressings are available.

Tapes tied to the ends of the outer cannula are secured around the neck. Proper tension allows insertion of one finger between the tape and skin. If the tapes are tied too tightly, they may compress the jugular vein; if the tapes are tied too loosely, the tube can obtrude with coughing. The tube should not be removed during the first 24 to 48 hours by any person unable to perform a tracheotomy because the tract to the trachea may occlude and not be immediately located.



• **Fig. 41.15** Tracheotomy incisions. Midline vertical incision *(a)* is made between cricoid cartilage and suprasternal notch. Transverse incision *(b)* is used for emergency tracheotomy and cricothyrotomy.

A sterile tube identical to the one inserted and a tracheotomy set accompany the patient from the OR and constantly remain with him or her until otherwise indicated by the surgeon's order.

A tracheotomy is the creation of an open wound. Although rigid sterile technique is not possible, every effort is made to keep contamination to a minimum. Only sterile equipment with minimal handling is used to prevent infection. Suctioning through a tracheostomy tube is done as a sterile procedure with a sterile catheter and gloves. Careful suctioning prevents trauma. The catheter is inserted without application of suction, which could injure the tracheal walls and suction out oxygen in the patient with borderline oxygen saturation levels. Suction is applied as the catheter is withdrawn. Sterile solution is run through the catheter after use to clean it and maintain patency. Disposable catheters are recommended; they are used once and discarded.

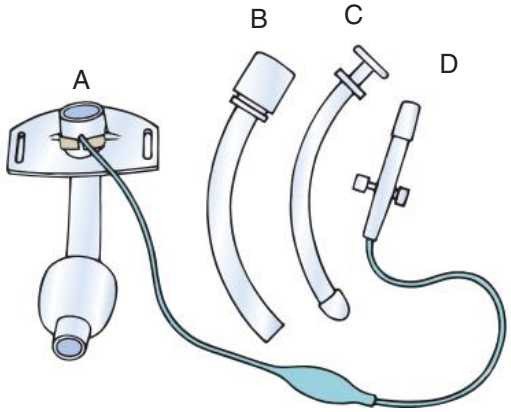
Some patients who have undergone tracheotomy come to the OR for a change of the tube or other procedure. These patients may require suctioning while waiting in the holding area. Knowledge of and preparation for each patient is a prime responsibility of the circulator. These patients require humidified air, which can be delivered by various devices, to keep secretions liquefied and prevent drying of tissues. Other needs are constant observation and special communication (e.g., pencil and paper, Magic Slate, and/or picture board).

Tracheostomy Tubes

Although an endotracheal tube may provide ventilation for short-term therapy, a tracheostomy tube is easier to suction and immobilize for extended use. It also reduces the possibility of laryngeal injury and tracheomalacia.

Most tubes have three parts—the outer cannula, inner cannula, and obturator (Fig. 41.16). The inner cannula is periodically removed and cleaned to prevent blockage by crusting of secretions. It is replaced immediately within the outer cannula so that the latter remains free of crusting. The obturator provides a smooth tip during tube insertion to prevent trauma to the tracheal wall. Some plastic tubes do not require an inner cannula because they remain relatively free of crust. If crusts do form, the tube is changed.

Some tubes have a built-in soft cuff that is inflated to eliminate any free space between the tube and the tracheal wall, thus preventing aspiration of drainage down the trachea. Cuffed tubes also facilitate function of any ventilatory apparatus.



• **Fig. 41.16** Tracheostomy tube. **A,** Outer cuffed cannula. **B,** Inner cannula. **C,** Obturator. **D,** Pilot balloon in inflation line.

A pilot balloon in the inflation line, attached to the outer cannula, indicates cuff inflation or deflation. Proper cuff inflation-deflation is very important. Irritation and pressure of the cuff against the tracheal wall can cause damage such as ulceration and necrosis of the mucosa, which can lead to infection, tracheobronchial fistula, erosion into the innominate artery, or stenosis from scarring.

Precautionary measures include deflation at regular intervals, by the physician's written order, to increase blood flow to the cuff site; use of a low-pressure or controlled-pressure cuff; constant monitoring of intracuff pressure; and minimum inflation to ensure a leak-free system. Overinflation can reduce the tube diameter, as well as cause the cuff to extend over the tip of the tube, thus obstructing ventilation. Or the tracheal wall may herniate over the tube end. Underinflation may cause subcutaneous emphysema. Cuffs also should inflate symmetrically. The amount of air needed for inflation varies with the size of the trachea and the tube. Understandably, less air is needed for larger tubes. Usually 2 to 5 mL of air provides a closed system.

Specific tubes have special variations, such as an opening in the wall opposite the bevel to permit ventilation in case of bevel occlusion. Others have a radiopaque tip that allows x-ray visualization of the tube position. Many have connectors, some of which are a built-in swivel type, permitting lightweight, flexible, easy connection to a ventilating system. These connectors reduce the hazard of accidental disconnection. Still others have a fenestration in the outer cannula, permitting air to flow through the larynx. These tubes are used to allow assessment of spontaneous breathing and coughing in preparation for decannulation in patients no longer requiring mechanical ventilation.

With air passing through the larynx, the patient can speak with the proximal end of the cannula plugged. A so-called speaking tube permits introduction of humidified air and oxygen through a special line, and with upward flow of the gas through the larynx, the patient can speak.

Tracheal Resection

Tracheal obstruction can result from trauma or a tumor, thus occluding the patient's airway. Localized erosion and scarring, causing narrowing and breakdown of the trachea, can develop from prolonged endotracheal intubation or a tracheotomy. An obstructive or stenotic lesion can be resected and the trachea reconstructed by end-to-end anastomosis.

Through a cervical, low-collar skin incision, the upper trachea and subglottis are mobilized. A right posterolateral thoracotomy incision is used for lesions in the distal trachea near the carina, where the trachea bifurcates into the right and left bronchi. A longitudinal incision is made in the stenotic area, and an anode tube (a flexible wire-reinforced endotracheal tube) is inserted into the distal trachea to maintain respiration. The trachea is transected circumferentially above and below the obstructed segment. The laryngeal attachments to the trachea are released, and the suprahyoid muscle is transected. Up to 5 to 6 cm of trachea can be resected and closed by primary anastomosis. The neck is flexed so that the edges of the trachea can be approximated without tension.

The neck may be kept flexed during postoperative healing by a heavy suture from the chin to the chest. The patient remains intubated, with the end of the tube located beyond the anastomosis at the carina (as a stent), for 1 or 2 days. Care is taken to prevent the endotracheal tube from entering the bronchus and only using one lung. Epidural anesthesia is often used, because using opioids can cause periods of apnea.

Surgical Procedures of the Anterior Neck

Many laryngologists and plastic surgeons, as well as some oral and general surgeons, perform neck dissection when cervical lymph nodes are involved in cancer of the head and neck. A multidisciplinary team, including a thoracic and/or general surgeon, may perform some complex resections and reconstructive procedures.

The patient may be positioned with the neck extended, usually over a thyroid elevator. The arms are secured at the sides of the body and not on armboards, thus preventing distortion of the body contour in the neck region. The OR bed may be tilted into reverse Trendelenburg's position.

Thyroid Procedures

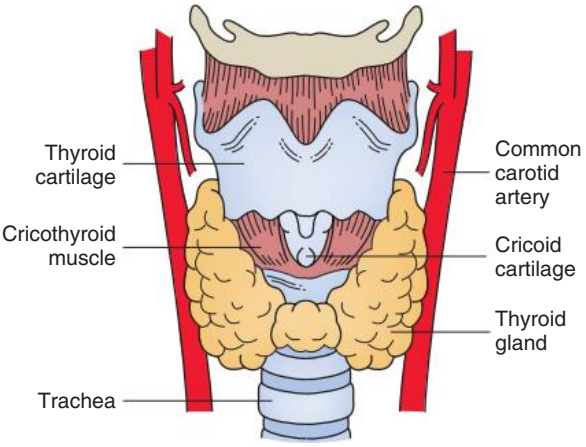
The thyroid gland, located in the anterior aspect of the neck, is composed of two vascular lobes that lie on either side of the trachea and are united by a narrow band, the isthmus (Fig. 41.17). The thyroid hormone controls the rate of body metabolism and may influence physical and mental growth.

Hyperthyroidism (Graves' disease), hypothyroidism, and an enlarged gland (goiter) are the main disorders of the thyroid gland. Drugs, radioactive iodine, and/or surgical resection are used to treat hyperthyroidism. This disease, which is rare in geriatric patients or the very young, affects women more frequently than men. Replacement of the thyroid hormone with drug therapy is the specific treatment for hypothyroidism. Oral administration of thyroid extract or iodine may reduce the size of the gland, but surgical excision is frequently necessary to remove benign or malignant tumors.

Emil Theodor Kocher (1841–1917), a Swiss surgeon, revolutionized thyroid surgical procedures for which he won the Nobel Peace Prize in 1909. Thanks to Jules Pean (1830–1898), who invented the hemostat in 1874 to control bleeding, Kocher demonstrated that if bleeding were controlled, patients would survive thyroidectomy. Before hemostasis, death from the procedure was around 70%. Kocher improved on the hemostat in 1882 with the development of the Kocher clamp and further increased the odds of many surgical procedures' success with advanced hemostasis. Preservation of the parathyroid glands in 1891 became an additional focus of thyroidectomy that enhanced the patient's metabolic physiology.

Thyroid Biopsy

A needle biopsy or an excisional biopsy may be performed to aid in establishing a diagnosis of thyroiditis or in differentiating between nodular goiter and carcinoma.



• **Fig. 41.17** Anterior view of thyroid gland.

Thyroidectomy

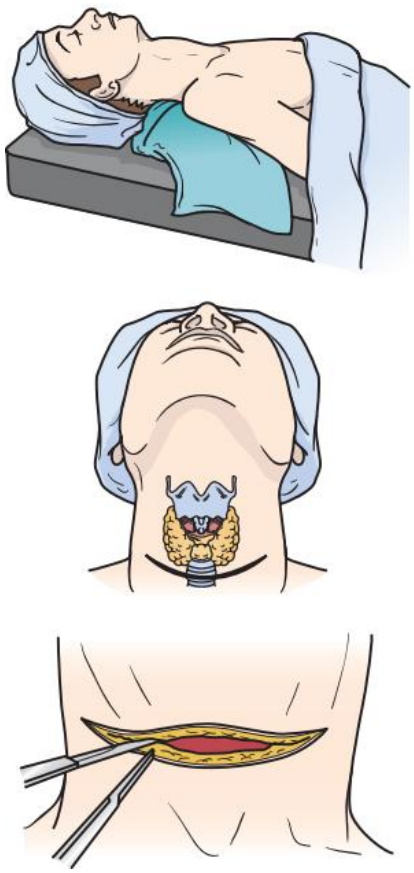
During all thyroidectomy procedures, care is exercised not to damage the laryngeal nerves and parathyroid glands. The patient is positioned supine with the neck hyperextended to provide good exposure of all structures (Fig. 41.18). A transverse collar incision is made in a natural skin crease about 1 inch (2.5 cm) above the clavicle. The cervical fascia is incised vertically in the midline.

Throughout the surgical procedure, meticulous hemostasis is maintained. Blood supply arises from the external carotid arteries to the upper poles of the thyroid gland and from the subclavian arteries to the lower poles. The superior laryngeal nerves, which innervate the cricothyroid muscles, and recurrent laryngeal nerves, which innervate the vocal cords, are identified. Trauma to these nerves can result in temporary or permanent laryngeal paralysis. Voice disturbances with hoarseness occur with paralysis of one vocal cord.

Postoperative complications of thyroidectomy include hematoma, edema of the glottis, injury to a recurrent laryngeal nerve, muscle rigidity and spasm (tetany), and acute thyrotoxicosis. A tracheotomy set should remain at the patient's bedside postoperatively for at least 24 hours in the event of respiratory obstruction.

A general surgeon usually performs thyroidectomy. Depending on the pathologic diagnosis, the surgeon chooses the most appropriate procedure for removal of a part of or the entire thyroid gland.

Thyroid Lobectomy. An entire lobe is removed, especially for toxic diffuse goiter, which is usually benign. In case of malignant growth, the lobe and lymph nodes in the neck that drain into the involved area may be dissected.



• **Fig. 41.18** Position and incision for thyroidectomy.

Subtotal Thyroidectomy. The usual procedure for hyperthyroidism is removal of approximately five sixths of the thyroid gland. This procedure generally relieves symptoms permanently because the remaining thyroid tissue secretes sufficient hormone for normal function.

Total Thyroidectomy. Excision of both lobes plus the isthmus may be the procedure of choice for palpable disease in both lobes.

Substernal Intrathoracic Thyroidectomy. Invasion of the gland into substernal and intrathoracic regions can cause tracheal obstruction. The sternum may have to be split to remove a large, adherent intrathoracic goiter.

Parathyroid Gland Procedures

The parathyroid glands are small endocrine glands that regulate metabolism of calcium and phosphorus. Four or more glands are located within or are attached to the substance of the thyroid gland (two on each side), or they may migrate into the neck or mediastinum. Primary hyperparathyroidism is associated with hypercalcemia, which may be secondary to renal, skeletal, or gastrointestinal disease. A single gland or multiple glands may be diseased and surgically excised. The incision and exposure are the same as described for thyroidectomy.

Subtotal Parathyroidectomy

A single diseased gland, confirmed by frozen section, is excised. Up to three and a half glands may be removed if all glands appear to be involved, as in diffuse hyperplastic disease. Parathyroid glands are handled by their pedicles to avoid crushing, suturing, or violating the capsule. Inadvertently implanted parathyroid tissue may cause recurrence of disease or persistent or recurrent hypercalcemia. A remnant of normal tissue is left to prevent hypoparathyroidism, which may cause severe tetany. Removed normal tissue may be cryopreserved for autotransplantation in muscle, usually in the forearm, if hypoparathyroidism develops or reoperation is necessary for recurrent or persistent hyperparathyroidism.

Total Parathyroidectomy With Autotransplantation

All parathyroid tissue is removed when all glands are abnormal. First described by William Halsted in 1907, a portion of a gland is immediately transplanted into a vascularized muscle, usually the sternocleidomastoid, which is in the surgical field. Some surgeons prefer to put the transplant in a forearm muscle. This procedure may be done when embedded parathyroid glands are removed in conjunction with a total thyroidectomy. Postoperative supplemental calcium and vitamin D should be considered for treatment of hypoparathyroidism.

Thyroglossal Duct Cystectomy. During fetal development, the thyroid gland descends through the thyroglossal duct from the foramen cecum near the base of the tongue to the neck below the larynx. In adulthood, remnants of this embryonic duct may form a cyst in the anterior midline of the neck. Excision requires removal of the entire cystic sac and a portion of hyoid bone that surrounds the duct.

Cervical and Scalene Lymph Node Biopsy. Biopsy specimens are taken of the cervical and/or scalene nodes for diagnosis of metastatic extension of cancer or tuberculosis into these lymphatic nodes. A thoracic surgeon may perform the procedure.

Neck Dissections

Tumors, benign and malignant, occur in the head and neck regions. Although the origin of many of these neoplasms is technically in

the head, the cervical lymph nodes frequently are involved secondarily by metastases from a primary head or neck malignant tumor. Treatment is directed toward definitive management for eradication of the tumor and metastases, with consideration for rehabilitation. In an attempt to eradicate all cancer foci, neck dissection may be performed at a time later than removal of a primary lesion of, for example, the parotid gland or tongue or simultaneously as a one-stage procedure. This composite resection removes the primary tumor and metastatic lesions at the same time en masse. Sometimes metastasis occurs before a primary lesion is discovered.

Various reconstructive techniques provide immediate restoration to improve speech, reestablish oral function, or prevent airway obstruction. Others involve delayed reconstruction. The method of repair depends on the type of defect resulting from excision of the lesion. Preoperatively, the patient's emotional stability is analyzed if the surgical procedure will result in a cosmetic deformity. Reconstruction is planned so that local tissue can be used whenever feasible and normal function is preserved whenever possible. The aim of reconstruction is to restore function and appearance.

Radical Neck Dissection

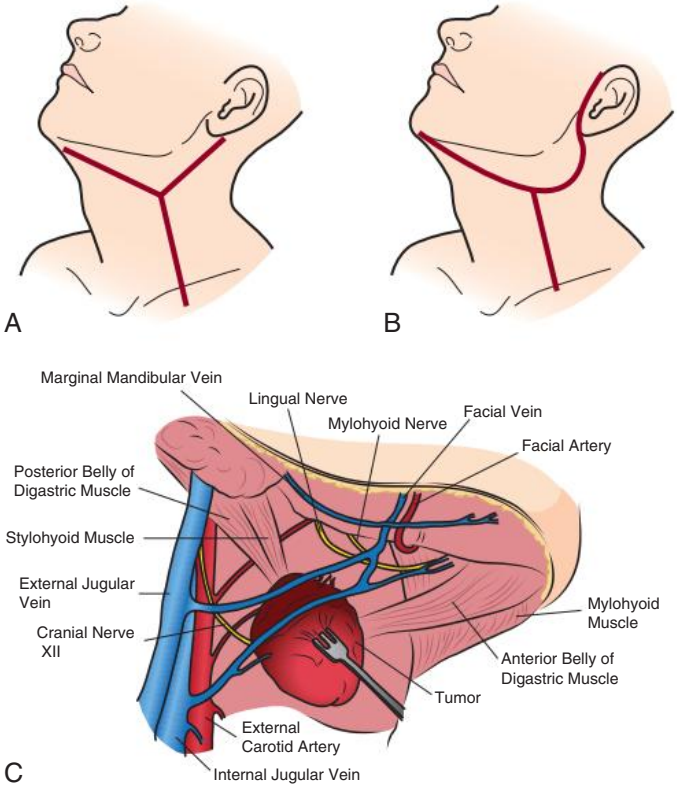
Malignant tumors of the oral or pharyngeal cavities, cutaneous malignant melanoma, and skin cancer in the head and neck region often require wide resection of the primary lesion and excision of all of the cervical lymph nodes on one or both sides of the neck. This procedure gives the patient with cancer of the cervical lymphatic chain a chance for cure and arrest of spread. When metastasis is known to be present or is highly suspected because of the location or stage of the malignancy, the surgical procedure is predicated on the assumption that metastases are regional and not distant.

A predominant cause of throat cancer is the human papillomavirus (HPV).[9] Current literature reflects that HPV-related cancer of the throat is found in a younger population of relatively otherwise healthy males. According to the Centers for Disease Control and Prevention (CDC), HPV cancers are decreasing since the introduction of the HPV vaccine. (More information can be found at www.cdc.gov.)[9] Many of these tumors present at the base of the tongue or near the tonsils. The scrub person should carefully keep all tonsillar specimens separate as left and right when sending them to pathology, because lymphatic spread of cancer is specific to the side of the throat affected. Correct identification of which side is involved can spare the patient a more extensive radical procedure.

The head and neck surgeon plans the surgical procedure with reconstruction in mind, so that the incisions will allow good exposure but provide as much local flap tissue as possible for reconstruction. Incisions used for the tumor resection will necessarily vary according to the type of reconstruction planned. No single surgical procedure can be used to treat all lesions, but certain basic features remain common to all neck dissections (Fig. 41.19).

All lymph-bearing tissue from the midline anteriorly to the trapezius muscle posteriorly and from the mandible superiorly to the clavicle inferiorly is removed. All tissue between the deep cervical fascia and the platysma muscle externally is removed except the carotid artery system; the vagus, phrenic, and hypoglossal nerves; and the brachial plexus.

The massive tissue resection (removal en bloc) includes the jugular vein, eleventh cranial (spinal accessory) nerve, sternocleidomastoid muscle, and submandibular salivary gland. Elimination of the motor nerve to the trapezius muscle contributes to muscular atrophy, subsequent shoulder drop on the affected side, and possibly decreased strength in raising the arm.



• **Fig. 41.19** Neck incisions for radical neck dissection. **A,** Block dissection. **B,** Modified Y-incision for block dissection to include radical parotidectomy. **C,** Submandibular surgical anatomy.

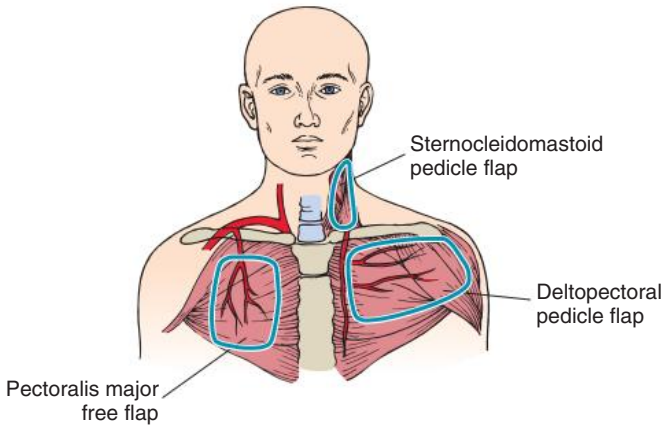
Various techniques are used to close the large defect in the anterior neck. When the occipital, posterior auricular, facial, and superior thyroid arteries can be preserved, arterialized skin flaps designed to incorporate branches from these vessels can be constructed with the length up to three or four times the width. Otherwise, the length of a flap should not exceed twice the width.

A deltopectoral pedicle flap or a pectoralis major myocutaneous free flap may be needed (Fig. 41.20). An exposed carotid artery is covered. Cervical flaps carrying their own blood supply may be used for this and to restore the oropharyngeal lining intraorally. A pedicle flap of sternocleidomastoid muscle from the clavicle may be an alternative.

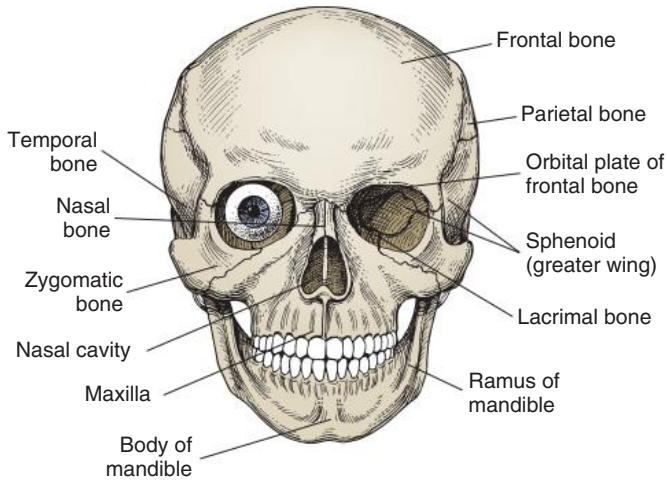
The mandible is preserved unless it is involved by direct extension of the tumor into the bone. Access through a mandibular osteotomy or partial mandibulectomy is usually required for effective resection in the posterior oral cavity. Solid bony continuity and realignment of the dental arches are established for functional restoration of speech and chewing. A revascularized free fibular graft, a bone graft from the rib or iliac crest, cancellous bone chips, or a composite graft may be used to stabilize the mandible.

Effective drainage of the wound is important to healing. This is accomplished by use of closed-wound suction drains inserted through stab wounds below the clavicle. Prevention of hematoma protects the viability of the thin skin flaps and facilitates approximation of wound surfaces.

A tracheotomy may be performed to protect the patient from respiratory distress in neck dissection alone. A tracheostomy is always done in a composite radical neck resection.



• **Fig. 41.20** Myocutaneous flap to close defect after radical neck dissection may be deltopectoral pedicle flap, pectoralis major free flap, or sternocleidomastoid pedicle flap.



• **Fig. 41.21** Anterior view of skull.

A feeding gastrostomy tube may be inserted for anticipated extended feeding. This permits suction to avoid aspiration and gastric distention in addition to providing a feeding route. The tube is usually inserted in the OR.

Potential complications of neck dissection are numerous, depending on the tumor itself, irradiation therapy, or necessary sacrifice of vital structures. Intraoperatively, hemorrhage may occur from injury to a major vessel or the thoracic duct. Postoperatively, invasion of overlying skin necrosis into a major vessel wall, such as the carotid artery, can cause an often-fatal blowout of the vessel. Slight previous bleeding may be a forewarning. Balloon occlusion of the carotid artery may be used to prevent hemorrhage.

Although reconstruction begins at the time of primary neck dissection, the patient usually requires considerable postoperative rehabilitation psychologically and staged procedures before cosmetic and functional reconstruction is complete.

The advent of robotic surgery has improved the process and outcome of throat cancer surgery. Transoral procedures are more refined using robotics and minimize the need for the disfigurement associated with radical neck surgery.

Face and Skull

Anatomy and Physiology of the Face

The face is the anterior part of the head, including the forehead, cheeks, nose, lips, and chin, but not the ears. The eyes, situated in the bony orbits, contribute to the features of the face, although they are not technically a part of the face.

The skeletal structure of the face and skull (Fig. 41.21) includes the frontal bone of the forehead. It forms the upper part of the orbits. Divided by **sutures** (i.e., lines of union between bones), the frontal bone joins the sphenoid and ethmoid and the paired nasal, lacrimal, maxilla, and zygomatic bones. The posterior orbits are formed by the sphenoid bone, which is shaped like a butterfly with extended wings, and the palatal bones. The medial walls are formed by the ethmoid, lacrimal, and nasal bones and maxilla. The lateral aspect is formed by the zygoma (malar bone), or the cheekbone. The irregularly shaped ethmoid bone also forms the roof and posterior lateral wall of each nasal cavity. The nasal bones form the bridge of the nose between the orbits.

The maxilla (the upper jaw that holds the palate) extends laterally to the zygoma and temporal bone, under the orbit, and along the anterior nasal cavity. The maxillary bones are paired and join in the midline between the nose and the oral cavity. The alveoli that hold the teeth are along the alveolar processes of the maxillae.

The ramus of the mandible (the arch-shaped bone of the lower jaw) articulates with temporal bones at the temporomandibular joints in front of the ears. The alveoli, the tooth-bearing bodies, meet at the alveolar process to form the chin (mental region).

The bony structure of the face is covered with muscles, superficial blood vessels and nerves, epidermis, and dermis. Other structures (i.e., ducts and sinuses [air spaces]) are also in the soft tissues or bony structure of the face.

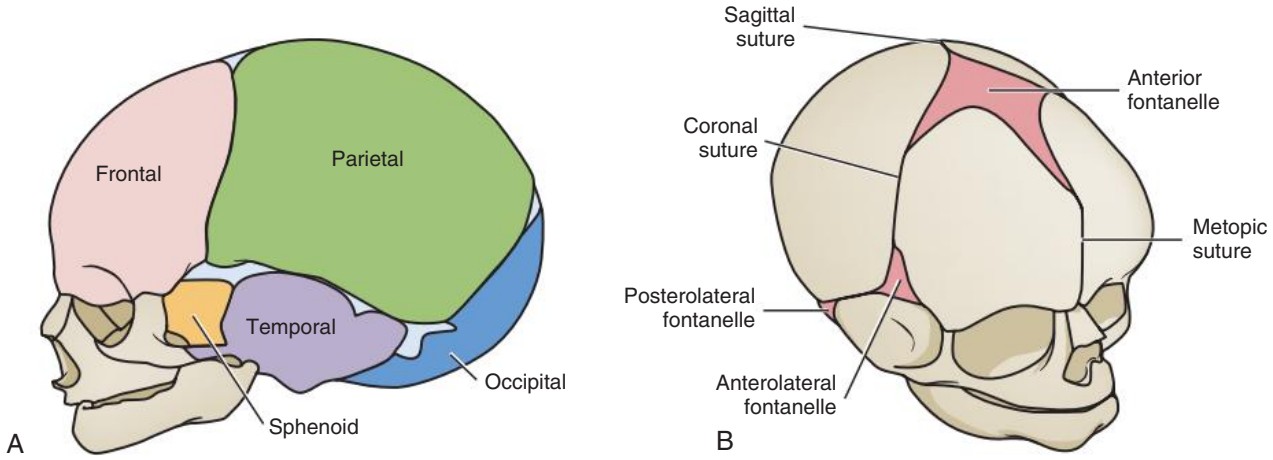
Considerations for Craniofacial Surgery

The term *craniofacial* refers to the cranium and face. Craniofacial surgery of increasing complexity has been performed since World War II. The approaches and techniques developed by French plastic surgeon Paul Tessier (1917–2008) have led to previously inaccessible anatomic areas. Tessier's accomplishments included the use of autologous bone and transcranial approach for correction of bony deformity of the eye orbits. He performed the first successful LeFort III osteotomy in 1958 that earned him the title of father of craniofacial surgery.

Exposure for dissection of soft tissues and bone to restore contour and symmetry in practically every type of facial deformity, whether congenital, neoplastic, or traumatic in origin, can be accomplished by a multidisciplinary team of surgeons. This team may include a plastic surgeon, neurosurgeon, anesthesia provider, ophthalmologist, oral surgeon, and otorhinolaryngologist. Some procedures require more than 100 separate maneuvers and may take as long as 14 to 16 hours to complete.

Many of the concepts developed for these very complex procedures are applied in the more common and less complicated procedures to reshape sections of the skull or reconstruct soft tissues. Craniofacial reconstruction should be performed as soon as indicated by the physiologic and psychologic effects of the deformity on the patient, regardless of age. An early surgical procedure not only decreases psychologic trauma but also may prevent craniofacial distortion caused by brain and nerve damage of a disease process or traumatic injury.

Analysis of three-dimensional CT scans and cephalometric tracings accurately superimposed on transparent photographs of the patient preoperatively is essential to determine the extent of



• **Fig. 41.22** **A,** Bones of the infant skull. **B,** Suture synarthroses of the infant skull.

the facial deformity and the plan for skeletal rearrangement. The exact size of the defects that will need bone grafts can be determined.

Many procedures involve correction of malocclusion of the mandible at the same time that the orbitocranial skeleton is restructured. Dental models are cut and mounted on an articulator for reference.

Hypotensive anesthesia reduces blood loss during these extensive procedures. The patient is continuously monitored throughout the procedure to estimate blood loss. A preoperative tracheotomy may be necessary to maintain an adequate airway postoperatively.

Craniofacial Anomalies

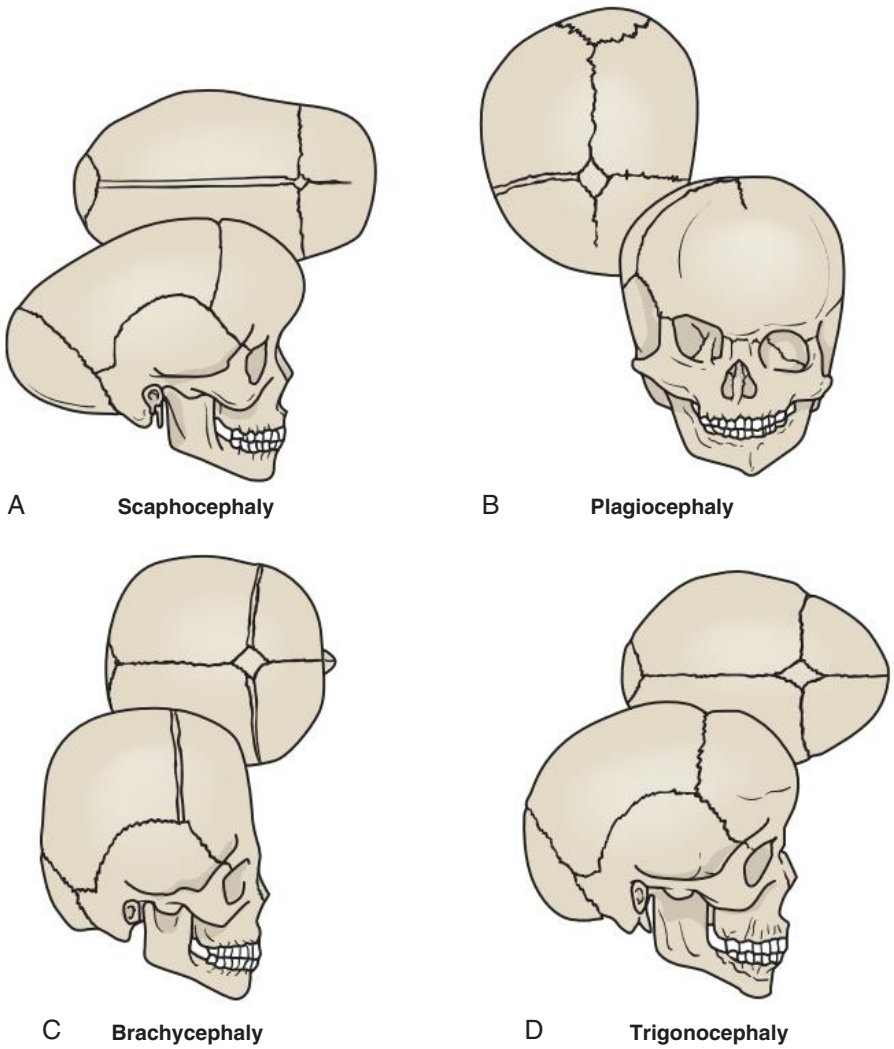
Congenital craniofacial anomalies have a monumental effect on the life and activities of children and their families. These children spend much of their early lives in medical and surgical treatment followed by psychosocial therapy. Not only are these children physically deformed in appearance, but they also often have impaired vision, speech, and hearing and difficulty with nutritional intake. In some circumstances the child may be mentally disabled or have other brain injury that results in seizures. Correction of the **anomaly** can preserve normal intelligence in an estimated 77% of neonates affected when other genetic problems are not involved. Most craniofacial defects are not genetic in origin.

Some of the anomalies are extreme and visually gruesome, but defects that are incompatible with life are complex critical issues to correct in the first few hours or days after birth. The first objective of surgical intervention is to support the child's life functions such as breathing, eating, communicating, and vision. The second objective is to bring the child's form into a more natural appearance. Fig. 41.22 depicts the primary areas of the infant's skull that are involved with craniofacial deformity.

The entire therapeutic process is a multidisciplinary effort of many specialized team members. Another issue to consider is that the child may have additional congenital defects of the internal organs or limbs that need to be addressed simultaneously with the head and neck.

Most of the anomalies associated with the head and neck have been categorized by the type of defect and its effect on the development of the face and skull.[10] The main syndromes are as follows:

1. *Craniosynostosis:* Premature fusion of one or more sutures of the skull. Can be unilateral or bilateral, causing facial abnormalities and increased intracranial pressure. Diagnosis is made via x-ray, cranial ultrasound, and three-dimensional CT imaging. Congenital craniosynostosis occurs in 5:10,000 births.[11]
   a. *Scaphocephaly:* Most common type. Closure of the sagittal suture causes an increased anteroposterior length (Fig. 41.23, *A*).
   b. *Plagiocephaly:* Caused by unilateral or unequal coronal synostosis and may involve the lambdoid suture. The face and head are asymmetric (Fig. 41.23, *B*).
   c. *Acrocephaly/oxycephaly/turricephaly:* Caused by fusion of the coronal and frontoethmoidal sutures that increases the vertical axis of the skull referred to as "tower head." Seen in Crouzon's disease and Apert's syndrome.
   d. *Brachycephaly:* Caused by bicoronal synostosis and sagittal shortening. The head is wide and short. Seen in Crouzon disease (see Fig. 41.23, *C*).
   e. *Trigonocephaly:* Least common. Caused by premature closure of metopic and frontoethmoidal (between the frontal and ethmoid bones) sutures. The skull is triangle shaped with the apex on the front of the forehead with hypotelorism (abnormal decrease in the bony distance between the eyes) (see Fig. 41.23, *D*).
2. *Hypertelorism:* A genetic defect that may appear independently or as a result of a midline facial **cleft** and/or encephalocele and causes an abnormal increase in the bony distance between the eyes measured between the medial orbital walls. Problems with binocular vision and an absent sense of smell (Fig. 41.24).
3. *Pierre Robin syndrome:* Micrognathia, mandibular hyperplasia, wide cleft palate, **glossoptosis** (may cause apnea), and feeding difficulties (Fig. 41.25).
4. *Crouzon disease:* Brachycephaly and turricephaly caused by craniosynostosis, midfacial retrusion associated with maxillary hypoplasia, shallow eye orbits to house the globe, optic nerve damage, "bird beak" nose, some mental retardation, and airway difficulty (Fig. 41.26).
5. *Treacher Collins syndrome:* Autosomal dominant defect that causes mandibulofacial dysostosis. Caused by lateral facial clefts through the maxilla and malar arches; narrow oropharynx and a high-arched palate with or without a cleft; external ear deformities with or without middle and inner ear defects and conductive hearing loss; lower eyelid deformities, including coloboma (notching of the iris) and partial to total absence of lower lashes; and nasal deformity. May result in esophageal collapse requiring a feeding tube and apnea requiring a tracheostomy (Fig. 41.27).



• **Fig. 41.23** Examples of craniosynostosis. **A,** Scaphocephaly. **B,** Plagiocephaly. **C,** Brachycephaly. **D,** Trigonocephaly.

• **Fig. 41.27** Treacher Collins syndrome. (From Neligan PC: *Plastic surgery,* ed 3, Philadelphia, 2013, Elsevier.)

6. *Craniofacial microsomia:* Caused by the intrauterine interruption of the development of the first and second branchial arches. Also known as oral-mandibular-auricular syndrome. Most common in males. Usually unilateral, but can be bilateral. Can accompany many other defects such as torticollis, craniosynostosis, microtia, facial clefts, absent lung or kidney, cranial nerve abnormality, vertebral malformations, eye malformation, oral feeding problems, and airway collapse.
7. *Apert syndrome:* Also known as acrocephalosyndactyly (autosomal dominant syndrome of anomalies of the extremities, head, and hands). The syndrome is characterized by coronal craniosynostosis; exorbitism; hypertelorism; maxillary hypoplasia; wide, hooked nose; narrow palate with median groove, with or without cleft; bilateral symmetric syndactyly of the hands and/or feet; and ankylosis of the elbows, shoulders, and hips. Airway obstruction is secondary to midface hypoplasia, necessitating a tracheostomy, and anomalies of the heart, lungs, and kidneys can be life threatening. Hearing can be a problem because of malformed eustachian tubes (Fig. 41.28).
8. *Microtia:* Small or absent ears.

Congenital craniofacial deformities are surgically treated by several types of cranial remodeling procedures. Some procedures require the child to wear midface external distraction devices that are tightened daily to cause the face to shift into a forward position. In some conditions the dome of the skull is reshaped by opening the fused sutures and wearing a helmet. Each congenital condition has varying degrees of intellectual disability associated with compression of the brain that must be released to minimize the damage.

Craniofacial Procedures

Midface Advancement

The base of the anterior cranial fossae can be exposed through a bifrontal incision to elevate a frontal bone flap. While the neurosurgeon is raising the flap, the plastic surgeon may take donor bone from a rib and/or the iliac crest if autologous bone grafts will be needed. Harvesting of bone from the calvaria (the upper, dome-like portion of the skull) may be preferred.

The facial skeleton is separated from the cranial base. The plastic surgeon raises the periorbita, orbital contents, and soft tissue over the dorsum of the nose. The subperiosteum of the anterior maxillae is elevated. Osteotomies are cut in the supraorbital region to mobilize the lateral walls. An anterior maxillary osteotomy, through an infraorbital approach, extends across and below the frontal processes of the maxillae. Osteotomies of the anterior cranial fossae and the medial and lateral orbital walls and floors are completed. The mobilized bones can be functionally advanced in three dimensions as desired. They are then stabilized with a plating system or wired into position.

To maintain stability, bone grafts also are wired into place in the resulting defects. Resorbable plates and fixation are available for use. Demineralized bone blocks, chips, or powder often is preferred to bone grafts to induce osteogenesis. The frontal bone flap is replaced, and the incision is closed.

Mandibular osteotomies may be done before closure to correct alignment of the jaws. Whether this is necessary or not, the mandible is stabilized after closure with intermaxillary wires and suspension wires to the zygomatic arch.

Depending on the deformity, variations of the intracranial and extracranial osteotomies are done to advance, align, or reposition the facial bones and reconstruct soft tissues. Many patients return to the OR for additional corrective procedures: eyelid ptosis and/or

extraocular muscle surgery performed by the ophthalmologist; dacryocystorhinostomy and/or nasal reconstruction performed by the rhinologist; and bone augmentation or resection of the maxillae and/or mandible for repositioning by the plastic surgeon or oral surgeon. During all procedures the surgeons avoid injury to optic and facial nerves and to arteries and veins.

Procedures of the Orbit

An abnormally wide space between (hypertelorism) or malposition (dystopia) of the bony orbits is usually secondary to other craniofacial malformations. The medial orbital walls by themselves may be moved to correct minimal hypertelorism. Advancement of the superior and lateral walls, rather than total orbit advancement, may suffice to correct a dystopia. A combined intracranial and extracranial approach may be necessary to change the angle of the orbits and reposition the medial canthal ligaments of the eyes.

Resection of Nasal or Paranasal Sinus Tumors

Radical craniofacial resection may be indicated to remove gigantic benign nasal dermoid tumors and malignant tumors of the paranasal sinuses. In a one-stage procedure, all involved soft tissue is excised with simultaneous correction of the underlying skeletal structure.

Basal cell carcinoma is a common type of nasal tumor. The surgical procedure may be performed alone or as combined therapy. Immediate repair by skin graft or pedicle flap accompanies excision of well-defined lesions. Reconstruction is postponed in multicentric (many-centered) cancer or if there is doubt regarding extension of the tumor. More advanced lesions require replacement of the nose by a prosthesis or a tissue flap.

Erosion of a growth in one of the sinuses into an adjacent nasal wall can occlude the air passage. Resection may include partial or total maxillectomy and removal of surrounding tissues. The cavity usually is covered by a skin graft. Unilateral enucleation of the eye may be necessary. A radical surgical procedure for an ethmoid tumor also may involve removal of part of the base of the skull and excision of the maxillary antrum and the palate on the affected side.

In providing maxillofacial prostheses to replace facial structures after various procedures, the prosthodontist works closely with the surgeon and radiation therapist. Splints or stents hold tissue grafts in place, seal cavities from each other, or unite bony segments. A dental prosthesis to close the defect in the upper jaw and an eye prosthesis after enucleation contribute to the patient's rehabilitation after an extensive surgical procedure.

Resection of Craniofacial Tumors and Dysplasia

Malignant tumors can originate from soft tissues of the face and scalp, the oropharyngeal mucosa, the ear canal, or the lacrimal gland. They can invade the base of the skull. Fibrous dysplasia, a congenital metabolic disturbance that causes an abnormal proliferation of fibrous tissue, can result in asymmetric distortion and expansion of craniofacial bones.

These conditions can collapse the paranasal sinuses; compress the optic nerve or chiasm, causing loss of vision; and cause other functional disabilities. An acute epistaxis (nosebleed) can be life threatening. A combined intracranial and extracranial approach may be used to completely remove the tumor or dysplastic bone. The remaining bony structures may be reshaped or repositioned. Bone grafts and/or prosthetic implants may be used for reconstruction of the forehead, orbits, nose, maxilla, and mandible.

Midfacial Fractures

The facial bones provide a shield for the brain. They also protect the senses of sight, smell, hearing, and taste. Although midfacial fractures and soft tissue injuries are seldom fatal, inadequate treatment can result in disfigurement and sensory impairment. For example, virtually all blindness secondary to trauma is permanent.

Facial fractures should be suspected when the patient complains of pain, malocclusion of the jaws, or diplopia (double vision). Swelling and asymmetry of the face may be obvious. Diagnosis is confirmed by x-ray or a CT scan to identify the bones involved. Rene Le Fort (1869–1951), a French plastic surgeon, pioneered fixation of midface fractures. The Le Fort classification of fractures, which is useful in determining the appropriate method of reduction and stabilization (Fig. 41.29), is as follows:

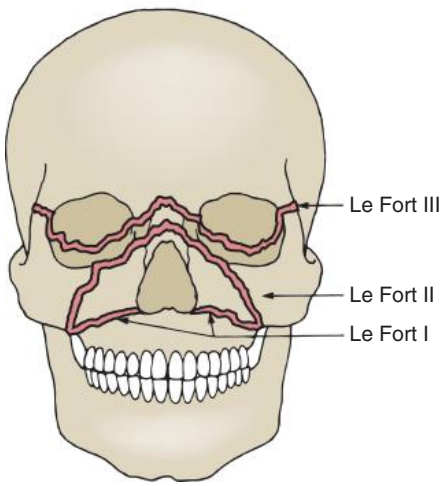
- *Le Fort I* fracture is a horizontal fracture of the maxilla, fragmenting the upper alveoli and palate.
- *Le Fort II* fracture is a pyramidal fracture of the frontal processes of the maxillae, the nasal bones, and the orbital floor. The maxillae are freely movable.
- *Le Fort III* fracture is a transverse fracture that includes zygomas, maxillae, and nasal bones and the ethmoid, sphenoid, and other orbital bones. This creates a craniofacial disjunction (separation).

Facial fractures are reduced, stabilized, and immobilized. Priorities of initial treatment after injury concern airway obstruction, possible cervical spine injury, and hemorrhage. Treatment of the fracture may be delayed. The surgeon follows the principles of approaching fractures from "inside out, downward up." This means that bony structures are repaired first, then the soft tissues; the mandible or most distal fracture is reduced first before working upward toward the cranium.

The method of bony repair is determined by the complexity of the fracture. Intermaxillary fixation combined with interdental wiring, external pin fixation, or rigid internal fixation effect stabilization. Minifacial and midfacial plates, microplates, and mandibular plates may be combined with arch bars or bone grafts.

Reduction of Orbital Fractures

If orbital contents are depressed into the maxillary sinus, surgical exploration through an orbital or a transspinal approach is indicated. The extent of the trauma should indicate the most appropriate



• **Fig. 41.29** Le Fort facial fractures.

surgical management. The injury may involve the rim or the floor of the orbit, or both, as follows:

- Fractures of the orbital rim, frequently associated with fractures of the zygoma, are usually detected by the resulting deformity. The fracture is reduced by appropriate means. Fragments are wired into place as necessary.
- A blowout fracture of the orbit may result from a direct blow to the eyeball, which is, in turn, transmitted to the very thin floor of the orbit. A typical fracture is in the medial third of the floor with dislocation of floor fragments into the maxillary sinus. The fracture occasionally may extend into the ethmoid plate. Consequently, orbital contents, which may include the inferior extraocular muscles, are usually herniated into the antrum. This produces limitation of upward gaze and some degree of enophthalmos (recession of the eyeball into the orbit).

The herniated orbital contents are reduced from the antrum back into the orbit with special attention to freeing the entrapped muscles. Plastic or silicone sheeting may be used to close the defect in the floor. Or the fragments may be elevated by packing the antrum through a Caldwell-Luc (sinus) approach. The diagnosis may be overlooked unless a laminogram is taken.

Reduction of Nasal Fractures

Fracture of the nasal bones and septum often accompanies other trauma to the head, such as a blowout fracture of the orbit (see earlier). If the zygoma or maxilla is involved, reduction may be accomplished through a small incision anterior to the ear and superior to the zygomatic arch. Periosteal elevators are used to raise depressed bone and cartilage fragments. Nasal fractures are splinted with nasal packs and an external splint.

Reduction of Zygomatic Fractures

Dislocations of the zygoma are more common than fractures of the cheekbone (malar bone). Zygomatic fractures always involve the orbital bones. Those of the zygomatic arch are particularly unstable and require intraosseous or transosseous wire fixation after internal reduction with counterpressure from underneath the arch. Transantral Steinmann pinning may be necessary to maintain reduction of fragments in severely fragmented fractures. Absorbable plates composed of biodegradable polymers for zygomaticomaxillary fractures are commercially available. The plates are usually resorbed by the body after 1 year.[12]

Maxillofacial and Mandibular Procedures

The term *maxillofacial* pertains to the part of the face formed by the upper and lower jaws. Most maxillofacial procedures are designed to reconstruct defects in the lips, buccal sulcus, maxilla, alveolar ridge, floor of the mouth, mandible, or chin. These defects may be a result of trauma or resection of tumor. Whenever feasible, intraoral incisions are used to minimize facial scarring.

Intermaxillary Fixation of Fractures

After closed or open reduction, fractures of the maxilla and mandible are usually immobilized by interdental wiring if the patient has upper and lower teeth. If the patient is edentulous (without teeth), open reduction and skeletal fixation by circumferential wiring over an intraoral splint or screws and connecting bars may be necessary.

Erich arch bars are shaped along the dental arches. Wires are passed between the teeth to anchor the splints on the upper and lower jaws. Each splint contains a series of small lugs. Tiny rubber bands, placed around opposing lugs, hold the teeth in occlusion. Splints frequently are not used for fixation of these fractures. The teeth may be held in occlusion by wires passed around opposing teeth. After fixation of the mandible or maxilla, wire cutters accompany the patient from the OR and remain at the bedside as long as wires or rubber bands are in place. If the patient experiences respiratory difficulty or vomiting, the wires may have to be cut to prevent aspiration. Fluids may be difficult to swallow.

If microplates can be used for rigid fixation, the interdental wiring may be released after the fixation procedure is completed.

Mandibular Fractures

Some fractures of the mandible can be immobilized by transoral placement of noncompression miniplates. This technique obviates the necessity of interdental wiring. Vitallium, titanium, or stainless steel plates and screws are used for rigid fixation.

Mandibular Reconstruction

Skeletal defects creating loss of mandibular continuity are usually a result of trauma or benign disease. Bone replacement is the most common method of restoring function and contour. The patient's own ilium provides cancellous bone that can be shaped into the configuration of the jaw. A composite graft of a freeze-dried cadaver mandible packed with autologous cancellous bone chips also can be used. These grafts fill a bony defect but do not provide soft tissue coverage. A vascularized iliac graft is preferable to reconstruct the mandible and a large intraoral defect.

Temporomandibular Joint Syndrome

Persistent pain and dysfunction of the temporomandibular joint (TMJ) can be associated with stress-related bruxism (tensing muscles and grinding teeth), the position of teeth, malocclusion, trauma, arthritis, and other degenerative changes in one or both joints. If TMJ syndrome is unresponsive to conservative treatment, surgical intervention may be indicated.

Arthroscopy. Arthroscopy, usually performed bilaterally, is used to diagnose problems such as scarring or adhesions that do not show up on a CT or MRI. Lysis of adhesions, mechanical debridement, and lavage of the TMJ may relieve symptoms. Repositioning or release of the fibrocartilaginous articular disc (meniscus) between the mandibular condyle and the glenoid fossa of the temporal bone may restore function.

A 1.7 or 1.9-mm arthroscope with a fiberoptic camera attached is locked into a cannula sheath inserted through an inferolateral puncture wound into the joint capsule. Continuous inflow and outflow of fluid, usually iced lactated Ringer's solution, is necessary to keep the joint distended for visibility and lavage. Therapeutic synovectomy and partial or complete meniscectomy may recontour the joint. A rotary shaver and/or the holmium:yttrium aluminum garnet (Ho:YAG) laser may be used. The laser rapidly resects and vaporizes cartilaginous tissue and coagulates bleeding vessels.

Arthroplasty. Open, direct visualization of the disc and condyle may be necessary to correct abnormal relationships. Either a preauricular or postauricular incision may be used to approach the TMJ. The condyle, fossa, and/or articular eminence may be reshaped or resurfaced. A damaged or displaced articular disc can be recontoured and repositioned. It is recontoured with a scalpel or by electrosurgical cutting and then repositioned and sutured in place. If the disc is torn or perforated, it is usually removed. A silicone elastomer implant or titanium alloy prosthesis may be used to reconstruct the joint. The jaw may be immobilized with interdental wiring to stabilize the TMJ during healing.

Orthognathic Surgery

The jaws can be reshaped or repositioned to correct functional bite disorders and/or for aesthetics. Occlusion (closure of teeth) depends on the anteroposterior relationship of the upper and lower jaws. The term *orthognathia,* derived from the Greek words *orthos,* meaning "straight," and *gnathos,* meaning "jaw," relates to treatment of conditions involving malposition of the maxilla or mandible, or both. Malocclusion occurs when teeth do not close together properly. It can cause difficulty in chewing and speaking, periodontal disease, and TMJ dysfunction. Psychologically debilitating facial deformity and bite disorders of genetic origin or as a result of growth disturbances or trauma include the following:

- *Prognathism:* One or both jaws project forward beyond the normal relationship with the cranial base. If the mandible (lower jaw) protrudes beyond the maxilla (upper jaw), it creates a prominence of chin, concave profile, and underbite. If the maxilla grows beyond the mandible, it creates an overbite.
- *Retrognathism:* One or both jaws are positioned posterior to the normal craniofacial relationship (i.e., behind the frontal plane of the forehead). In reference to the mandible, the condition is commonly known as a receding chin; this may create an overbite.
- *Apertognathia:* The front teeth do not close because the back teeth come together first, creating an open bite.
- *Micrognathia:* The dental arch, usually of the mandible, is too small to accommodate the teeth. Teeth are pushed out of alignment because they are crowded together.
- *Asymmetry:* A discrepancy in size, shape, or position of the jaws creates an imbalance between the right and left sides of the face.

Preoperative orthodontia may be required to align and level the teeth. The ultimate goal is to achieve functional stability of dentofacial structures with acceptable facial aesthetics. Surgical correction may include extraction of one or more teeth, maxillary and/or mandibular osteotomies with repositioning of bone segments, and/or repositioning of alveoli. Intraorally, bilateral maxillary osteotomies may be performed in conjunction with mandibular osteotomies, or either of these procedures can be done independently to change the shape of the facial contour.

Le Fort Osteotomy. For maxillary deformities, an incision is made in the mucosa of the upper lip. Osteotomies (i.e., bone cuts) are made in the medial and lateral maxillary sinus walls. The vomer is cut just above the floor of the nose. Pterygoid plates are sectioned from the maxilla. The maxilla is movable for reduction, augmentation, or repositioning. The maxilla can be detached from the base of the skull, maintaining vascular supply via the soft palate, and cut into segments to reconstruct the lower face as described for midface advancement. Usually miniplates anchored with screws bridge the osteotomy cuts.

Mandibular Osteotomy. Sagittal split osteotomies through the ramus and vertical osteotomies through the molar region on each side allow backward or forward repositioning of the mandible. If moved posteriorly, bone on the anterior aspect is trimmed for good medullary bone contact. Rigid fixation may be obtained with miniplates or with screws placed percutaneously through stab wounds. The latter are stabilized with an external fixator. If plates and screws are used, intermaxillary fixation as described for fractures may not be necessary.

Postoperative orthodontia may be required to complete closure of spaces around the osteotomies and thus stabilize occlusal function.

Mandibulectomy. Partial or total removal of the lower jaw is performed for extension of a tumor into the bone of the floor of the mouth. It may be performed with glossectomy and radical neck dissection for wide excision. The resultant chin recession is referred to as an Andy Gump deformity. Mandibular replacement combines bone graft and synthetic materials for restoration of speech and appearance.

A compound osseocutaneous flap from the iliac crest, with microvascular anastomosis of the deep circumflex iliac artery vascular pedicle, may be transferred for reconstruction. If the patient is dentulous, the relationship of opposing teeth is maintained; if edentulous, the patient wears a denture. Whenever possible, mandible-sparing procedures are done for carcinoma of the tongue.

42 Thoracic Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Identify the pertinent anatomy of the thoracic cavity.
- Describe patient positioning for each type of thoracic incision.
- Discuss the setup of water-seal chest drainage.

KEY TERMS AND DEFINITIONS

Bougie Long, tapered, flexible dilator. Some bougies can be lighted for transillumination of a tubular anatomic structure, such as the esophagus.
Decortication Stripping adhesions from the surface of the pleura.
Fundus Dome-like top of stomach near where the esophagus inserts.
Lobectomy Removal of a lobe of the lung.
Mediastinum Cavity within the chest, between the pleura, that contains the esophagus, trachea, pericardium, and great vessels.
Pleurodesis Introduction of a chemical sclerosing agent into the chest. A powdered antibiotic, talc, or caustic chemical is instilled between the parietal and visceral layers of the pleura to fuse them by creating fibrous adhesions. The procedure can use dry chemicals or wet paste.
Plication Systematic rows of sutures that stabilize and secure a muscular region such as the diaphragm.
Pneumonectomy Removal of a lung.
Poudrage Full-strength dry powder is placed between pleural tissue layers to create adhesions.
Slurry Loose, moist paste made of fluid and powdered agent; used to intentionally create adhesions between two serous surfaces inside a cavity.
Thoracoscopy Rigid endoscopic procedure performed by percutaneous puncture of the thorax.

Anatomy and Physiology of the Thorax

An essential balance must be maintained between atmospheric pressure outside the chest and internal pressures within the thoracic cavity to sustain the vital function of respiration. Knowledge of the anatomy and physiology of the chest and thoracic cavity is necessary for an understanding of thoracic surgery.

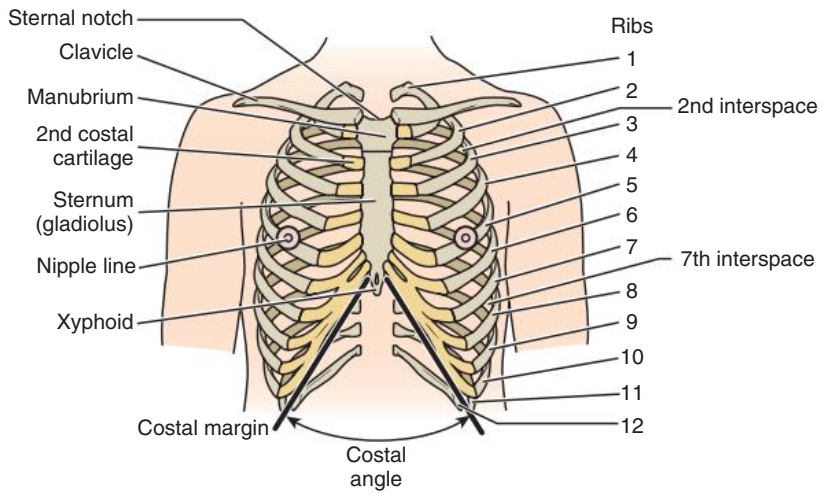
Thoracic Cavity

The thorax, or chest, is the portion of the trunk between the neck and the abdomen. The thoracic cavity is divided into right and left pleural compartments separated by the **mediastinum**, which is a separate enclosed space located centrally. Alterations in pressure affecting one side of the thoracic cavity or the mediastinum cause a positional shift of the other compartments.

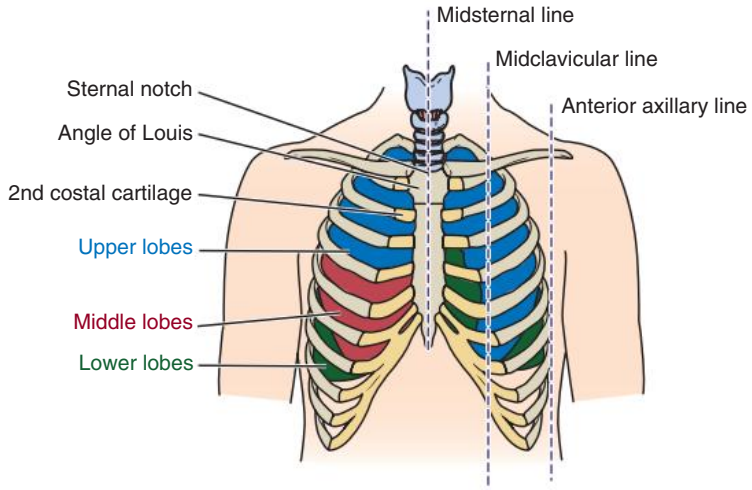
The bony framework of the thoracic cavity consists of the sternum and costal cartilage anteriorly, 12 pairs of ribs laterally, and 12 thoracic vertebrae posteriorly, all encased within soft tissue. The framework is bounded superiorly by structures of the lower part of the neck and inferiorly by the diaphragm. Eleven external and internal intercostal muscles, which lie between the ribs, have a corresponding artery, vein, and nerve, which require meticulous dissection to avoid inadvertent injury. The arterial blood supply is derived from the subclavian artery, internal thoracic artery, and the thoracic aorta. Venous drainage is through the mammary veins anteriorly and the azygos and hemiazygos veins posteriorly. Lymphatic drainage is through the parasternal nodes that follow the internal thoracic artery. Innervation is from the anterior roots of the thoracic spine (T1-T11) to the parietal pleura.

The first seven ribs articulate anteriorly in the midline with the sternum, which is composed of three parts: the manubrium (superiorly), the gladiolus (medially), and the xyphoid process (inferiorly). Ribs one and two articulate with the clavicle and the manubrium. The manubrium and gladiolus join in a projection referred to as the angle of Lewis, a surgical landmark (Fig. 42.1).

Ribs three through seven articulate with the gladiolus (the main sternal body) via the costal cartilage. The eighth, ninth, and



• **Fig. 42.1** Surgical landmarks of the bony ribcage.



• **Fig. 42.2** Surgical landmarks: lines of direction.

tenth ribs are joined anteriorly to the cartilage of the rib above each; the eleventh and twelfth ribs have no anterior fixation. The surgical incisional lines of direction in Fig. 42.2 bilaterally overlie the lobes of the lungs on a vertical axis, with the sternum (gladiolus) as the thoracic reference point.

The ribs articulate posteriorly with the thoracic vertebrae. The esophagus, trachea, and great vessels leading to and from the neck and arms pass through the small space between the manubrium and the vertebrae. Any structure pushing into this narrow opening (e.g., a mediastinal tumor) may obstruct breathing, venous return from the neck and arms, and swallowing.

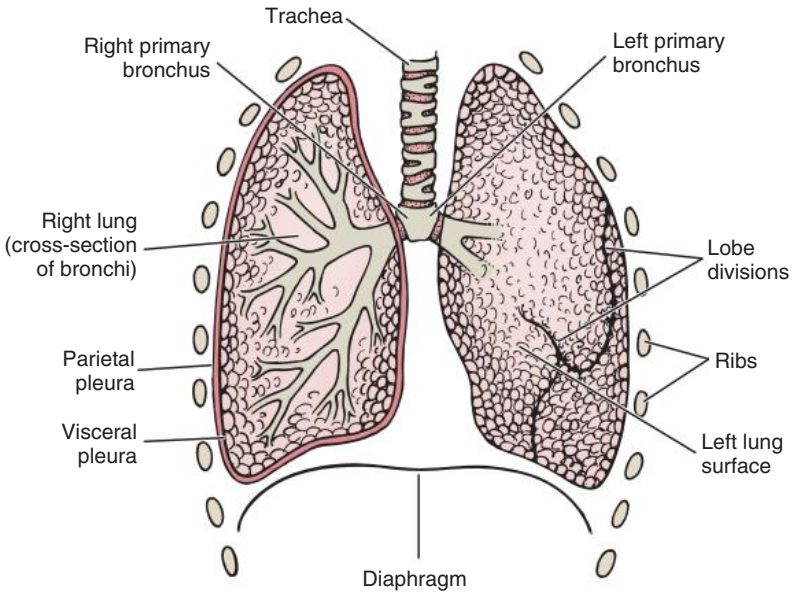
Lungs

The lungs lie in the right and left pleural cavities (Fig. 42.3). The main function of these porous, spongy, conical organs is oxygenation of the blood with inspired air and expiration of carbon dioxide. The apex of each extends to the neck; the base rests on the superior surface of the diaphragm.

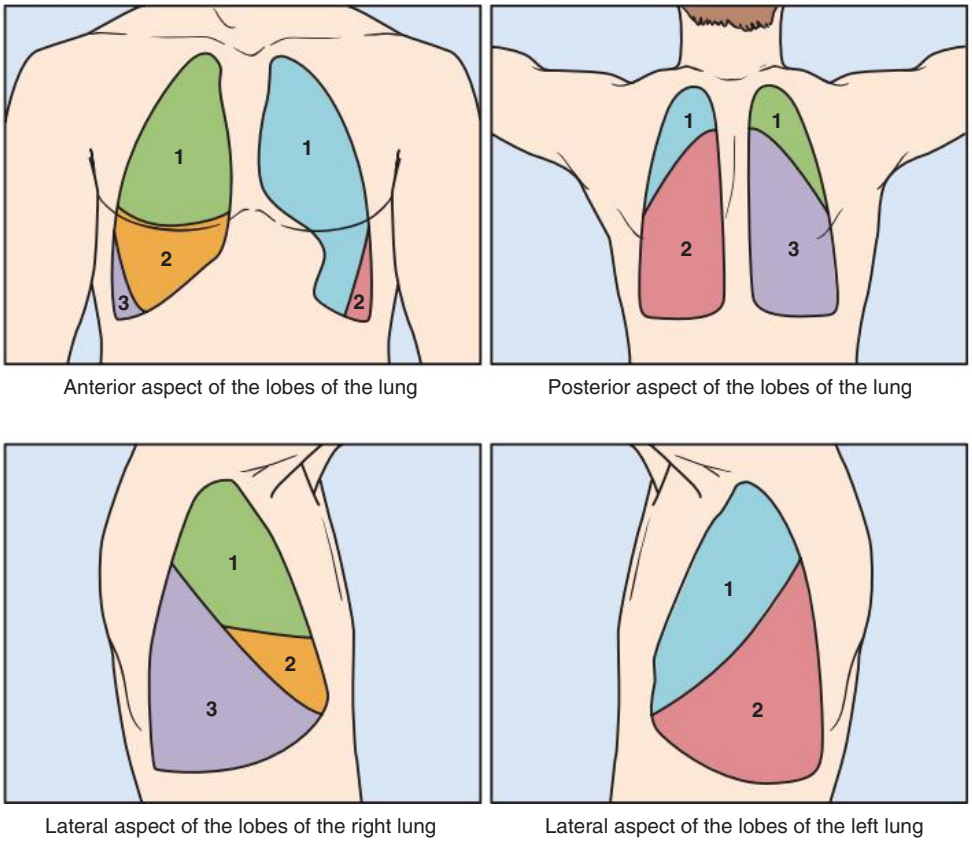
The right lung, which has three lobes, an oblique fissure, and a straighter bronchus, is larger than the left lung, which has two lobes and a more angled bronchus. Blood supply is derived from the two pulmonary arteries and drains into the four pulmonary veins. Lymphatics drain into the bronchopulmonary nodes and into the thoracic duct. Innervation is through the pulmonary plexuses.

The lungs are enveloped by a serous membrane, referred to as the pleura. The pleura has two layers. The external parietal layer lines the inner surface of the thorax. The inner visceral layer covers the surface of the lung. Small amounts of serous fluid (transudate) are secreted between these layers to allow for smooth interface without friction. Excess inflammation or fluid accumulation causes pain and impaired respiratory effort. If infected, the transudate becomes exudate containing increased numbers of white blood cells. Severe inflammation causes fibrosis and adhesions of the pleural tissues.

The trachea divides at the carina into two main branches—the bronchi—leading to the right and left lungs. The right lung, with three lobes, is wider and broader than the left lung. This is because the liver is positioned beneath the diaphragm directly below the base. The left lung has only two lobes and is thinner, longer, and narrower. It shares space in the left side of the chest with the heart, which rests in an area of the left lung referred to as the cardiac notch (Fig. 42.4).



• **Fig. 42.3** Respiratory system within thoracic cavity.



Anterior aspect of the lobes of the lung | Posterior aspect of the lobes of the lung

Lateral aspect of the lobes of the right lung | Lateral aspect of the lobes of the left lung

• **Fig. 42.4** Location of the lobes of the right and left lungs. Patient positioning will be determined for optimal access of the affected lobes or entire lung.

The bronchopulmonary segments within each lung are wedges of tissue separated by veins and thin connective membrane. Although configuration of the segments differs, and variations in the bronchi and blood vessels exist between the right and left lungs, it is generally accepted that both lungs normally have 10 bronchopulmonary segments. Despite not being demarcated by surface fissures, these segments represent zones of distribution of the secondary bronchi and may be excised individually when the segment contains a small lesion, thus preserving the uninvolved portion.

Each segmental bronchus subdivides into numerous, increasingly smaller branches that eventually end in terminal bronchioles.

These fine tubules invested by smooth muscles can constrict to close off the air passage, as in asthma. The terminal bronchioles give rise to respiratory bronchioles from which arise the alveoli. The approximately 300 million alveoli are the functional units wherein oxygenation takes place at the capillary level.

The hilus of the lung, on the mediastinal surface, is the point of entry for the primary bronchus, nerves, and blood vessels. The right primary bronchus is straighter and is a more direct continuation of the trachea. Arterial supply to the lung tissue is derived from the bronchial arteries. Venous drainage is through the bronchial veins, which empty into the azygos system. The pulmonary veins and arteries to and from the heart provide systemic pulmonary circulation. Innervation of the breathing mechanism is by the autonomic nervous system.

Mediastinum

The mediastinum has superior, anterior, middle, and posterior sections, each containing anatomic structures. The thymus lies in the anterior and superior sections, the thoracic aorta lies in the posterior section, the base of the heart and the great vessels lie in the middle, and the esophagus and trachea lie in the superior section. The organs are surrounded and suspended by the loose tissue diffused throughout the mediastinum.

Diaphragm

The diaphragm is a half dome of muscular tissue composed of four embryonic segments: (1) dorsal mesentery, (2) septum transversum, (3) two pleuroperitoneal folds, and (4) cervical myotomes that border the inferior aspect of the thoracic cavity. It originates from the six lower ribs on each side and attaches to the xyphoid and the external and internal arcuate ligaments. Abnormal separation of any of these layers changes the pressure gradient between the peritoneal cavity and the thorax, causing a shift of intraabdominal organs cephalad into the chest.

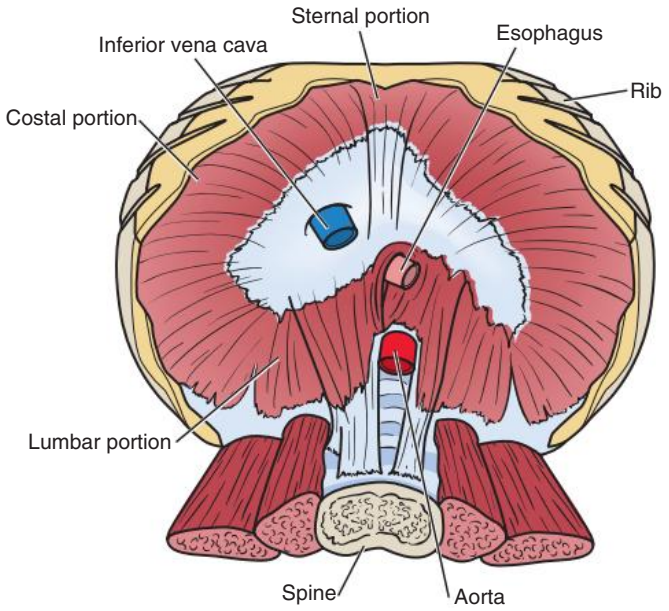
The arterial blood supply arises from the right and left phrenic, intercostal, and internal thoracic arteries. Venous drainage is via the inferior vena cava, the azygos vein on the right, and hemiazygos veins on the left. Innervation is from the phrenic nerve that arises from the fourth cervical ramus.

The esophagus, aorta, and vena cava pass from the thorax through the diaphragm into the abdominal cavity via three separate openings. Associated vessels and nerves, such as the vagus nerve, follow these three structures through the diaphragm to major organ systems (Fig. 42.5).

Physiology

The size of the thorax varies with the bellows action of the thoracic wall and diaphragm, increasing with inspiration and decreasing with expiration. A partial vacuum between the parietal and visceral pleurae expands the lungs. A negative (subatmospheric) pressure normally within the thorax is essential to life.

Alterations of intrapleural pressure are of major concern because an uncontrolled opening in the thoracic wall and pressure change can be fatal. Uncontrolled increased positive pressure in one side causes a collapse of the lung on the other side. Referred to as a mediastinal shift, this reaction occurs with entrance of either air or fluid into the pleural cavity, compressing the opposite lung and causing dyspnea. When the mediastinum has moved its limit, it can no longer accommodate a great pressure change; the lung on the affected side collapses. Air in the pleural space between the parietal and visceral pleurae constitutes pneumothorax. Blood in the pleural space constitutes hemothorax.



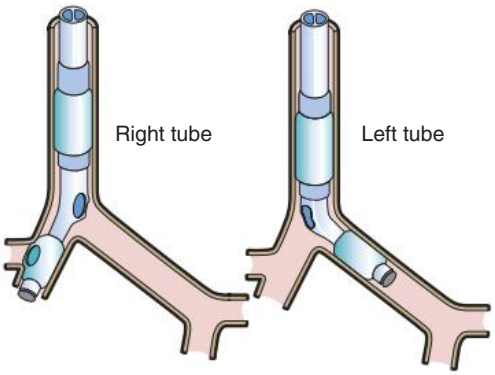
• **Fig. 42.5** Inferior view of diaphragm with orientation of vena cava, aorta, and esophagus.

A mediastinal shift disturbs heart action and circulation. Changes in pressure balance within the thorax reduce vital capacity—the greatest amount of air that can be exchanged in one breath. Many diseases and conditions (e.g., anesthesia, thoracic tumors, chest trauma) alter vital capacity.

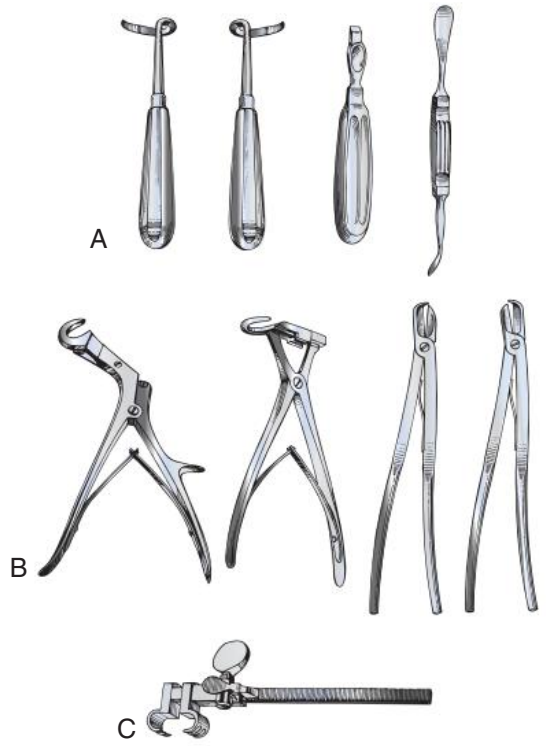
Special Features of Thoracic Surgery

Entry into the thoracic cavity can be accompanied by pulmonary distress. Team members especially skilled in meeting emergency situations are essential. Patients require close observation and monitoring because changes may occur rapidly. A pulmonary artery catheter is inserted to monitor pulmonary capillary wedge pressures and arterial blood gases. Equipment for bronchoscopy, esophagoscopy, and mediastinoscopy must be readily available. Other preparations are routinely completed for entry into the chest for intrathoracic procedures, as follows:

1. Endotracheal anesthesia permits the lungs to expand and function even when subjected to atmospheric pressure. Administration of anesthesia under controlled positive pressure prevents physiologic imbalance and lung collapse in the presence of controlled pneumothorax. Use of a double-lumen endotracheal tube permits expansion of the unaffected lung and collapse of the lung on the surgical side (Fig. 42.6). At the conclusion of the surgical procedure the affected lung is re-expanded by the anesthesia provider, and negative pressure in the chest is restored. Portable chest x-rays may be taken immediately to assess the status of the surgical area, pleural cavities, and lung re-expansion.
2. Instrumentation includes a basic laparotomy setup with the addition of thoracic instruments. These include bone instruments and a power saw (Fig. 42.7 shows rib strippers/rasps, shears, and an approximator/contractor); a large self-retaining chest retractor/rib spreader (Fig. 42.8); bronchus clamps and lung forceps (Fig. 42.9); and long instruments for work in a deep incision. Specialty retractors are used to hold lung tissue and displace the bones of the shoulder girdle (Fig. 42.10).
3. A variety of sutures may be used for soft tissues, vessels, and bone. The bronchus usually is closed with staples.



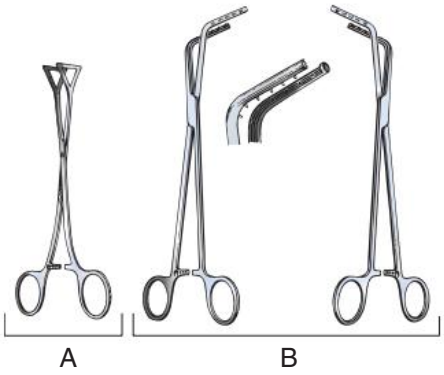
• **Fig. 42.6** Double-lumen endotracheal tube.



• **Fig. 42.7** Rib instruments. **A,** Strippers/rasps. **B,** Shears. **C,** Approximator/contractor.

• **Fig. 42.8** Self-retaining chest retractor/rib spreader.

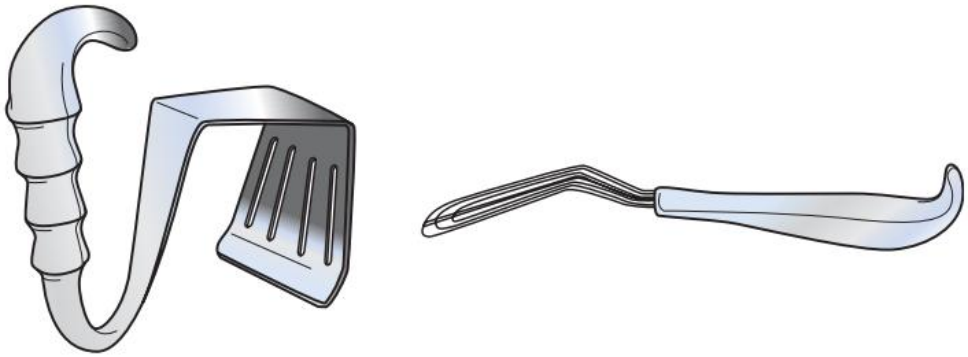
4. Sponges for hemostasis or blunt dissection are placed on long ring-handled forceps. Periosteal bleeding may be controlled by electrocoagulation. Bone wax may be needed to control bone marrow oozing.
5. Blood for transfusion should be available at all times. Hemorrhage is a major threat intraoperatively and postoperatively. Blood may be salvaged for autotransfusion by cell saver, and a postoperative drainage salvage reservoir and autotransfusion drain may be used.
6. The surgical field is potentially contaminated by secretions and contact with open air passages when a bronchus is opened and sutured. Used items and instruments are isolated in a discard basin. Maintenance of a dry field is important to prevent aspiration of blood and fluid, which predisposes the patient to postoperative pneumonia.
7. An airtight pleural cavity must be restored and negative pressure maintained for maximum pulmonary function postoperatively. Except after a few specific procedures, a sterile, closed water-seal drainage system is essential. Chest tubes are inserted through a stab wound and anchored to the chest wall with suture and tape. Two or three tubes are sometimes inserted into the pleural space and connected to separate drainage systems (Fig. 42.11, *A*). The tube at the base of the pleural space is usually inserted at the seventh costal interspace, near the anterior axillary line, to evacuate fluid. An upper tube, if indicated, is inserted at the apex through the anterior chest wall at the third costal interspace to evacuate air leaking from the lung. Positioning of the chest tubes can vary if the patient has a pneumothorax (Fig. 42.11, *B*). Key points to remember include:
   a. Connections must be physically tight and securely taped at the time of dressing application. The taped connections should not obscure the observation of drainage.
   b. System components must be kept below the level of the patient's body to prevent reentry of air or fluid from the drainage collection system into the pleural cavity.
   c. Tubes may be clamped before insertion and connection to the drainage system, depending on the surgeon's preference. Tubes are not routinely clamped at other times unless the surgeon specifically requests them. Specialized tube clamps are used for this purpose.



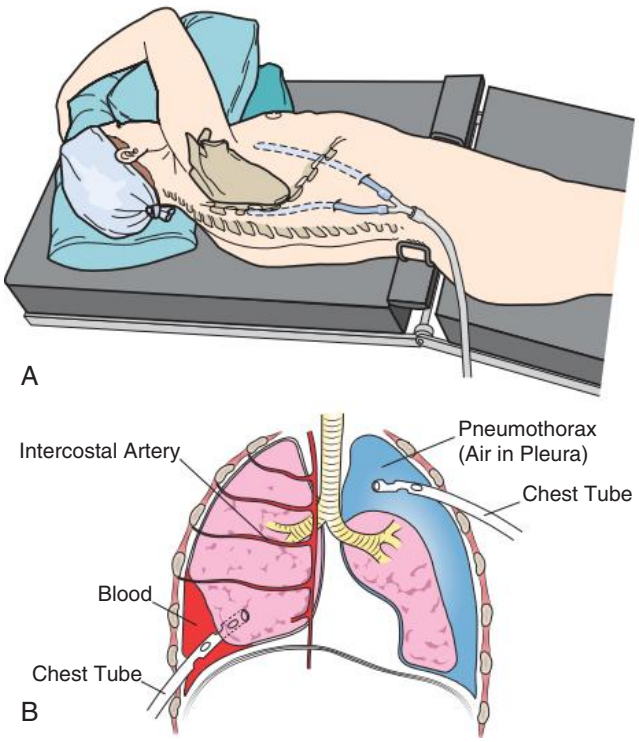
• **Fig. 42.9** Thoracic tissue forceps. **A,** Bronchus clamps. **B,** Lung forceps.

Access to the Thorax

Surgeon preference and the procedure determine the method of entrance into the thorax. Access may be gained by an anterior, lateral, or posterior approach, or a combination of these. Entrance through the ribcage may be intercostal between the ribs, through the periosteal bed of an unresected rib, or by rib resection. By incising near the top of a rib the surgeon protects nerves and vessels that lie in the intercostal spaces. An intercostal approach may be used to drain an empyema pocket or mediastinal abscess or to obtain a biopsy specimen of lymph nodes or of a lung.



• **Fig. 42.10** Specialty lung and thoracic retractors.



• **Fig. 42.11** **A,** Patient in lateral position with upper and lower chest tubes in place. **B,** Placement of chest tubes for air evacuation and blood drainage in pneumothorax.

To enter the thorax via the periosteal bed, the periosteum of the rib is incised and removed from the unresected rib, and an incision is made through the bed. For entrance via a rib resection, the periosteum is incised and removed superiorly and inferiorly with a periosteal elevator and the rib is divided. Rib spreaders increase exposure, but if the exposure is still inadequate, the rib located above or below the incision also may be resected.

Endoscopy

Elective surgery depends on accurate diagnosis by radiologic and physiologic pulmonary function studies and by biochemical, cytologic, and histologic determinations and evaluations. Frequently, endoscopic procedures are performed to obtain secretions and tissue biopsy specimens.[1] Some lesions can be treated endoscopically.

Bronchoscopy

Disorders of the bronchus are most commonly infection, the presence of a foreign body, trauma, or neoplasms. Diagnosis is made by radiologic study and endoscopy. Bronchography (x-ray study of the tracheobronchial tree) is frequently done in conjunction with bronchoscopy. Bronchoscopy (direct visualization of the tracheobronchial tree through a bronchoscope) is done for the following purposes:

- *Diagnosis:* Securing an uncontaminated secretion for culture, obtaining a biopsy specimen, or finding the cause of a cough or hemoptysis
- *Intervention:* Removing a foreign body, excising a small tumor, applying medication, aspirating the bronchi, or providing an airway during performance of a tracheotomy

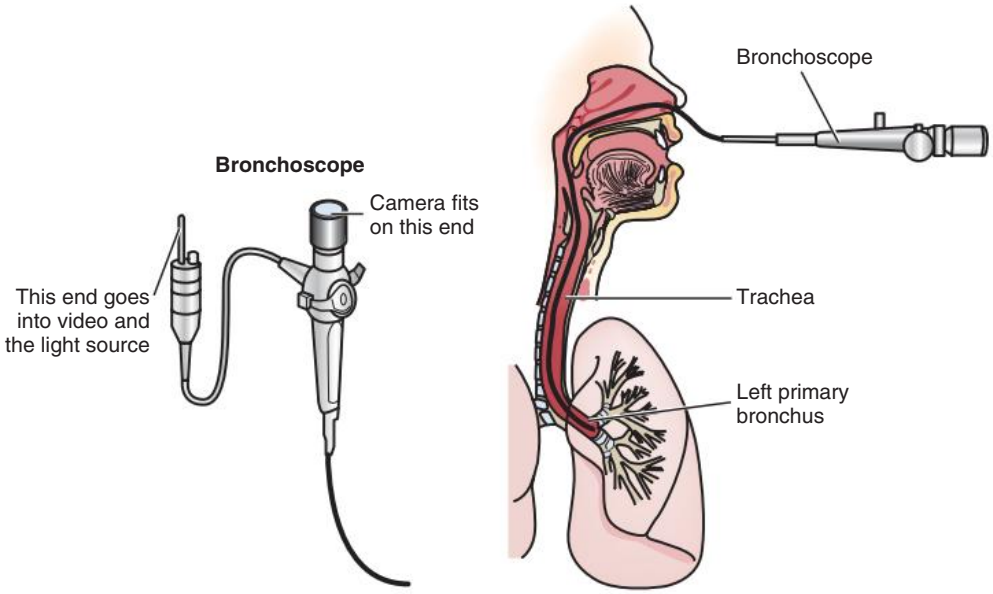
Foreign bodies in the trachea and bronchi are very serious, requiring a careful history and immediate bronchoscopy with preparation for a potential tracheotomy. Maintaining a safe airway during extraction is a major risk. If the airway is not seriously obstructed, the aspirated foreign body may remain in the bronchus for months without producing symptoms until suppuration develops. Coughing and hemoptysis bring the patient to the physician. Snares and graspers can be used to retrieve foreign bodies.

Bronchoscopes are of two types: a rigid hollow metal tube and a flexible fiberoptic type. The rigid bronchoscope commonly uses a fiberoptic light carrier attached to a light source to allow visualization of the trachea and primary bronchi. It is the scope of choice for foreign body retrieval and determination of persistent bleeding. It has a side channel incorporated into the length of the instrument and perforations along the sides of the tube to allow oxygenation of bronchi and administration of anesthetic gases if general anesthesia is used.

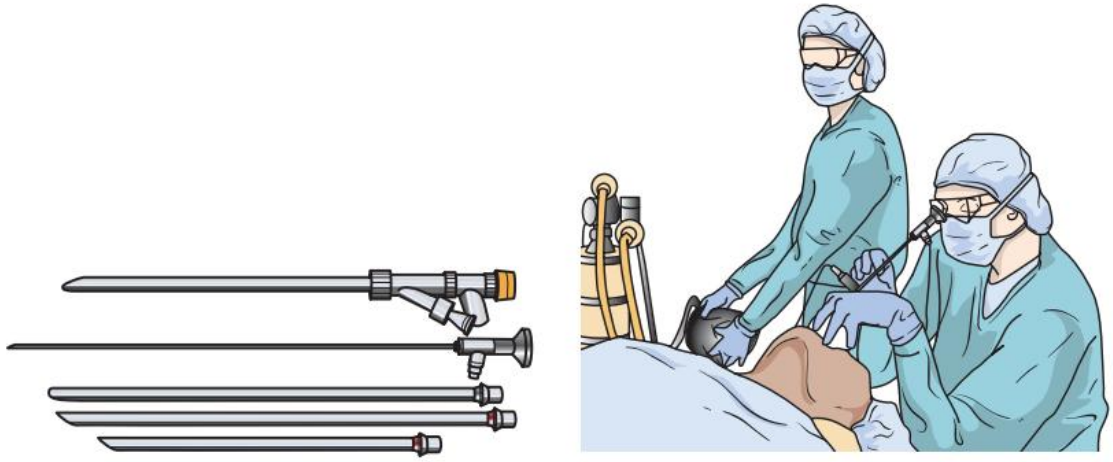
Aspirating tubes, foreign body or biopsy forceps, and carbon dioxide (CO_2) lasers are manipulated through the rigid bronchoscope. Both rigid and flexible fiberoptic bronchoscopes are used for diagnostic and therapeutic procedures.

Flexible bronchoscopy is used frequently for the patient with decreased range of neck motion. Flexible bronchoscopy can be performed via the nasopharynx or orally to the trachea and into the bronchial tree (Fig. 42.12).

Tiny forceps and biopsy brushes can be inserted through the working channel of the flexible fiberoptic bronchoscope to obtain a tissue biopsy specimen. Because the diameter is smaller, the flexible fiberoptic scope reaches into the bronchi of the upper, middle, and lower lobes for examination and/or biopsy. Diagnostic needle aspiration, forceps biopsy, and bronchial brushings and washings are performed in accessible areas. Mediastinal lymph



• **Fig. 42.12** Flexible bronchoscopy.



• **Fig. 42.13** Rigid bronchoscopy.

nodes can be aspirated through the flexible bronchoscope. Various types and lengths of aspirating tubes, forceps, and brushes are used to remove tissue and secretions. The neodymium:yttrium-aluminum-garnet (Nd:YAG) or argon laser can be used with either a rigid or a flexible bronchoscope.

Electromagnetic navigation bronchoscopy (ENB) uses preoperative CT scans to plan a real-time navigation path.[2] A steerable sensor can target the lesion even if it is in a difficult to reach location. The sensor can be locked in place, and the surgeon may identify it using blue or green dye or a microcoil can be deployed as a marker. Resection can take place using bronchoscopic instrumentation.

If the gag reflex can be controlled, oral rigid bronchoscopy can be performed with the patient under local anesthesia and intravenous sedation. General anesthesia may be necessary. The bronchoscope is inserted over the tongue and through the vocal cords to the trachea. The patient's head is turned to the right to visualize the left bronchus and to the left for the right bronchus (Fig. 42.13).

The bronchi may be examined to ascertain the patency of the tracheobronchial tree or to locate the source of an obstruction or bleeding. The person who assists the bronchoscopist introduces tips of instruments into the scope. Everyone involved with bronchoscopy should wear personal protective equipment (gown, gloves, mask, hair cover, and eye protection) to protect themselves from bronchial secretions and blood.

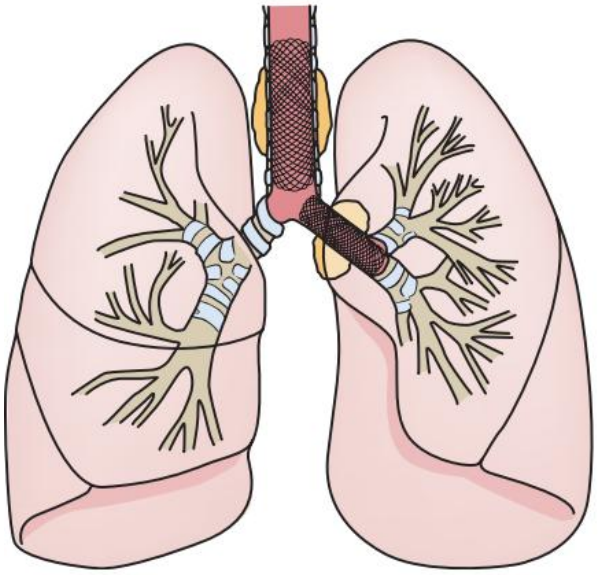
Some pulmonary lesions are treated by laser. The CO_2 laser is used for stenosis, granulation tissue, or other obstructive lesions that are not highly vascular. Video-assisted, flexible, fiberoptic laser bronchoscopy is more commonly performed using the Nd:YAG laser. This laser is preferred for vascular lesions, such as neoplasms, to produce hemostasis as it cuts. The argon laser is used for photodynamic therapy to shrink or destroy bronchial tumors. Everyone in the room, including the patient, is required to wear appropriate eye protection of the correct optical density for the type of laser in use.

Airway Stents

Airway obstruction can be relieved by insertion of metal mesh or silicone rubber stents.[3] These may be straight configuration, T-shaped, or T-Y bifurcation prostheses (Fig. 42.14). Metal stents are permanent and deployed via a rigid bronchoscope over a guidewire. The interstices of the mesh allow for tissue ingrowth, providing long-term palliation. Silicone stents are also deployed through a rigid bronchoscope but are removable.

Positioning is confirmed with x-rays or bronchoscopy. Daily moisture inhalation with a nebulizer is necessary to keep the area moist. Frequent suction may be necessary if the patient cannot clear secretions. Lasers cannot be used in the presence of the stent. They will cause overheating of the tissues as well as uneven pressure and distortion of the lumen of the stent.

The most common reasons for using airway stents are for palliation of obstructing neoplasm, postradiation therapy, after lung transplantation, and after fistula repair. Postoperative complications can include stent migration, avulsion, fistula formation, bleeding, and infection.



• **Fig. 42.14** Tracheal and bronchus straight stents.

A sterile bronchoscope should be used for each patient. Thorough cleaning of the bronchoscope and instrumentation is necessary immediately after the procedure. Terminal sterilization is recommended before storage.

Mediastinoscopy

Mediastinoscopy may immediately follow bronchoscopy. To prevent needless thoracotomy, mediastinoscopy is performed for assessment of resectability in patients with suspected bronchogenic carcinoma and for diagnosis of mediastinal lesions.

Mediastinoscopy uncovers mediastinal lymph nodes for direct visualization and biopsy.[4] Subaortic nodes draining the left lobe of the lung may be out of reach for biopsy with this technique. With the scope the mediastinoscopist can see down to the carina and about 4 cm distal to it along each bronchus. If more than one biopsy specimen is obtained, each specimen should be placed in a separate container and identified by location. The procedure gives a high percentage of accurate diagnoses and information in staging the extent of a lesion and determining its operability for curative resection. Sometimes a frozen section is done while the patient is in the OR, with resection performed immediately after a report from the pathologist.

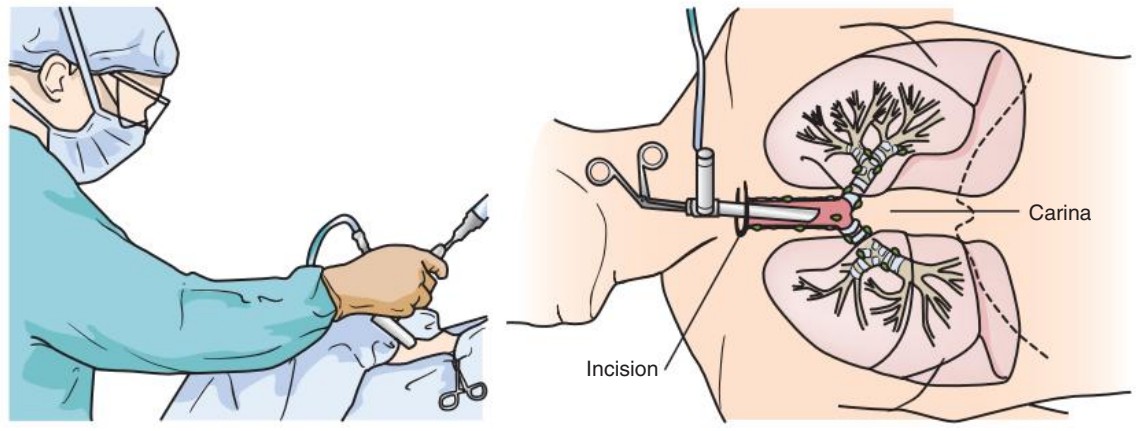
General endotracheal anesthesia is used. The patient is supine with the neck hyperextended and the head turned slightly to the right. A small transverse incision is made in or about 2 cm above the suprasternal notch between the borders of the sternocleidomastoid muscle (Fig. 42.15).

Dissection is carried down to the pretracheal fascia. After blunt dissection the sterile mediastinoscope is passed behind the suprasternal notch and advanced behind the aortic arch into the superior mediastinum to the level of the carina. Care is exercised because of the proximity of the great vessels to the insertion point of the scope.

Bleeding is controlled by coagulation with an insulated electrosurgical suction tip. Although mediastinoscopy usually is performed without complication, major bleeding may require immediate thoracotomy. A chest x-ray frequently is obtained after mediastinoscopy.

Thoracostomy

Closed thoracostomy is performed to establish continuous drainage of fluid from the chest (usually purulent from sepsis or drainage of



• **Fig. 42.15** Mediastinoscopy through incision at sternal notch. **A,** Insertion of mediastinoscope through suprasternal notch incision. **B,** Mediastinoscope in position

blood) or to aid in restoring negative pressure in the thoracic cavity. It involves insertion of a tube through an intercostal space via a trocar and cannula.

Thoracoscopy

Thoracoscopy provides visualization of the pleural space, parietal and visceral pleurae, mediastinum, pericardium, and thoracic wall. The need for evaluation of pleural effusion (i.e., the accumulation of fluid, pus, or blood in the pleural space) and the need for obtaining biopsy specimens of pleural or lung tumors are the most common reasons for thoracoscopy.[5]

Definitive treatment of spontaneous pneumothorax (e.g., in patients with cystic fibrosis or in pleural effusion from cancer), using a sclerosing agent for chemical **pleurodesis** such as a **slurry** mixture or powder (**poudrage**), may be performed under thoracoscopic guidance. Materials used for pleurodesis include one or more of the following agents placed through a port:

- Adriamycin
- Bacille Calmette-Guérin
- Bleomycin
- *Corynebacterium parvum*
- Doxycycline
- Doxorubicin
- Fluorouracil
- Iodopovidone
- Nitrogen mustard (alkylating agent)
- Minocycline
- Mitoxantrone
- Quinacrine hydrochloride
- Radioisotopes
- Talc slurry or plain talc powder
- Tetracycline
- Thiotepa

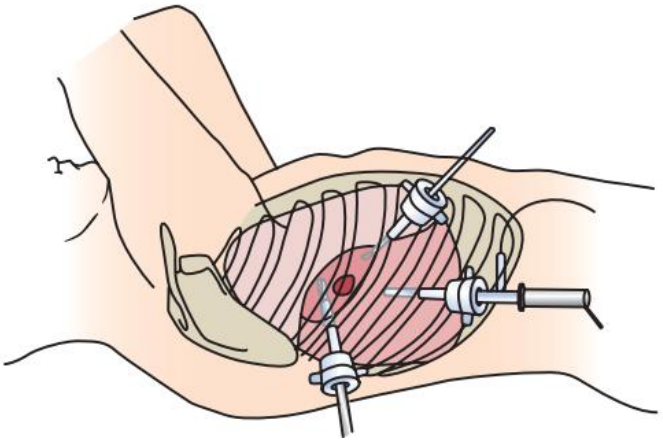
Fusion of the two pleural layers with a sclerosing agent prevents serous fluid production and accumulation in the chest.

Some of these agents can become systemic, causing side effects such as bone marrow depression. Several types of sclerosing agents, such as *C. parvum,* work only in the presence of malignancy and are not effective for pneumothorax and normal pleura. Talc can have a residual radiolucent quality that can interfere with chest x-rays.

In patients with empyema and adhesions a fibrous thickening on the visceral or parietal pleura may restrict pulmonary ventilation. Pulmonary **decortication** (membrane stripping) removes the restrictive layer or membrane over the lung to re-expand the entrapped lung and fill space remaining after drainage of an empyemic cavity (Fig. 42.16).

Thoracoscopic techniques include video-assisted thoracic surgery (VATS) and robotic single-port VATS for bullous emphysema, **pneumonectomy**, and debulking of thoracic tumors. Single-port robotics are used for selected cases in which instrumentation can be easily maneuvered.[6] Some procedures incorporate aspects of endoscopic and open techniques. An axillary approach to thoracoscopy provides good access to the apex of the lung and satisfactory aesthetic incisional closure. An intercostal incision for thoracoscopy is usually preferred, but in some patients resection of a rib may be necessary to facilitate access to the intrapleural space.

A laser can be used to vaporize thickened tissues between the visceral pleura and the lung or between the parietal pleura and the chest wall that impede breathing. Thoracoscopy is used effectively for separation of tissue layers.



• **Fig. 42.16** Thoracoscopy for lung biopsy.

General anesthesia is necessary. The patient is in a partial or full lateral thoracotomy position, depending on the preferred access portal sites that the surgeon selects. A small skin incision is made over and carried through the intercostal space of choice. The surgeon incises the parietal pleura to enter the pleural cavity.

After the anesthesia provider deflates the lung, the sterile thoracoscope is inserted into the pleural cavity. Pressures should not exceed 10 mm Hg. When the procedure is completed, the scope is removed and a chest tube is inserted and connected to a sterile, closed water-seal drainage system to remove residual air and fluid.

Complications of thoracoscopy include bleeding; injury to thoracic nerves, ducts, or vessels; atelectasis; and respiratory failure. Contraindications to the procedure are a fused lung, inability to tolerate a unilateral deflated lung, and cardiac instability.

Thoracic Incisional Approaches

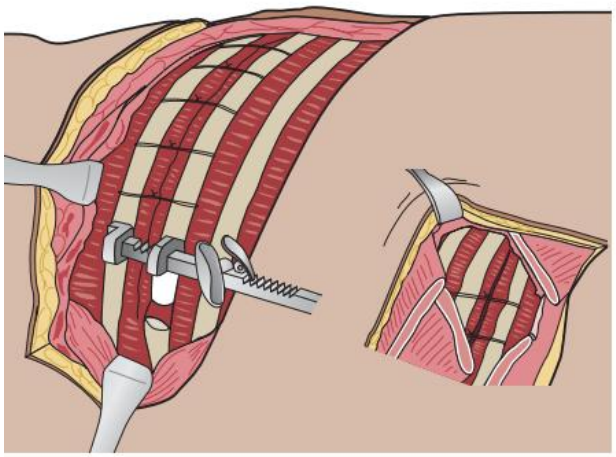
Factors influencing the location of the thoracic incision include the following:

- Adequate exposure into the thoracic cavity
- Physiologic intrapleural pressure changes and constant movement of the chest
- Maintenance of integrity of the chest wall and diaphragm
- Condition of the underlying pleura and lung
- Objective of a minimally invasive procedure, if possible

Because of its continuity with the neck and abdominal structures, the thoracic cavity may be entered for neck and upper abdominal procedures as well as for thoracic procedures. Examples include a thoracic aortic aneurysm and pathologic conditions of the esophagus.

Posterolateral Thoracotomy

With the patient in a lateral chest position, a posterolateral incision permits maximum exposure to the lung, esophagus, diaphragm, and descending aorta for exploration of the thoracic cavity. Beginning anteriorly in the submammary fold, about at nipple level, a curved incision is made, extending below the scapular tip, following the course of the underlying ribs. Then curving upward and posteriorly, the incision may be carried as high as the spine of the scapula. Subcutaneous tissue is incised; the latissimus dorsi, lower margin of the trapezius, rhomboideus, and serratus muscles are divided; and bleeders are ligated. In dividing the serratus muscle, special precaution is taken to avoid the neurovascular bundle on the surface.



• **Fig. 42.17** Rib approximation at closure of thoracotomy.

During closure the ribs are reapproximated with a rib approximator/contractor and sutures, the intercostal muscles are sutured, and the incision in the periosteal bed and pleura is closed (Fig. 42.17). Muscles are reapproximated anatomically and sutured; subcutaneous tissue and skin are closed.

Posterolateral thoracotomy is used for pulmonary resections, for repair of a hiatal hernia, and for procedures on the thoracic esophagus or posterior mediastinum.

Anterolateral Thoracotomy

For an anterolateral incision the patient is supine. Supports are placed under the affected side to tilt the shoulder 20 to 45 degrees for extension of the incision posteriorly. A pad behind the buttocks may rotate the hips slightly.

A submammary incision, directly below the breast but above the costal margin, extends from the anterior midline to the midaxillary or posterior axillary line. To avoid the axillary apex and a painful scar, the posterior end of the incision is curved downward. Superiorly, access is desired at about the fourth interspace. Further anterior exposure can be gained, if desired, by transecting the sternum and continuing the incision to the contralateral interspace. The pectoralis muscles are divided, the serratus anterior fibers are separated, the intercostal muscles are divided, and the thorax is entered through an intercostal space. When an anterior incision extends to the sternal border, internal mammary arteries and veins are ligated and divided. If the incision is carried far laterally or posteriorly, injury to the long thoracic nerve must be avoided to prevent a winged scapula.

During closure the sternum is reapproximated with heavy suture, the ribs are approximated with pericostal sutures, and the muscles, subcutaneous tissue, and skin are closed.

Anterolateral thoracotomy is used for resection of a pulmonary cyst or a local lesion or for open lung biopsy.

• **Fig. 42.18** Left thoracoabdominal incision with patient in lateral position.

Thoracoabdominal Incision

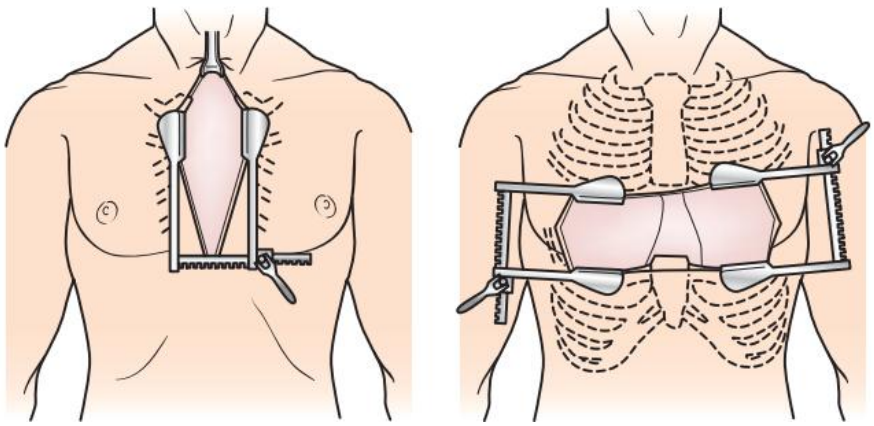
With the patient in a lateral position the thoracoabdominal incision extends from the posterior axillary line to the abdominal midline, paralleling the selected interspace (usually the seventh or eighth). After insertion of a rib spreader the incision in the intercostal muscles and pleura may be extended posteriorly from within for added exposure. The diaphragm may be divided peripherally. This incision exposes the upper abdomen, retroperitoneal area, and lower aspect of the chest (Fig. 42.18).

In closure the diaphragm is closed with interrupted sutures. The costal margin is secured by approximating the margins of the divided costal cartilages with suture. Tissue layers are closed in reverse order of incision.

A thoracoabdominal incision is used for repair of a hiatal hernia, for esophagectomy, and in general surgery for resection of retroperitoneal tumors and cardioesophageal lesions.

Median Sternotomy

The patient is supine for a median sternotomy. A vertical incision extends through the midline from the suprasternal notch to the xyphoid process (Fig. 42.19). A power reciprocating saw is used to split the sternum in primary incisions. A median sternotomy



• **Fig. 42.19** Median sternotomy for lung procedures.

incision is used for simultaneous bilateral pulmonary surgical procedures, for treatment of mediastinal neoplasms or trauma, for pulmonary embolectomy and cardiac and aortic procedures, and for access to the lower cervical and upper thoracic vertebrae. This incision may be preferred for resection of peripheral neoplasms in patients with impaired pulmonary function, particularly in the upper and middle lobes of the lungs. Reoperative procedures require the use of an oscillating saw to open the sternum.

In closure, heavy-gauge stainless steel sutures are often used to close the sternum. Alternative techniques incorporate the use of implantable titanium locking clips (e.g., Sternal Talon) for rigid fixation of the sternum. The clips and instrumentation are supplied nonsterile and must be processed in the same manner as screw and plate sets.

For the use of locking clips the patient's sternum is measured for depth and width with calipers. The clips are two-part interlocking devices (male and female ends) that are seated in the split sternum with aligning forceps and snapped together using reduction clamps to join the bone segments together. As the clip components are united, ratcheted teeth hold the two parts together. Care is taken to ensure that underlying tissue is not entrapped in the clip assembly. The surface of the united clip is marked with margins along the ratchets indicating a "safe zone," which means that the clip is correctly placed and snapped together. A small screw on the female half is turned to physically lock the clip. Three locking clips are usually used.

For emergent reentry into the sternum the screw can be turned to release the ratchets and open the closed clip. The clips can be removed after the bone has healed. Sternal locking clips are implants and should be documented in the patient's record. The locking clip components should be restocked in the set according to size. The clips are for single use only and not reprocessed after individual patient use.

Partial Sternotomy

When partial sternotomy is used the distal sternum is cut vertically to the level of the manubrium. The patient has a smaller incision and becomes ambulatory sooner postoperatively.

Parasternotomy

Parasternotomy incisions are being used more frequently for minimally invasive cardiac procedures. An incision to the left or right of the sternum, without splitting the sternum, allows for visualization of the inner thorax.

Alternative Thoracotomy Incisions

The following alternative incisions may be used:

- A transaxillary approach for lung biopsy or wedge resection, particularly in the lower lobe, for thoracic sympathectomy or exposure of the second to fifth thoracic ganglia, or for exposure for thoracic outlet syndrome. This vertical incision causes minimal injury to muscles of the chest wall and preserves muscles of the shoulder.
- A supraclavicular (scalene) approach for phrenic nerve section, cervicothoracic sympathectomy, axillary vein thrombosis, or thoracic outlet syndrome. The incision is parallel to the clavicle. The first rib may be resected.
- Cervical mediastinotomy for drainage high in the mediastinum, such as after esophageal perforation.
- Anterior approach for upper dorsal sympathectomy, exposing upper thoracic ganglia.

Lung-Assist Devices

Extracorporeal Membrane Oxygenator

An extracorporeal membrane oxygenator (ECMO) is used as a resuscitative device for adults or children who have potentially reversible respiratory and/or cardiac failure.[7] It also is commonly used to prolong extracorporeal circulation when the patient is in distress after removal from cardiopulmonary bypass. The machine is designed like a cardiopulmonary bypass machine. ECMO was developed and first used to sustain neonates in 1975 by Robert H. Bartlett, M.D. (1939–), from the University of Michigan Health System. The use of ECMO has decreased the loss of cognitive function caused by anoxic brain damage. When used in combination with intentional controlled hypothermia, ECMO offers a better chance of little or no cognitive deficit.

The patient's hemoglobin is maintained at 12 to 15 g/dL during treatment by administration of packed red blood cells. Adequate platelet volume is augmented by administration of platelets and monitoring clotting times. Renal protection is critical because while on ECMO the body begins an inflammatory response followed by a diuretic phase within 48 hours. During this period the patient's body weight increases because of retained fluids. If urine output is low, the patient is given diuretics to stimulate the renal tubules and minimize fluid retention. Some patients require adjunct hemodialysis to give the kidneys a rest period. Periodic blood cultures are done. Hyperalimentation is done to ensure nutritional status.

ECMO also can be used for a short interim period (several days) to sustain the patient's life while waiting for an organ transplant or after major trauma. Potential complications include bleeding caused by the high-dose anticoagulants required to minimize clotting.[8] The literature reports a survival rate of 44% for pediatrics and 27% for adults when used as a resuscitation measure. Activating ECMO immediately increases the chance for survival. Children in distress and arrest greater than 13 minutes before implementation of ECMO have not been successfully resuscitated.

The following are two methods of extracorporeal membrane oxygenation:

- *Venoarterial bypass:* Cannulation points include the common carotid artery and the internal jugular vein or the femoral artery and the femoral vein. Venoarterial bypass supports both the heart and lungs by removing deoxygenated venous blood via a vein, removing carbon dioxide, adding oxygen, and returning the oxygenated blood to the body via an artery. The device is used for patients of all ages. It is the method of choice for cardiopulmonary assistance in the preterm neonate because other appropriately sized assistive devices are unavailable.
- *Venovenous bypass:* The right atrium and the femoral vein are common sites for cannulation. Venovenous bypass supports pulmonary function by oxygenating venous blood and decreasing the circulating venous carbon dioxide level. The advantages are lower mechanical flow rates and decreased risk for arterial emboli. The patient receives ventilatory assistance, which supplements the oxygenation process.

Intravascular Oxygenator

A lung-assist device such as an intravascular oxygenator (IVOX) may be used temporarily to assist the adult patient with respiratory failure or acute respiratory distress syndrome (ARDS). The IVOX allows the patient's damaged lungs to heal. The device is inserted into the common femoral vein and advanced into the

vena cava. A chest x-ray is performed to verify placement. It has hundreds of thin-walled hollow fibers made of polypropylene coated with gas-permeable membranes. The gas conduit that exits from the skin has two tubes: one delivers oxygen, and the other removes carbon dioxide via diffusion.

The oxygen inlet tube is connected to a pump to produce a flow of oxygen through the lumina of the fibers into venous blood. Carbon dioxide transfers through the outflow membrane, controlled by a vacuum pump. It can provide up to 50% of the patient's gas exchange requirements by bypassing the volume of oxygen to the lungs. By decreasing the airway pressure in the lungs, damaged tissue has a better chance to heal. The IVOX requires minimal anticoagulation and can remain in place for several weeks.

IVOX is less expensive and simpler to operate than ECMO. It is useful for patients who have had lung transplantation and cannot withstand the ventilating pressures associated with oxygenation.

Thoracic Surgical Procedures

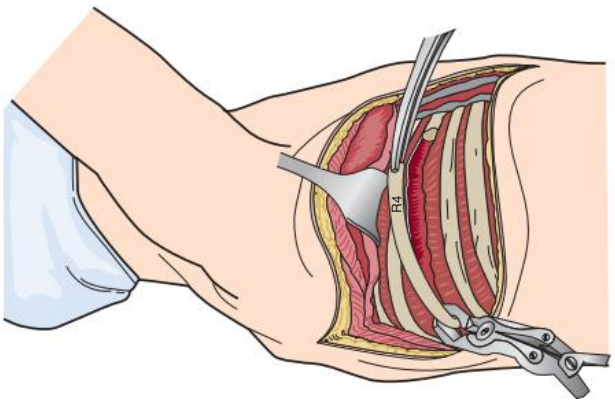
Pulmonary resection often is the procedure of choice for malignant tumors and benign diseases such as bullous emphysema and tuberculosis. A bronchopleural fistula and pulmonary fibrosis are also among concerns of the thoracic surgeon.

Rib Resection

Rib resection for donor bone procurement requires much of the same instrumentation used for open thoracotomy. A segment of rib is removed (Fig. 42.20). Reconstructive procedures of the ear, mandible, or facial structures commonly use autologous rib grafts. Equipment and supplies should be immediately available for open thoracotomy or closed chest drainage if hemothorax or pneumothorax should occur.

Mediastinotomy

Anterior mediastinotomy may be indicated when x-rays show hilar or mediastinal nodal involvement inaccessible to mediastinoscopy. With the patient supine and under general anesthesia, an incision is made over the right or left third costal cartilage. The cartilage bed is incised. Extrapleural dissection is carried toward the hilus of the lung, and a biopsy specimen is obtained. If the desired nodes are deep, a mediastinoscope may be inserted through the incision to obtain the biopsy specimen. Alternatively, the pleural space may be entered for a lung biopsy. If this space is entered, closed water-seal chest drainage is required. If it is not entered, the incision is closed in layers without drainage. Mediastinotomy allows assessment of the extent of a lesion or a deformity.



• **Fig. 42.20** Segmental rib resection.

Excision of Lesions

A median sternotomy (i.e., a vertical sternal splitting procedure) may be necessary to resect a cyst or a benign or malignant tumor in the upper anterior mediastinum. Through a posterolateral thoracotomy incision, a tumor may be resected or an abscess drained in the posterior mediastinum.

Correction of a Pectus Deformity

Congenital deformities of the chest wall are usually corrected in childhood. Pectus carinatum (pigeon chest) is forward projection of the sternum, resembling the keel of a boat. Pectus excavatum (funnel chest), which is more common, is caused by elongation of costal cartilages, which pushes the sternum back toward the spine.

Surgical correction of pectus excavatum, sometimes delayed until adolescence or adulthood, is performed to relieve respiratory distress or pressure on the heart from mechanical compression or for cosmetic improvement. Various techniques may be used.

Usually with the patient supine and the upper chest slightly hyperextended, costal cartilages are exposed by muscle splitting and/or division through an anterior midline or horizontal inframammary incision. Involved costal cartilages and deformed rib ends are freed from sternal attachments and resected or straightened. The sternum is mobilized and restored to normal position, and its corrected position is maintained by fixation. An alternative method corrects the contour deformity with a prosthesis introduced through an inframammary incision. Dacron patches on the posterior surface stabilize the prosthesis. Additional discussion of corrections for pectus deformity can be found in Chapter 8.

Thoracotomy

An incision through the thoracic wall (i.e., thoracotomy) is indicated for drainage of pleural spaces, exploration of the thoracic cavity, or cardiac and pulmonary procedures. Thoracic surgical procedures, exclusive of cardiac procedures, include exploratory thoracotomy, open thoracotomy, and open chest drainage.

Exploratory Thoracotomy

Exploratory thoracotomy is performed as an open procedure to confirm the diagnosis and extent of involvement of bronchogenic carcinoma or other chest disease, such as a mediastinal lesion, when the pathologic process cannot be confirmed by endoscopy. A biopsy specimen is obtained, most often from the lower margin of the upper lobe, for disseminated lung disease. This may be done through an anterior thoracotomy with the patient under local anesthesia.

Biopsy specimens are also usually obtained from the mediastinal lymph nodes. Through a posterolateral incision, the lungs and hemithorax are exposed after the ribs are spread and the pleura is opened. Interstitial bleeding and chest trauma are other indications for exploration.

Open thoracotomy may be used for spontaneous pneumothorax, for large air leaks that prevent re-expansion of the lung, or for persistent leaks and incomplete lung re-expansion. This type of pneumothorax usually occurs from rupture of a bleb on the lung surface. By posterolateral incision through the fourth interspace,

an apical bleb may be ligated or the involved segmental area of the lung resected. Abrasion or cauterization of the parietal pleura effects adhesion to the visceral pleura, thereby eliminating future rupture of blebs.

Open chest drainage also is used to eliminate an empyemic cavity, which accompanies chronic disease and lung adherence to the chest wall. With this procedure, portions of one or two ribs are removed to aid in the establishment of drainage.

Lung Resection

All or part of a diseased or traumatized lung may be resected (Fig. 42.21). Generally the indications are neoplasms; emphysematous blebs; and fungal infection, localized residual lung abscess, tuberculosis, and/or bronchiectasis resistant to nonsurgical treatment.[9] Neoplasms are the predominant indication. An anterior intercostal incision with division of costal cartilages above and below the incision may be used for excision of pulmonary nodules or lung biopsy.

A posterolateral incision is commonly used for **lobectomy** and pneumonectomy. Endotracheal anesthesia is used. Special precautions in pulmonary resection include meticulous hemostasis and closure of the bronchus, as well as continual attention to cardiopulmonary function preoperatively, intraoperatively, and postoperatively. Particular hazards are hemorrhage, which is difficult to control because of the size and friability of major pulmonary vessels and the proximity of the lungs to the heart; cardiopulmonary insufficiency; and the risk for injury to other intrathoracic structures, such as the vagus, phrenic, and left recurrent nerves and the esophagus. Specific resections include surgical resection, wedge resection, lobectomy, bronchoplastic reconstruction, and pneumonectomy.

Segmental Resection

Removal of individual bronchovascular segments of a lobe is preferred when wide excision is not necessary, such as for a pathologic process confined to a segment or for acute hemorrhage. The arteries, veins, and bronchus of the involved segment are ligated and divided. The segment is separated from surrounding lung tissue and removed. The proximal bronchial stump is closed with sutures or staples.

Wedge Resection

Wedge resection is a conservative procedure performed when a lesion is thought to be benign. Along with an adequate margin of normal lung tissue, the diseased peripheral portion of a lobe is removed, and the lung tissue is sutured. A stapler may expedite removal and closure. A frozen section is done. If a benign diagnosis is confirmed, the wound is closed in layers, and a chest tube is inserted for closed water-seal drainage. If the lesion proves to be malignant, lobectomy or another appropriate procedure may be done. The advantage of wedge resection is its simplicity, with minimal blood loss and procedure time.

Lobectomy

One or more lobes of a lung are excised when disease or neoplasm is confined to the lobe. The remaining portion of the lung expands to fill the space formerly occupied by the removed lobe. Through a posterolateral incision, entrance to the chest may be intercostal or by rib resection. The pulmonary pleura is incised and freed from the hilus of the lobe. The arteries and veins to the pulmonary tissue being resected are ligated and divided. The bronchus of the lobe is identified by lung inflation while the bronchus to be resected is clamped.

Suction of blood and secretions from the open bronchus may precede closure of the bronchus by sutures or staples. A suture line in the bronchus is covered with a flap of parietal pleura to prevent leakage. Dissection is completed, the specimen is removed, and the chest is closed.

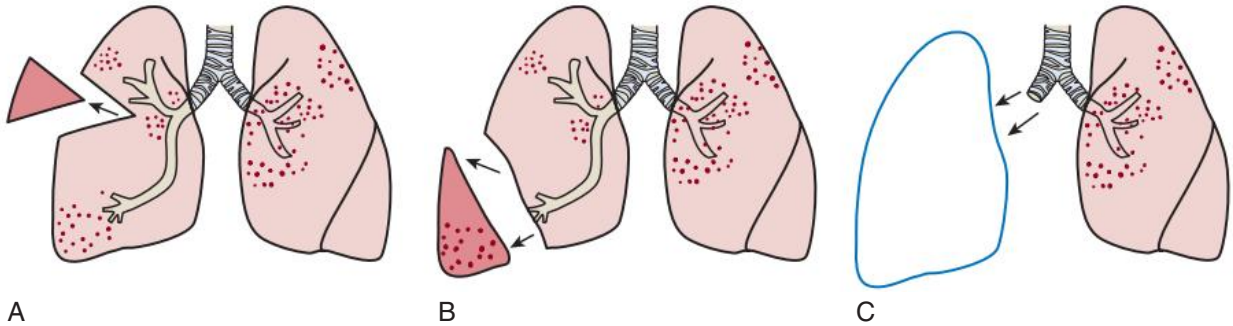
Bronchoplastic Reconstruction

Extensive partial pulmonary resection may be followed by bronchoplastic reconstruction to ensure maximum preservation of residual pulmonary tissue. These techniques require successful bronchial anastomoses to retain a patent airway to the bronchioles.

Pneumonectomy

Major indications for excision of an entire lung are malignant neoplasms and extensive unilateral pulmonary disease. The chest wall is opened by a posterolateral incision, the pleura is incised, the lung is exposed, and the pleural cavity is examined. After immobilization of the lung the hilus is dissected free on all sides. The pulmonary artery and veins are ligated and divided. The bronchus is clamped, divided, and closed with sutures or staples. The bronchus is checked for air leaks by instillation of normal saline solution, and the bronchial stump is covered with surrounding pleura. After wound closure, intrathoracic pressure is measured and residual air aspirated from the hemithorax until the desired pressure is reached. Use of chest drainage is governed by surgeon preference, but usually no chest tube is inserted.

Sacrifice of one lung places the entire responsibility for respiratory and circulatory function on the remaining lung. Potential complications are respiratory insufficiency, cardiac dysrhythmia, and a predisposition for infection because of dead space. The empty hemithorax gradually fills with fluid and



• **Fig. 42.21** Types of lung resections. **A,** Wedge resection. **B,** Lobectomy. **C,** Pneumonectomy.

eventually consolidates, thus preventing a mediastinal shift. Dehiscence of the bronchial closure may produce a bronchopleural fistula.

Lung Reduction

Lung reduction can be performed for patients who have emphysematous lung disease. In emphysema the lungs have become enlarged because the air sacs are destroyed. By reducing the size of the lungs, efficiency is improved. Minimally invasive techniques have been used with great success. Clinical trials are in process to validate the efficacy of the techniques.

Patient selection for the procedure is based on the patient's cardiac profile, pulmonary function, and exercise tolerance. Patients with severe disease of the heart or lungs and those who are older than 70 years are usually poor surgical risks for the procedure and are not surgical candidates.

Thoracoplasty

Thoracoplasty is usually done extrapleurally. The chest wall is mobilized to obliterate the pleural cavity or reduce thoracic space by resection of one or more ribs. Indications are inadequate expansion of the lung to fill the pleural space after resection, persistent shift of the mediastinum to the empty space after pneumonectomy, or chronic empyema. Tissue fibroses, contracts, and eventually obliterates the space. Thoracoplasty is reserved for patients in whom excessive space in the chest cannot be eliminated satisfactorily by other means to maintain the mediastinum in the midline.

Transplantation of Thoracic Organs

Transplantation of either a single lung or both lungs may be an option for the patient with end-stage pulmonary fibrosis, obstructive lung disease, or cystic fibrosis.

Thymectomy

The thymus gland lies on the pericardium in the anterior mediastinum from its origin in the cervical region around the trachea (Fig. 42.22). The two lobes are separated from the arch of the aorta and great vessels by a layer of fascia. In an adult the thymus has become smaller and in some cases negligible in size.

Thymectomy is usually performed through a median sternotomy, but the gland may be excised through a transcervical incision. The pericardium, the innominate vein, a portion of the superior vena cava, and a portion of the lung are removed en bloc to resect a thymoma. The phrenic nerve is spared to prevent diaphragmatic paralysis. Thymectomy without en bloc resection may be done to relieve symptoms of myasthenia gravis.

Thoracic Outlet Syndrome

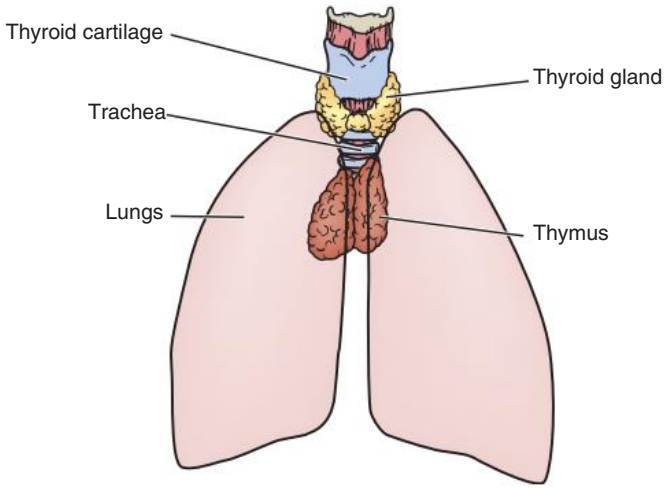
The thoracic outlet is an area bordered by the manubrium anteriorly, the first rib anterolaterally, and the first thoracic vertebra posteriorly.[10] The subclavian artery and vein, the vertebral artery, and the brachial plexus pass through this space (Fig. 42.23). After a neck injury or other postural deformity, changes can occur in the anterior and/or middle scalene muscles, causing intermittent pressure on these vessels and nerves. Symptoms include swelling, sweating, and pain and paresthesia of the upper extremities extending into the fingertips.

Diagnosis is made by having the patient raise the arms over the head and simultaneously observing for the Selmonosky triad, which is supraclavicular tenderness, pallor and paresthesia of the affected hand, and weakness of the fourth and fifth digits.[10]

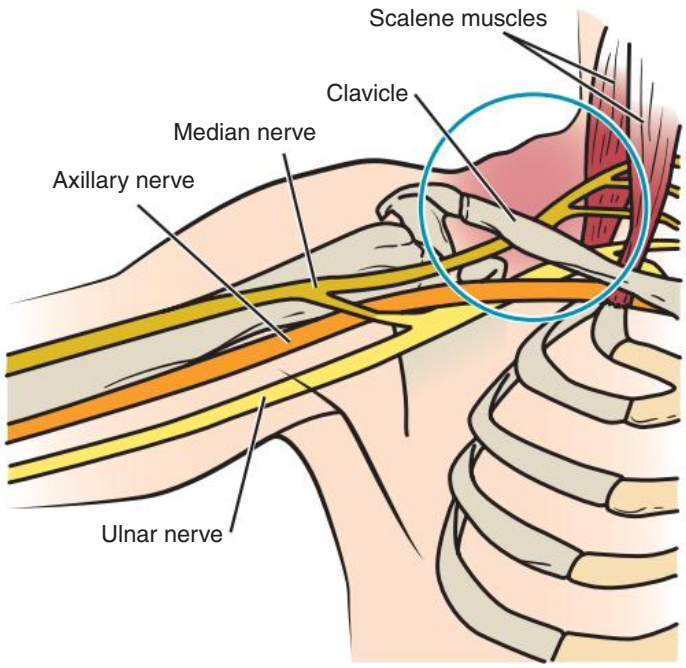
When conservative treatment fails to relieve pain, scalenectomy or scalenotomy is performed. A supraclavicular incision with resection of the first rib or a transaxillary incision is used. In extreme circumstances, bilateral resection of the first rib may be necessary.[10]

Chest Trauma

Trauma to the chest varies in severity and may result in injury to the thoracic wall or intrathoracic organs such as the heart and lungs. If the trauma is severe, the patient is plunged into a critical condition. Rapid initial evaluation of the extent of injury is necessary to preserve life, with priority needs met first. These include



• **Fig. 42.22** Thymus gland.



• **Fig. 42.23** Thoracic outlet syndrome.

resuscitation with relief of airway obstruction, treatment of shock and blood loss, and restoration of normal cardiorespiratory dynamics to the extent possible. Impairment of these dynamics may be caused by various factors such as disturbance of lung expansion or cardiac tamponade.

Trauma is categorized as blunt or penetrating. Blunt trauma usually results from a fall, blow, severe cough, blast, or deceleration injury. The patient may have little overt evidence of chest injury, even though he or she may be bleeding internally from pulmonary contusion. Penetrating wounds are usually caused by a low- or high-velocity missile, such as a knife stab or bullet. Surgical exploration may be required to control bleeding and/or air leak. Open thoracotomy may be performed in the emergency department and the patient is brought to the operating room (OR) with the chest open for further exploration of the wound and for closure.

Blunt Trauma

Fractured Ribs

Rib fracture is the most common injury to the chest wall, and the fourth to the eighth ribs are the ones mainly involved. Pain may be relieved by an intercostal nerve block. Surgical treatment is usually not required unless sharp edges or displaced bone fragments puncture the pleura or lung. Extensive pneumothorax requires immediate re-expansion of the lungs.

Multiple rib or sternal fractures often produce an unstable chest wall, resulting in flail chest. Normal respiration changes to paradoxic motion of the chest wall. The chest wall collapses on inspiration and expands on expiration. This results in ineffective respiration and coughing. As the chest wall expands, the free-floating sternum is sucked inward, thus impairing ventilation and producing hypoxia. The following measures are used to stabilize the chest wall:

1. Internal stabilization is achieved by controlled mechanical ventilation. An endotracheal tube or tracheostomy tube may be necessary to decrease pulmonary resistance and increase perfusion. Frequent suctioning maintains a clear airway; thus paradoxic motion and dead air space decrease.
2. Surgical stabilization is achieved by inserting pins or wiring fractures together. Fracture of the sternum, scapulae, and clavicles also may be involved in the injury.

Ruptured Organs

Blunt trauma can cause rupture of the diaphragm, aorta, or thoracic tracheobronchial tree, necessitating emergency thoracotomy. Contusions of the lung and pericardium may cause hemorrhage.

Penetrating Wounds

Anatomic visualization of the path of the projectile or instrument producing injury is important. A knife, for example, should not be removed except under the direction of a physician because it may be penetrating the heart or a major vessel.

Sucking Chest Wound

An open chest wound must be converted to a closed chest wound. Air rushes into an open wound, building up atmospheric positive pressure inside the pleural space. Pneumothorax followed by a mediastinal shift ensues.

Pneumothorax is relieved and further air prevented from entering the chest during respiration by suturing the wound and inserting one or more chest tubes.

Thoracentesis

Air or blood in the pleural cavity may be detected on x-ray and aspirated by a needle and syringe. A chest tube may be inserted into the pleural space percutaneously for closed thoracostomy drainage. If bleeding persists, the chest is opened and vessels are ligated or repaired.

Intrathoracic Esophageal Procedures

Esophageal disorders may be congenital, or they may be acquired by trauma or disease. Thoracic surgeons may perform esophageal resections for a benign tumor (e.g., leiomyoma) or for relief of obstruction in the thoracic esophagus (e.g., stricture, stenosis, achalasia). Esophageal myotomy with or without fundoplication may relieve obstruction in the lower segment. Resections are performed for malignant tumors.

Early detection of esophageal carcinoma increases the rate of cure by surgical resection. Unfortunately, symptoms are not usually apparent in the early stages, so carcinoma of the esophagus generally presents a poor prognosis. Most surgical procedures provide palliation rather than cure. Radical en bloc mediastinectomy may become the procedure of choice, but esophagectomy is more commonly performed.

Esophagectomy

For esophagectomy the patient is in a lateral position. A posterolateral thoracotomy or thoracoabdominal incision is extended across the chest wall to expose the affected segment of the esophagus (i.e., upper, middle, or lower third). The thoracic cavity is opened, and the mediastinal pleura is incised. The esophagus is dissected away from the aorta and transected above and below the lesion.

For combined thoracoabdominal exposure of a lesion in the lower third of the esophagus, the diaphragm is opened and the stomach mobilized for transection and intrathoracic esophagogastrostomy. In some patients, resection and anastomosis may be performed without thoracotomy by means of a substernal resection to avoid morbidity associated with thoracoabdominal exposure.

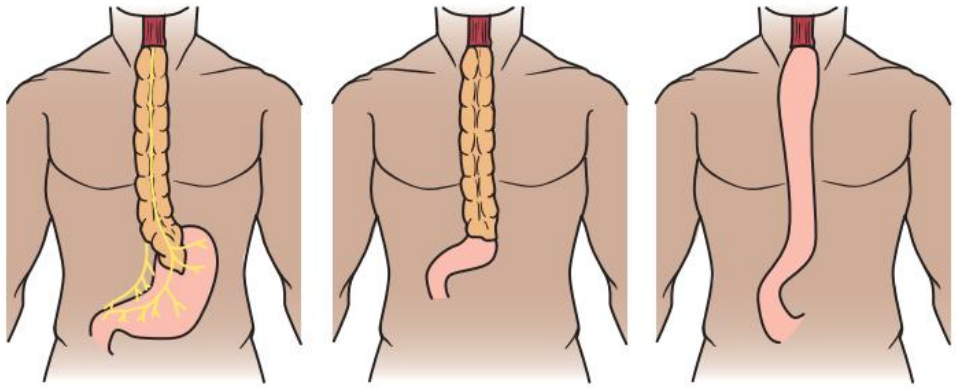
High esophageal resection followed by hypopharyngeal reconstruction may be the procedure of choice for tumors in the upper third of the esophagus. Total esophagectomy for tumors in the middle third may be carried out through abdominal and cervical incisions, without thoracotomy. The stomach is mobilized for esophagogastric anastomosis in the neck. Examples of esophageal autologous tissue replacement are depicted in Fig. 42.24.

Repair of a Hiatal Hernia

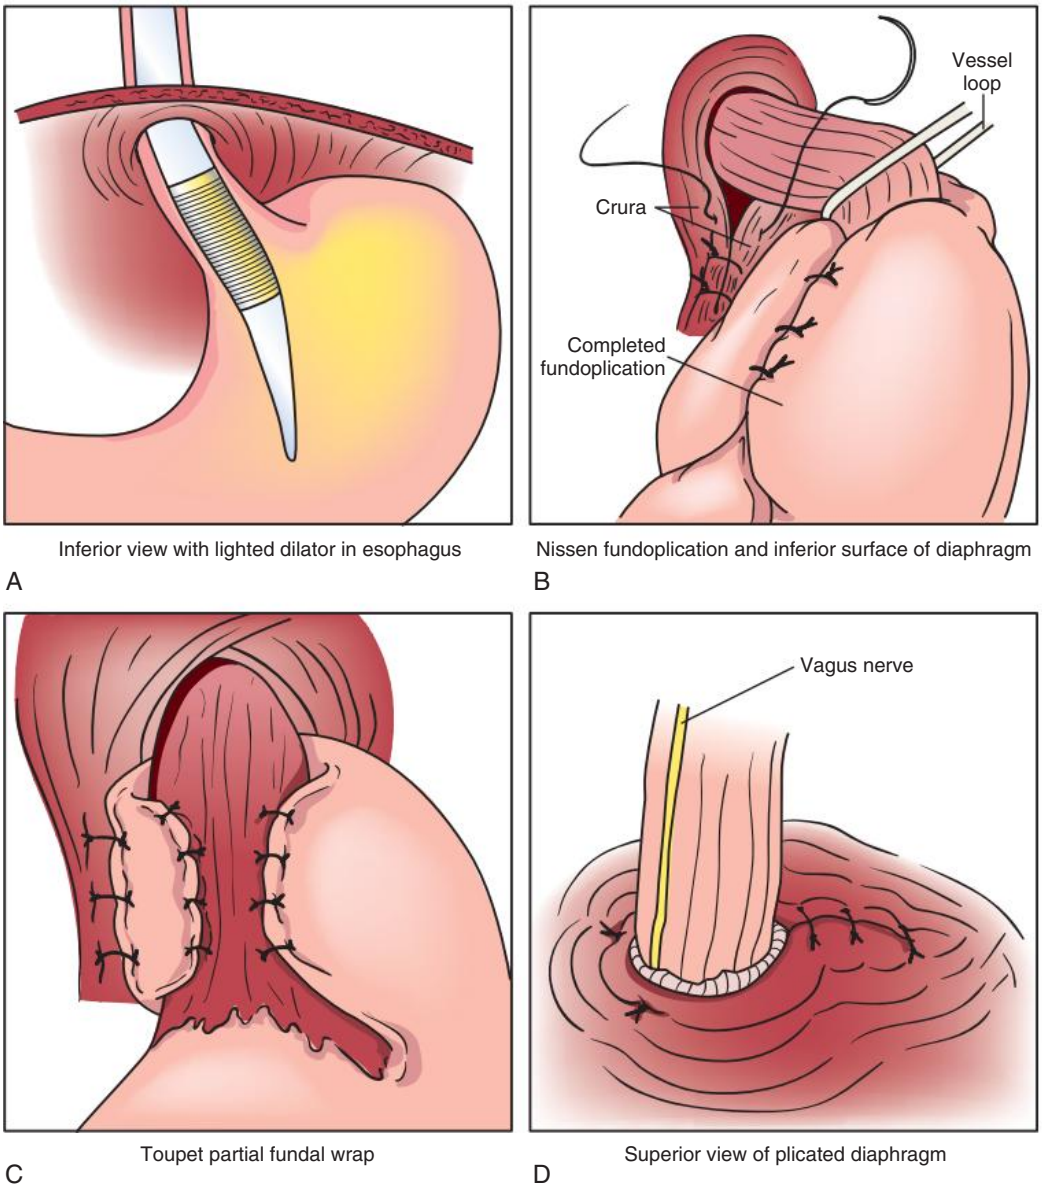
Repair of herniation of the stomach through the diaphragm may be performed by a general surgeon or by a thoracic surgeon using thoracic routines, such as chest tube insertion with closed water-seal drainage. **Plication** (stitching) the **fundus** of the stomach is part of the procedure. The surgeon will use a full fundal wrap (Nissen fundoplication) or a partial fundal wrap (Toupet) (Fig. 42.25). Some surgeons will transilluminate the esophagus with a lighted **bougie** for easier visualization of the structure during open and endoscopic hiatal hernia surgery.

The thoracic approach is preferred in the following situations:

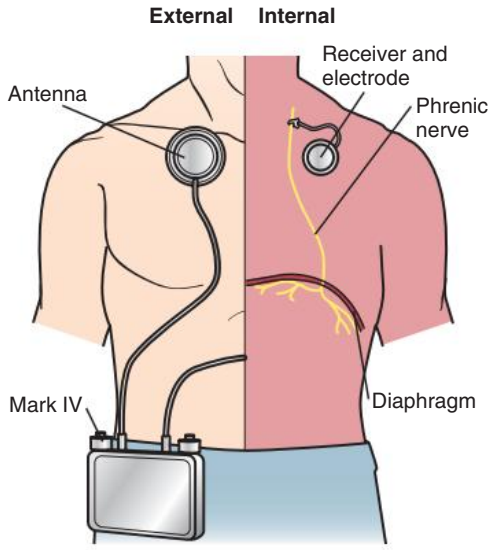
- When exposure from an abdominal approach would be difficult, as with an obese patient



• **Fig. 42.24** Three approaches to esophageal replacement after esophagectomy.



• **Fig. 42.25** Hiatal hernia repair. **A,** Inferior view with lighted dilator. **B,** Nissen fundoplication and inferior surface of diaphragm. **C,** Toupet partial fundal wrap. **D,** Superior view of plicated diaphragm.



• **Fig. 42.26** Diaphragmatic pacer for paralyzed diaphragm.

- When the hernia is incarcerated into the thoracic cavity and would be difficult to reduce through the diaphragm into the abdomen
- When the hernia is recurrent and direct visualization will facilitate the procedure
- When herniation is caused by blunt trauma or a penetrating abdominothoracic wound

Diaphragmatic Pacemaker

Injury to the phrenic nerve can cause full or partial paralysis of the diaphragm. A battery-powered pacing device can be used to stimulate nerve impulses that cause the diaphragm to contract and relax. The device is partially external and partially internal with leads (Fig. 42.26).

Complications of Thoracic Surgery

Continuous movement of the chest causes postoperative pain. The patient is likely to breathe shallowly and not adequately raise secretions that accumulate as a result of inhaled anesthetics and sedation. Obstruction in the bronchi from retained secretions can lead to pneumonia and/or atelectasis. The plan of care should include preoperative teaching of breathing techniques to assist the patient in clearing airway secretions.

Development of one pulmonary complication frequently predisposes the patient to development of another. Other potential complications are pneumothorax from an air leak, hemothorax from hemorrhage, and pleural effusion. Empyema and persistent undrained fluid or air pockets can develop in intrathoracic spaces. A bronchopleural fistula may necessitate closure. Pulmonary shunting is also a major complication.

Chylothorax, the leakage of chyle from the thoracic duct of the lymphatic system into the pleural space, is a potential complication of thoracic surgery. This complication may occur in response to trauma or neoplasm, or after a surgical procedure in the chest cavity. Surgical repair of the thoracic duct is performed.

ARDS, also known as progressive pulmonary insufficiency or shock lung, may develop in the first 24 to 48 hours after a traumatic injury, such as pulmonary contusion or from diffuse or aspiration pneumonia. Beginning with dyspnea, grunting respirations, and tachycardia, signs progress to cyanosis, hypoxemia, and alveolar infiltration. Mortality is high. An IVOX/intravenacaval blood gas exchanger may be used as a temporary booster lung for a patient with ARDS or acute respiratory failure.

Cardiac Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- Identify the pertinent anatomy of the heart and great vessels.
- List the types of conduits used for coronary artery bypass grafting.
- Describe the function of a cardiac pacemaker.

KEY TERMS AND DEFINITIONS

Ablation Intentional destruction of tissue for therapeutic purposes.
Bicaval Two places on the vena cava.
Biventricular Both ventricles are affected.
Cardioplegia Solution infused into the heart for myocardial preservation during surgery.
Cardiopulmonary bypass Oxygenation of blood during heart surgery.
Conduit Tubular passage for blood.
De-airing Venting air from the chambers of the heart.
Echocardiography Means of observing the heart through sound waves displayed on a screen by using a probe.
Euvolemic Equilibrium of fluid balance in the body.
Ostia Natural opening into the coronary arteries.
Pedunculated Attached by a vascular stalk.
Pledget A Teflon felt attached to a suture to prevent tissue tearing during stitching.
Redo Return to the operating room for additional surgery during the postoperative phase. Usually denotes an emergency such as bleeding.
Tamponade The pericardium and surrounding tissue fills with blood and fluid causing restricted heart motion. Cardiac output is diminished.

Anatomy of the Heart and Great Vessels

Cardiac procedures involve the heart and associated great vessels. To understand diagnostic procedures, hemodynamic monitoring, myocardial preservation techniques, and **cardiopulmonary bypass** (CPB) used in conjunction with cardiac surgery requires knowledge of the normal anatomy and physiology of the heart.

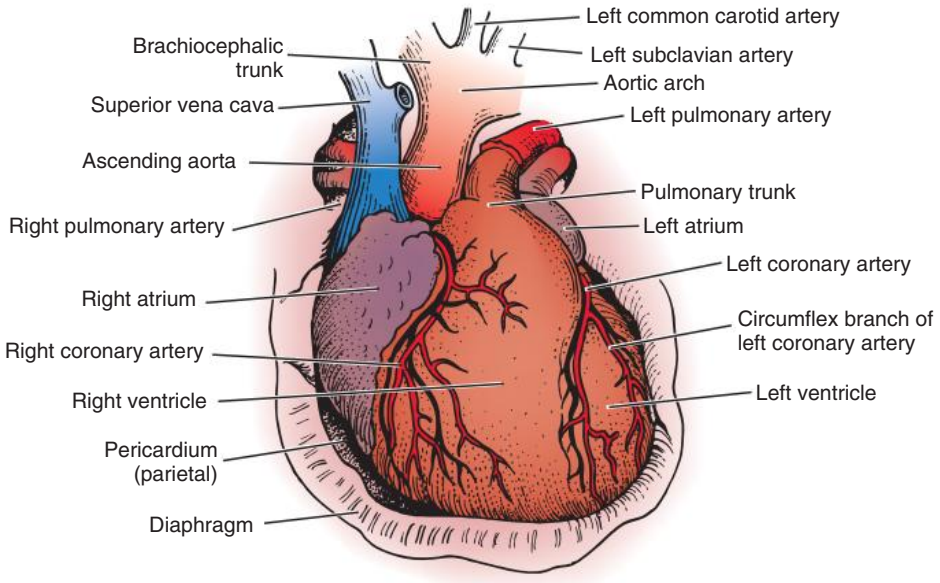
The cardiovascular system supplies oxygen and nutrients to body cells and carries waste away from cells by the flow of blood through the system. The heart, blood, and lymph vessels constitute this circulatory system. The heart—the hollow muscular organ located in the thorax—maintains the circulation of blood throughout the body.

Heart

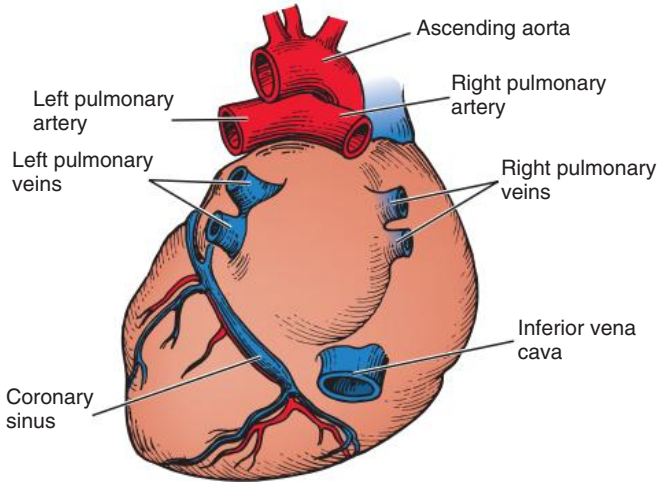
The heart is located in the middle mediastinum slightly left of midline. The heart is a four-chambered muscular "pump" enveloped by a closed, double-layered fibroserous sac—the pericardium. The outer parietal layer forms the sac that contains a small amount of clear serous fluid that lubricates the heart's moving surfaces. The base of the pericardium is attached to the diaphragm; the apex surrounds the great vessels arising from the base of the heart (Figs. 43.1 and 43.2).

The layers of the heart are the epicardium (outer visceral pericardium), myocardium (muscle fibers), and endocardium (inner membrane lining) (Fig. 43.3). Divided into right and left halves by an oblique longitudinal septum, each half of the heart has two chambers: a thin-walled upper atrium and a thick-walled lower ventricle. The right side of the heart pumps the pulmonary circulation, and the left side of the heart pumps blood into the systemic circulation. The right atrium receives desaturated blood from the inferior and superior venae cavae and the coronary veins.

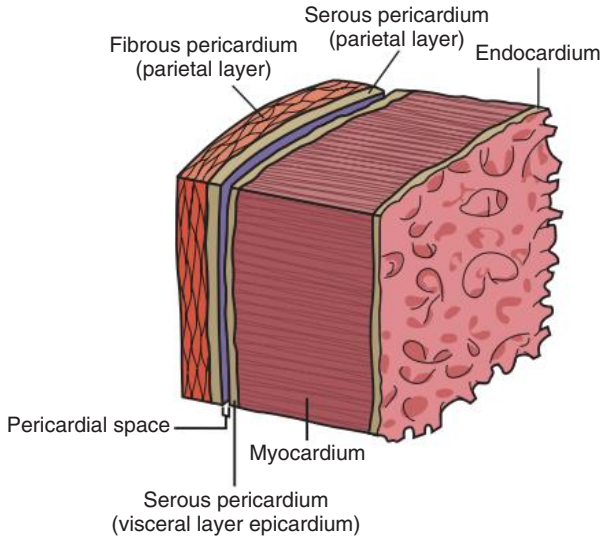
The left atrium receives oxygenated blood from the pulmonary veins. The left ventricle pumps blood into the aorta and the coronary arteries. The heart's rounded apex, formed by the left ventricle, is behind the sixth rib slightly to the left of the sternum. The base is formed by the atria and great vessels.



• **Fig. 43.1** Anterior view of the heart and great vessels.



• **Fig. 43.2** Posterior view of the heart and great vessels.



• **Fig. 43.3** Cross-section of the cardiac wall.

Valves

Four heart valves promote unobstructed unidirectional blood flow through the chambers (Fig. 43.4). These valves are of the following two types:

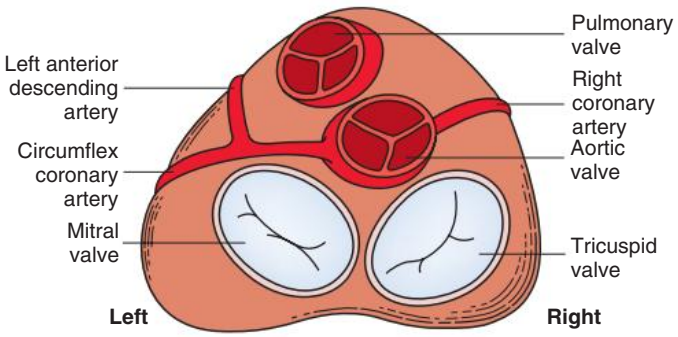
1. *Atrioventricular (AV) valves:* The bases of the cusps (the endocardial leaflets) of these valves attach to the fibrous ring that surrounds their opening between the atrium and ventricle on each side of the heart.
   a. The right tricuspid valve has three cusps and lies between the right atrium and ventricle.
   b. The left mitral valve has two cusps and lies between the left atrium and ventricle.
2. *Semilunar valves:* These valves open to allow blood to flow from the heart chambers into the great vessels.
   a. The pulmonary valve between the right ventricle and the pulmonary trunk has three cusps.
   b. The aortic valve between the left ventricle and the aorta has three cusps.

When the ventricle begins to contract, the AV cusps float up to close the opening, preventing a backflow of blood, as the semilunar valves open. Sequential heart sounds (S_1 and S_2) are heard by stethoscope as the valves open and close.

Coronary Circulation

Coronary circulation supplies oxygen directly to the heart muscle and is predominantly anatomically right or left. The coronary arteries arise from the aorta just above the aortic valve and, with their branches, supply oxygen and nutrients to the heart muscle. The coronary arteries fill during the diastolic, or relaxation, phase. The left coronary artery divides shortly after its origin into two main trunks:

1. The anterior descending or interventricular branch courses toward the apex of the heart. Its branches distribute over the anterolateral wall of the left ventricle. Septal branches supply the anterior interventricular septum.
2. The circumflex branch passes posteriorly. Following the AV groove and passing under the left atrial appendage, it meets the



• **Fig. 43.4** Cardiac valves: superior view with atria removed.

right coronary artery at the base of the junction of both ventricles.

The right coronary artery is directed to the right, passing to the posterior aspect of the heart and eventually running between the two ventricles. Its branches supply the posterior interventricular septum. The desaturated coronary blood returns to the venous circulation through the coronary sinus.

The vagus nerve (parasympathetic nervous system) and cardiac branches of the cervical and upper thoracic ganglia (sympathetic nervous system) innervate the heart.

Physiology of the Heart

Electrical Conduction System

The conduction system of the heart (Fig. 43.5) permits synchronous contraction of the atria followed by contraction of the ventricles. The right and left sides of the heart function simultaneously but independently. Muscular contractions of the atria and ventricles are controlled by an electrical impulse that originates in the sinoatrial (SA) node. This "pacemaker" is a dense network of specialized Purkinje fibers that begin at the junction of the right atrium and superior vena cava. These fibers become continuous with muscle fibers of the atrium at the node's periphery. The stimulus is passed to the smaller AV node beneath the endocardium in the interatrial septum. A mass of interwoven conductive tissue, this node's specialized fibers are continuous with atrial muscle fibers and the AV bundle of His.

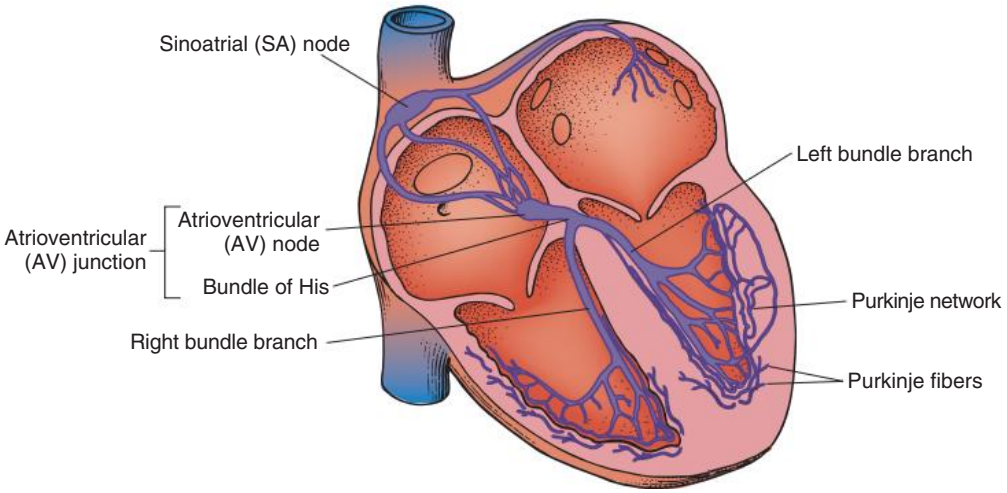
The bundle of His provides conduction relay between the atria and ventricles. Arising from the AV node, the band of conducting tissue passes on both sides of the interventricular septum, its branches dividing and subdividing to penetrate every area of ventricular muscle and to transmit contraction impulses to the ventricles. Extensions of conductive tissue provide coordinated excitation of myocardium in both atria and ventricles. Each atrial contraction (depolarization) is followed by a period of recharging (repolarization) during which the ventricles contract. Ventricular contraction is followed by a period of recovery while the chambers fill with blood as the atria contract.

Cardiac Cycle

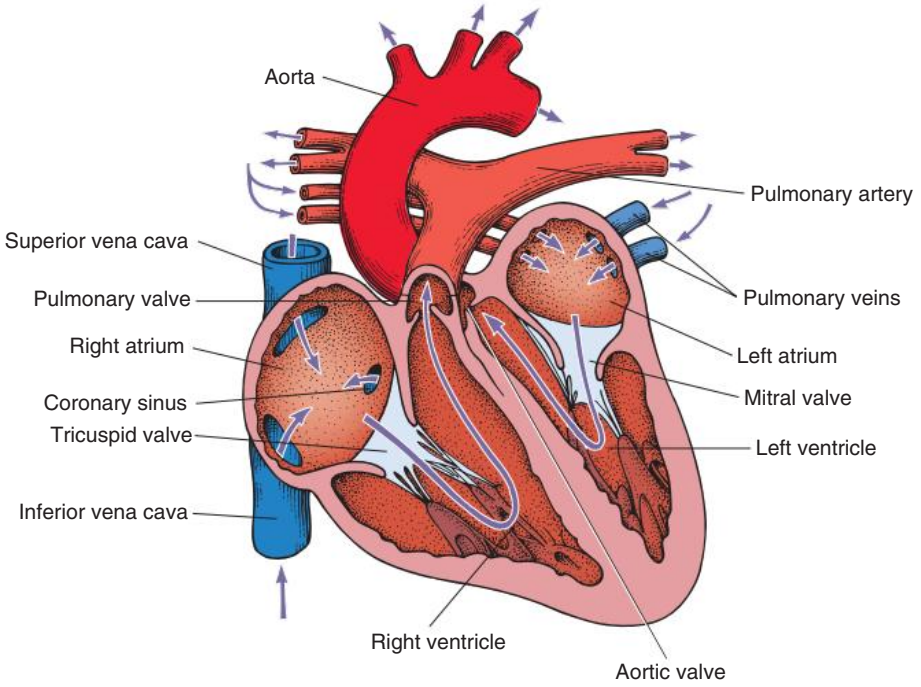
Myocardial contraction is referred to as *systole;* cardiac relaxation is referred to as *diastole.* Venous blood from the entire body enters the right atrium via the superior and inferior venae cavae and passes through the tricuspid valve to the right ventricle, from which it is ejected through the pulmonary valve into the pulmonary arterial trunk (Fig. 43.6). Right and left pulmonary arteries originating from the trunk carry the blood to the lungs, where it takes up oxygen and gives off carbon dioxide. Oxygenated blood is transported from the lungs to the left atrium by the pulmonary veins and enters the left ventricle through the mitral valve. Contraction of the left ventricle propels blood through the aortic valve into the aorta, from which it is carried to all parts of the body by arterial branches.

The highest pressure reached during left ventricular systole is the systolic blood pressure. After contraction the ventricle relaxes, during which time systemic intraarterial pressure falls to its lowest level—the diastolic blood pressure. Each contraction of the right ventricle forces blood through the pulmonary valve into the pulmonary arteries to the lungs. In summary, there are two circulations, as follows:

1. *Pulmonary:* From the right ventricle to the lungs and back to the left atrium.
2. *Systemic:* From the left ventricle to the aorta, to body tissues and organs, and back to the right atrium.



• **Fig. 43.5** Conducting system within the heart. Electrical system is composed of sinoatrial (SA) node; atrioventricular (AV) node and bundle of His at AV junction; left bundle branch; right bundle branch; and Purkinje network of Purkinje fibers.



• **Fig. 43.6** Circulation of blood through heart. *Arrows* indicate direction of flow from superior vena cava and inferior vena cava into right atrium, through tricuspid valve into right ventricle, and through pulmonary valve into pulmonary artery. Blood flows from pulmonary veins into left atrium, through mitral valve into left ventricle, and through aortic valve into aorta.

Special Features of Cardiac Surgery

Cardiovascular surgery encompasses the spectrum of clinical pathologic processes associated with congenital anomalies and acquired diseases of the circulatory system. The often-complex surgical procedures involving the heart, great vessels, and peripheral blood vessels mandate the need for experienced operating room (OR) teams with special education and training.

The goal of cardiovascular surgeons is to restore or preserve adequate cardiac output and circulation of blood to the brain and tissues throughout the body. Technologic advancements in diagnosis, anesthesia, hemodynamic monitoring, extracorporeal circulation, myocardial preservation, prosthetic devices, and transplantation have made possible the correction of many defects and the treatment of cardiovascular diseases.

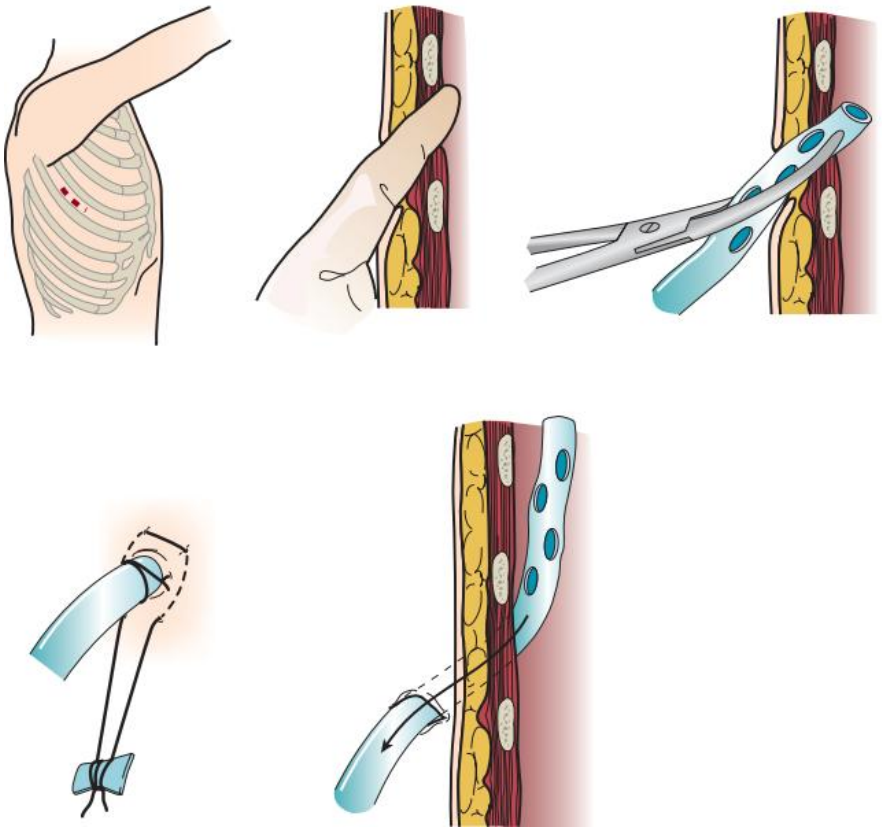
Cardiac surgery, more than any other surgical specialty, owes its success to teams of experts in chemistry, biology, immunology, biomedical engineering, and electronics, who work cooperatively with courageous surgeons and cardiologists.

Congenital malformations corrected in infancy or early childhood are discussed in Chapter 8. This chapter focuses on surgical procedures performed for acquired heart diseases in adults. The principles of general and thoracic surgery apply to cardiac surgery, but the following factors require emphasis:

- Extra minutes are not available, and seconds save lives.
- The team concept is of utmost importance. An experienced team working together can handle emergencies expeditiously.
- Comprehensive physical and psychologic preparation of the patient precedes a surgical procedure. Postoperatively the patient is taken to an intensive care unit (ICU). The patient is continuously monitored intraoperatively and postoperatively, including during transport to the ICU.

1. The OR for cardiovascular surgery should be equipped with the following:
   a. Cardiac defibrillator, pacemaker, and intraaortic counterpulsation devices.
   b. **Cardioplegia** (to induce cardiac arrest) and inotropic (to modify cardiac muscle contractility) drugs, including but not limited to the following:
      (1) Calcium channel blockers
      (2) Dopamine (Intropin)
      (3) Dobutamine (Dobutrex)
      (4) Epinephrine (Adrenalin)
      (5) Intravenous (IV) nitroglycerin
      (6) Milrinone (Primacor)
   c. Laboratory facilities for blood gas, acid-base balance determinations, potassium, glucose, and hematocrit. Modern analyzers have microprocessors to determine values.
2. The basic thoracic setup is used with the addition of cardiovascular instruments (i.e., various noncrushing vascular and anastomosis clamps, cardiotomy suction tips and sump tubes, and cardiovascular sutures).
3. Prosthetic devices are sterilized by the manufacturer. Care is taken to maintain sterility during placement in the patient. Many types of valves, patches, grafts, and catheters are available. They should be biocompatible, nonthrombogenic, and nonbiodegradable.

   Valves are made of either a bioprosthetic component or metal.[1] Bioprosthetic valves are preserved with glutaraldehyde. They are rinsed in fresh sterile saline three times to remove the preservative.[1] Some surgeons culture the valve before implantation.
4. Local and/or systemic hypothermia may be used intraoperatively to reduce the body's need for oxygen and to preserve



• **Fig. 43.7** Chest tube insertion.

myocardial function. Commercial preparations of sterile slush for local hypothermia are convenient.

5. Intraoperative autotransfusion is often used for blood volume replacement. Blood substitutes such as hetastarch, an albumin substitute for plasma expansion, may be administered. Properly crossmatched blood should be available for transfusion in the event of excessive blood loss. Platelets, stored at room temperature, may be given after CPB to enhance clotting. Often little or no blood is needed for transfusion in many procedures when CPB is used. Also, medications such as aprotinin (Trasylol) may be infused to protect platelet function during CPB.
6. Closed water-seal drainage or suction drainage is used postoperatively to drain the mediastinum and/or pleural space(s) (Fig. 43.7).
7. Many devices are available for cardiac pacing, ventricular support, and treatment of cardiogenic shock. A portable cardiopulmonary support system, external pulsatile pump, and other devices are used. It is critical that these devices be properly sterilized and handled. Read package labels and inserts for the specific manufacturer's instructions.

   The circulating nurse should affix labels and record serial numbers and identifying data in the patient's chart. In the event of a mechanical failure, this information becomes important. Lot numbers are logged according to facility policy and procedure.
8. The scrub person should set up a separate table for assembling devices. Check to be certain that all parts are available and functional. A missing component could be catastrophic.

Commonly Used Incisions for Cardiac Surgery

Several different approaches can be used for entering the chest cavity for cardiac surgery (Fig. 43.8).

Median Sternotomy

For median sternotomy the patient is supine. A median sternotomy incision is used for operations of the heart, ascending aorta, and anterior mediastinal structures, including the thymus and tumors that lie anterior to the heart.

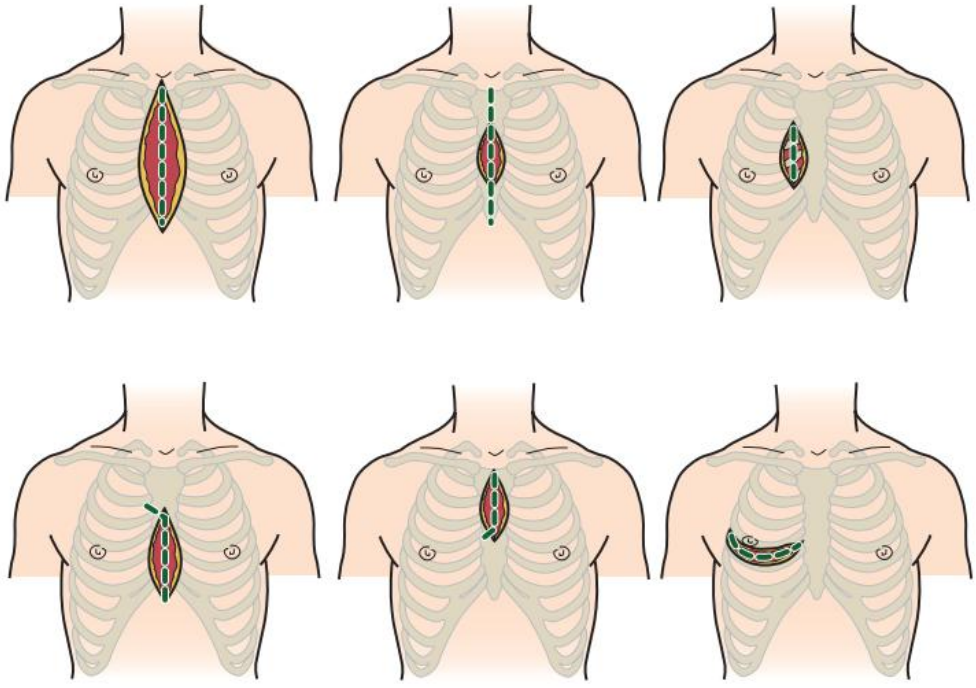
A vertical incision extends through the midline from the suprasternal notch to approximately 2 inches below the xyphoid process (Fig. 43.9). Retrosternal tissue is dissected. The bony sternum is split (divided) with a powered sternal saw. Caution is used to avoid injury to underlying mediastinal structures, especially if the chest has been opened before. The blade has a safety guard to prevent penetration into the mediastinum.

At closure, heavy-gauge stainless steel wires are placed around or through the sternum, tightly pulled together, and twisted (Fig. 43.10). The ends are buried in the sternum. Other nonabsorbable sutures may be used to provide firm fixation. The linea alba, subcutaneous tissue, and skin are sutured.

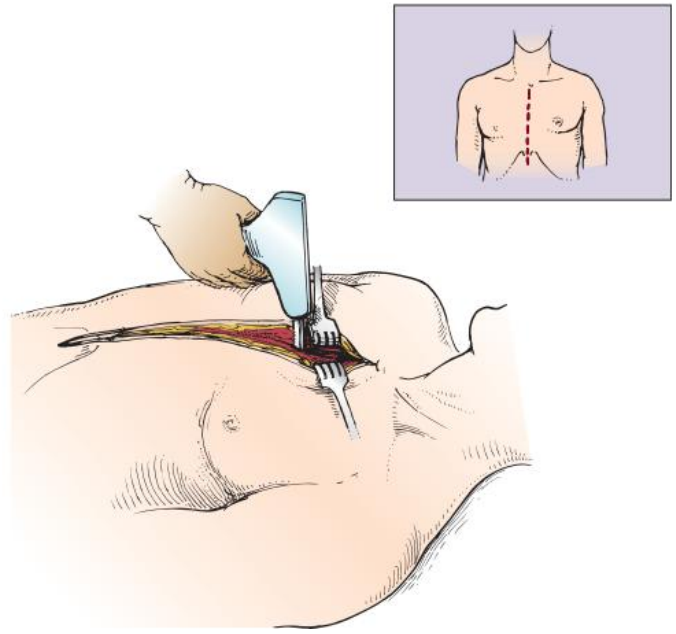
Complications are brachial plexus injury from bed-mounted retractors, costochondral separation caused by retraction, infection, nonunion, and keloid formation.

Paramedian Thoracotomy

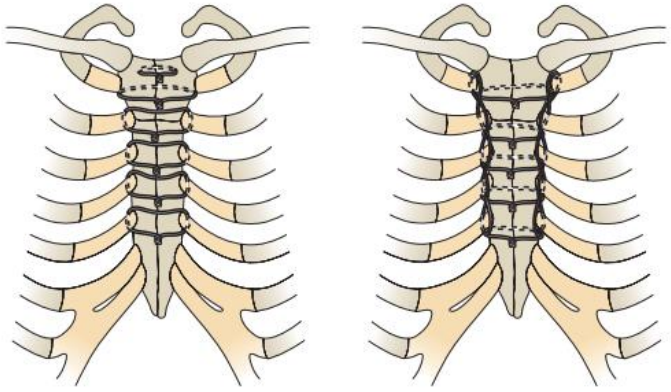
An incision is made to either the immediate left or right of the sternum for minimally invasive cardiac procedures. A paramedian



• **Fig. 43.8** Incisional approaches for cardiac surgery.



• **Fig. 43.9** Median sternotomy. (From Waldhausen JA, Pierce WS, Campbell DB, editors: *Surgery of the chest,* ed 6, St. Louis, 1996, Mosby.)



• **Fig. 43.10** Sternal closure with wire.

incision on the left side also may be used to perform a biopsy of lymph nodes that reside in the aortopulmonary window that cannot be reached with a mediastinoscope or computed tomography (CT)-guided percutaneous needle. This approach is the Chamberlain procedure.

Transsternal Bilateral Thoracotomy

A bilateral submammary incision is made with the patient supine for transsternal bilateral thoracotomy. In the midline the incision curves superiorly to cross the sternum at the fourth intercostal space level. Lateral extension is to the midaxillary line. The pleural cavity is entered via the interspace after division of the pectoralis muscles. The internal mammary arteries and veins are ligated and divided. The sternum is divided horizontally.

At closure, the sternum is reapproximated securely, the ribs are approximated with pericostal sutures, and the remaining tissue layers are closed.

This incision is referred to as a clamshell and is mostly used for bilateral lung transplants. This incision is less commonly used and causes more discomfort for the patient.

Anterolateral or Posterolateral Thoracotomy

Anterolateral or posterolateral incisions may be preferred for some cardiac procedures such as valve procedures. For some procedures involving the posterior aspect of the heart, the thoracotomy incision is made on the right side (opposite side) of the chest.

Invasive Hemodynamic Monitoring

Although placement of invasive pressure monitoring lines is not their responsibility, perioperative nurses should be aware of the implications of data and the potential for complications, such as thrombus, dysrhythmias, embolus, cardiac arrest, and postoperative infection. For assessment of tissue perfusion, invasive hemodynamic monitoring is used to determine blood pressure in major arteries, veins, and the heart chambers. Indwelling catheter lines are inserted to measure the following:

- Radial and femoral artery pressures
- Central venous pressure (CVP)
- Pulmonary artery pressure. The Swan-Ganz catheter line determines right atrial, right ventricular, and pulmonary capillary wedge pressures of left ventricular function. It is also used to determine cardiac function as it measures cardiac output, index, oxygen saturation of the central venous system, and systemic vascular resistance that, along with pulmonary artery pressures, helps determine whether a patient is hypovolemic, hypervolemic, or **euvolemic**.

Indwelling intravascular catheters are inserted preoperatively. During a surgical procedure they provide information relative to the effects of anesthetic agents, surgical manipulation of the heart, hypothermia, extracorporeal circulation, induced ischemia, and cardiac arrest. A registered nurse may draw blood samples from the pressure lines at intervals during CPB perfusion for blood gas analysis. Catheter patency is maintained with heparinized flush solutions.

The catheter is flushed with heparinized 5% dextrose in water because inadvertent overload with this solution is less dangerous than is overload with normal saline. Also, an air filter is attached to the end of the pressure tubing as a precaution against fatal air embolism. Every part of the line and filter must be flushed and free of air, or the pressure bag could force a bubble into the left atrium, causing an embolus. In the absence of mitral valve disease, left atrial pressure at the end of atrial diastole, just before the mitral valve opens, indicates left ventricular end-diastolic pressure and therefore left ventricular filling pressure and function.

Postoperatively, hemodynamic monitoring detects dysrhythmias caused by impaired myocardial perfusion, transient reduction in cardiac output with subsequent hypotension, hypovolemia secondary to hemorrhage, and **tamponade**. Circulating blood volume, pulmonary volume overload leading to pulmonary edema, and reactions to titrated vasopressor drugs also can be identified.

Intraoperative Monitoring

Noninvasive technologies are used intraoperatively to evaluate the effectiveness of some repairs and/or tissue perfusion. These technologies include the following:

- *Transesophageal echocardiography (TEE):* A transesophageal ultrasound probe is used for assessment of graft patency, myocardial perfusion, adequacy of valve replacement, or ventricular function. A Doppler color flow probe also may be useful to quantitatively assess other repairs.
- *Electrophysiologic measurements:* A computerized mapping system is used to identify the focus of dysrhythmias.
- *Near-infrared reflectance spectroscopy:* A device equipped with a sensor is attached to the patient's head. Light transmitted through the skin and skull to the brain is reflected to light detectors in the sensor. Changes in oxygen levels in the brain change light absorption. These changes may alert the anesthesia provider and surgeon to a developing oxygen deficit.

Cardiopulmonary Bypass

CPB is the technique of oxygenating and perfusing blood by means of a mechanical pump-oxygenator system. This apparatus temporarily substitutes for the function of the patient's heart and lungs during cardiac surgery. CPB is used for most intracardiac (open heart) and coronary artery procedures. Venous blood is diverted from the body to the machine for oxygenation (extracorporeal circulation) and is pumped back to the patient (Fig. 43.11).

In preparation for bypass, the patient is systemically heparinized to prevent clot formation within the CPB circuit. Two- or three-stage venous cannulas are inserted into the right atrial appendage and the inferior vena cava.

Venous and arterial cannulation for CPB can be achieved with cannulation of the femoral or subclavian artery and femoral vein. Special arterial cannulas are available for this, and a large-bore chest tube may be used for the femoral venous cannulation.

Bicaval cannulation is done by inserting venous cannulas into the inferior and superior venae cavae. A cannula for return of oxygenated blood to the systemic circulation is placed in the ascending aorta. The femoral or subclavian artery can be used as an alternative site in the presence of an ascending aneurysm, extensive adhesions, or severe calcification of the aorta. Cannulas are connected to the machine by sterile tubing before institution of bypass. During bypass, the lungs are kept deflated and immobilized.

Minimally invasive surgery has given rise to vacuum-assisted venous drainage (VAVD) for the attainment of a bloodless field. This method requires less priming medium for the machine and uses smaller cannulas. VAVD adds negative pressure of 225 to 240 mm Hg to the venous lines for faster decompression of the heart.

The perfusionist who operates the CPB machine must be familiar with its function, care, and operation. The perfusionist may be employed by the cardiac surgeon, a group practice, or the hospital.

Components of a Bypass System

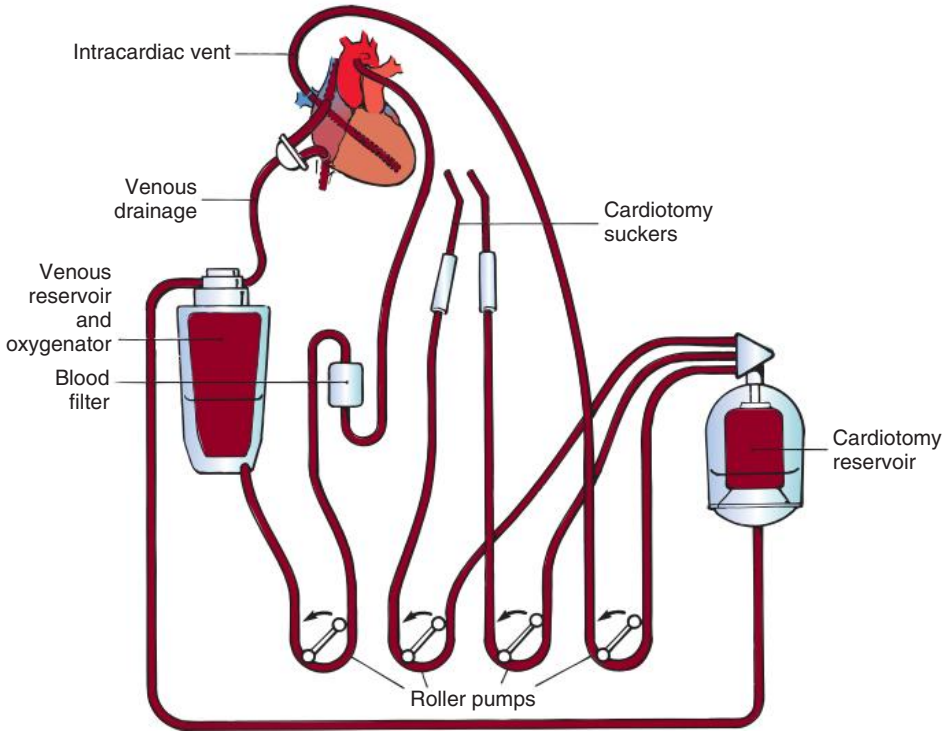
Oxygenator

Oxygen is taken up and carbon dioxide is removed from the blood. The types of oxygenators include the following:

- *Bubble:* Bubbles of oxygen are supplied to the blood by direct blood/gas contact.
- *Membrane:* Oxygen and carbon dioxide diffuse through a permeable Teflon or polyethylene membrane that contains the blood. This method diminishes blood-gas interface. Several types of disposable membrane oxygenators are available.
- *Microporous membrane:* Blood film is separated from ventilating gas by a microporous polypropylene membrane folded like an accordion and operated like a bubble oxygenator. BP in this oxygenator exceeds gas pressure at all times, thus precluding gas bubbles passing through the microporous membrane.

Heat Exchanger

Incorporated in the circuit, a heat exchanger regulates blood temperature. Water at a thermostatically controlled temperature circulates through the exchanger, which can rapidly produce, control, or correct systemic hypothermia. Hypothermia is often used in conjunction with bypass to reduce oxygen demands of tissues and protect the myocardium during arrest.



• **Fig. 43.11** Cardiopulmonary bypass circuit. (From Waldhausen JA, Pierce WS, Campbell DB, editors: *Surgery of the chest,* ed 6, St. Louis, 1996, Mosby.)

Pump

Rollers turning over sterile plastic tubing propel reheated oxygenated blood in a relatively nonpulsatile flow through a blood filter and bubble trap to the arterial cannula for recirculation through the body. The rate of flow can be varied. It is calculated according to patient weight or body surface area. Reduced flow accompanies hypothermia.

Perfusion

Immediately before the surgical procedure, the machine is primed (filled) with a combination of crystalloid and colloid solutions, a balanced electrolyte component, and a cardiopreservative solution including sodium bicarbonate and heparinized plasma volume expander. Some circuits are heparin coated by the manufacturer.

For a hemodilution technique of priming, the system is filled with fluid that will replace blood diverted to the pump-oxygenator system and is recirculated through the circuit to remove air bubbles. The priming solution should be of sufficient volume and of a suitable hematocrit level so that when mixed with the patient's blood, the resultant buffered plasma will be capable of achieving adequate perfusion and preventing myocardial acidosis. Blood is added as needed to maintain an adequate oxygen-carrying capacity and perfusion rate.

The bypass may be partial or total. In a partial bypass, only a portion of venous return is routed to the pump-oxygenator circuitry; the remaining portion follows the normal systemic circulation. In a total bypass, all venous return is diverted to the machine for total-body perfusion.

Umbilical tapes or Silastic vessel loops are placed around the venae cavae and tightened like a tourniquet to ensure complete drainage and a bloodless field when bicaval drainage is used. The heart is arrested when perfusion tubing is secure.

During perfusion, the patient is monitored intensely (i.e., arterial and venous pressures, body and blood temperatures, blood gases and electrolytes, urinary output, and oxygen consumption). General anesthesia may be maintained by an anesthetic vaporizer that adds vapor to the oxygenating mixture or by IV anesthetic.

As the procedure nears completion, the patient is rewarmed to normal body temperature. The cross-clamp is removed from the aorta, and as blood fills the heart the heartbeat is restored. Mechanical ventilation is reestablished, and the patient is gradually weaned from CPB.

After discontinuance of bypass, the cannulas are removed and purse-string sutures around insertion sites are tied. A test dose of protamine sulfate is administered. If the patient is reaction-free, the full dose is continued until the heparin is completely reversed.

CPB may also be employed in conjunction with deep hypothermia during neurosurgical procedures, in major organ transplantation, and for pulmonary embolectomy (Trendelenburg's operation). It is also used to assist in the event of ventricular failure, to treat some types of pulmonary dysfunctions, and to perfuse an isolated segment of the body for cancer chemotherapy.

De-airing

If an open chamber procedure has been performed, **de-airing** (venting all the air from inside the heart) of the left ventricle is necessary before the aortic cross-clamp is removed. De-airing is done by placing a needle through the heart muscle into the left ventricle and removing the room air. Failure to remove room air from a heart chamber places the patient at risk for air embolus and possible stroke. Care is taken to include the needle in the final surgical count.

In **redo** heart procedures, the tip of the heart may be bound to the inner aspect of the chest, preventing adequate de-airing. Carbon dioxide (CO_2) is used to remedy this situation. CO_2 is

heavier than room air and is prophylactically infused into the surgical site continuously during the procedure to minimize the need for de-airing by displacing room air in the chambers of the heart. Residual CO_2 is resorbed by the body without consequence to the patient. De-airing is still performed at the conclusion of the bypass procedure when CO_2 is used.

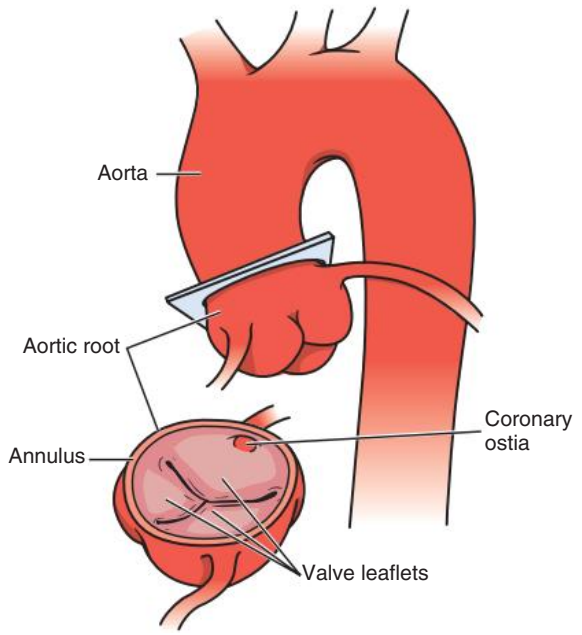
Myocardial Preservation

A bloodless, motionless field allows direct vision of the heart and its interior for repair of coronary circulation or intracardiac defects. CPB isolates the heart while the body is perfused with oxygenated blood. Cardiac arrest is purposely induced. During bypass, the perfusionist is in control of the patient's body temperature, oxygenation, and preservation of the body and brain. The surgeon assumes responsibility for preservation of the heart. Bypass time is kept to a minimum because injury from myocardial ischemia is time related.

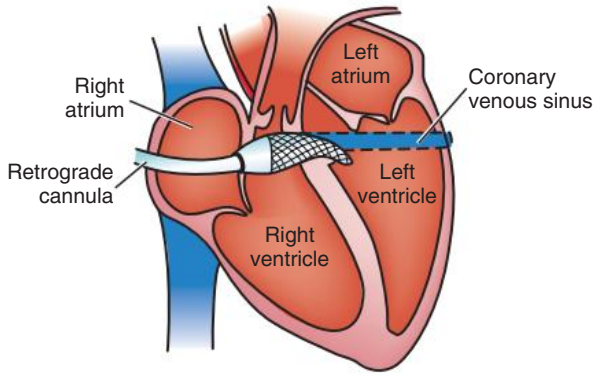
Deliberate cardiac arrest may be effected by one or a combination of the following methods:

1. *Aortic cross-clamping:* The aorta is occluded with a vascular clamp proximal to the aortic cannula to block systemic circulation. Ischemic (anoxic) cardiac arrest occurs as the blocked systemic blood within the heart becomes deoxygenated and cardiac metabolic needs are depleted. This technique can be maintained for only a limited period, because myocardial damage and necrosis will occur when the oxygen supply and energy required to maintain the subcellular system are depleted. Cerebrospinal fluid pressure may increase.
2. *Cardioplegia:* Most cardiac surgery is based on the use of cardioplegic solutions used alone or in combination with other techniques discussed. These are preparations of a small amount of potassium in crystalloid, blood, or other solution. Cardioplegia is delivered into the aortic root through the coronary **ostia** or into the coronary sinus through the right atrium.
   - *Antegrade infusion:* A catheter is placed into the coronary ostia via the ascending aorta above the aortic valve and below the aortic cross-clamp (Fig. 43.12). Cardioplegia is infused and flows into the coronary circulation. It is kept out of the left ventricle by a competent aortic valve and systemically by the aortic cross-clamp. Between 500 and 1000 mL of solution at 70 mm Hg pressure is initially used. Additional amounts are administered with each anastomosis. Severe coronary disease may cause uneven doses of cardioplegia and interfere with perfusion.
   - *Retrograde infusion:* A catheter is placed into the coronary sinus through the right atrium (Fig. 43.13). Cardioplegia is infused passively at 100 or 200 mL/min and is delivered to the myocardium by first traversing the venous system of the heart and then into the arterial system of the coronary circulation. This method is used during valve surgery and in bypass surgery when proximal lesions of the coronary arteries prohibit adequate antegrade delivery.
   - Retrograde cardioplegia does not perfuse the right ventricle or the capillary system of the left ventricle as well as antegrade methods. A better continuous flow is attained by placing a venous suction tip near the ostia.
   - When cardioplegic solution is injected into the coronary artery system, hyperkalemia immediately induces complete electromechanical cardiac arrest. The composition and temperature of the solution and infusion techniques can be determined for each patient's disease process. Some solutions have a calcium antagonist, such as verapamil or nifedipine, to help prevent myocardial ischemia. Some are infused warm; others are infused cold for less myocardial ischemia. Infusion may be continuous or intermittent. In severe proximal coronary disease it may be necessary to give antegrade and retrograde for even distribution of the solution.
   - Coronary perfusion pressure during administration of the cardioplegic solution may influence regional delivery. When the solution is flushed out of the collateral circulation at the end of the surgical procedure, the heartbeat may resume spontaneously. If not, ventricular fibrillation is treated with countershock.
3. *Hypothermia:* Hypothermia reduces systemic metabolic needs and oxygen requirements. It exerts a protective effect during CPB through a temperature-related decrease of intracellular metabolism, thus allowing tissues to tolerate a prolonged period of decreased perfusion. Hypothermia is an essential component to ischemic myocardial preservation, but because of its calcium-loading effect, cardioplegic arrest precedes initiation of hypothermia.

Local hypothermia can be induced by topical application of iced saline slush around the heart or iced lactated Ringer's solution to the heart externally and/or internally. Cardiac arrest



• **Fig. 43.12** Aortic root with coronary ostia of coronary arteries.



• **Fig. 43.13** Coronary sinus with retrograde cannula in place.

also can be induced by deliberately lowering systemic body temperature moderately to 78.8° to 89.6° F (26° to 32° C) or deeply to below 78.8° F (26° C). This is achieved by a cooling perfusate in the heart-lung machine.

Complications of Cardiopulmonary Bypass

Although excellent results are obtained with most procedures, significant derangements can occur after CPB. These are most obvious in infants or after prolonged surgical procedures in adults. Alterations in clotting may occur as a result of heparinization of blood, mechanical damage to platelets and clotting factors, and direct exposure of blood to oxygen. If trauma or transfusion reaction hemolyzes red blood cells, viscosity in renal tubules may cause tubular necrosis and renal failure.

Inadequate or extended perfusion and oxygenation may promote tissue anoxia and metabolic acidosis. Fluid and electrolyte balance merits close watching, particularly for hypervolemia. The patient must remain in a euvolemic state to prevent fluid overload. When nonblood fluids are used to prime the pump, they may diffuse into interstitial spaces. As this fluid returns to circulation postoperatively, hypervolemia may result. Furthermore, increased levels of aldosterone and antidiuretic hormone induced by the stress of surgery cause retention of sodium and water. Fluids are restricted for 24 hours postoperatively. Cerebral edema and encephalopathy at times ensue, for unknown reasons. These developments are generally temporary.

Postpump psychosis consists of visual and auditory hallucinations and paranoid delusions. This often terminates when the patient is transferred from the ICU.

The most severe pulmonary complication of extracorporeal circulation is postperfusion lung syndrome. Its cause is unknown. It is often fatal because of the development of atelectasis, pulmonary edema, and hemorrhage. Metabolic acidosis during bypass may lead to low cardiac output syndrome postoperatively. This occurs most frequently in patients with long histories of cardiac disease.

Diagnostic Procedures

Interference in any part of the circulatory system can jeopardize survival. A surgical procedure is preceded by extensive cardiovascular assessment on the basis of noninvasive and invasive studies that dictate subsequent treatment.

Noninvasive Procedures

Routine examination and electrocardiography are augmented by determination of venous pressure, cardiac output, circulation time, and blood chemistry studies. Chest x-ray reveals the heart's size, position, and outline. Screening or functional capacity testing, such as stress testing, is informative. Pulmonary function tests may detect left ventricular failure. **Echocardiography** with ultrasonic waves reveals the heart structure and gives information pertinent to congenital heart disease and valvular disease.

Invasive Procedures

X-ray visualization after injection of a nontoxic radiopaque substance permits study of the heart chambers, great vessels, and coronary circulation.

Radionuclide Imaging

Radionuclide imaging may be used to detect regional reductions in myocardial blood flow and thus help confirm or deny the diagnosis of myocardial infarction (necrosis of a portion of the myocardium caused by obstruction in a coronary artery). When a patient has "balanced disease," meaning equally blocked throughout all coronary distributions, the radionuclide uptake may be evenly distributed and be questionably interpreted as "normal." The cardiologist will compare all diagnostic findings and determine whether cardiac catheterization is the next step to definitive diagnosis despite a "normal" test.

Calcium scoring is also used to determine coronary lesions. This test measures the amount of calcium present in the coronary arteries and is graded to determine the severity of disease.

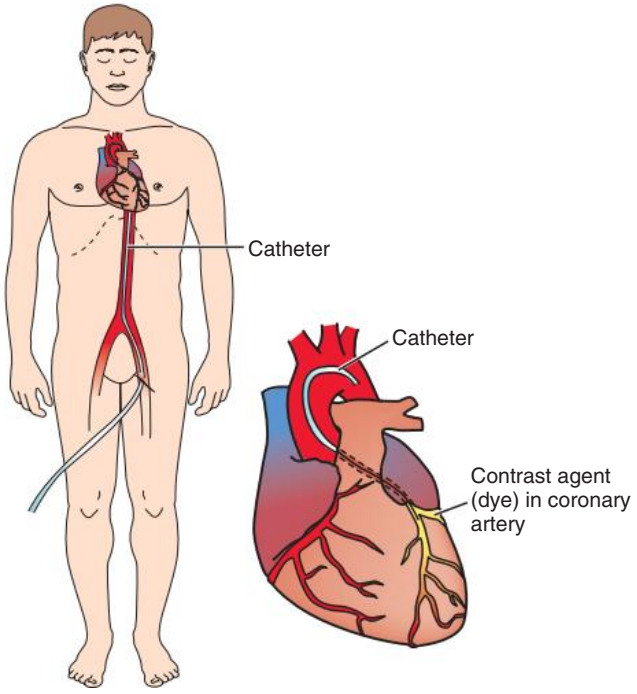
Angiography

Angiocardiography with intravascular injection of a radiopaque substance permits x-rays of the heart chambers, thoracic vessels, and coronary arteries. Rapid serial x-rays or motion pictures on an enlarged fluoroscopic screen show the heart's outline and the passage of contrast materials in the great vessels. Selective angiocardiography or coronary angiography is done in association with cardiac catheterization to evaluate coronary artery disease and determine the extent of obstructive disease in the coronary vessels. Aneurysms also may be diagnosed by angiography.

Cardiac Catheterization

Under image intensification fluoroscopy, a sterile catheter is introduced through a cutdown into a brachial vessel in the arm or percutaneously into a femoral vessel in the groin and is passed into the heart or a coronary artery (Fig. 43.14). The procedure permits the following:

- Evaluation of heart function
- Measurements of intracardiac and aortic pressure
- Visualization of the heart chambers
- Calculation of a valve area to determine stenosis



• **Fig. 43.14** Cardiac catheterization through the femoral artery with the injection contrast agent.

Catheterization is used to diagnose coronary artery disease, valvular heart disease, myocardial disease, or congenital anomalies. It is the ultimate tool for diagnosis of ischemic heart disease.

For study of the coronary arteries, a single catheter is passed and its tip is inserted into the ostia of the arteries for injection of contrast medium and tracing of solution flow. Cinefluorograms record findings. After removal of the catheter, the incision is closed and pressure dressings are applied.

For right-sided heart catheterization, a pulmonary artery catheter is inserted through the vein to obtain pressures in the right atrium and ventricle, pulmonary artery, and pulmonary artery wedge. Measurements of thermodilution, cardiac output, and oxygen saturation also may be obtained. The right internal jugular vein may be cannulated, and a bioptome (a specially designed biopsy forceps) may be advanced to obtain a right endomyocardial biopsy specimen. For left-sided heart catheterization, a catheter is inserted into an artery and advanced through the aortic valve into the left ventricle.

Physiologic monitoring with a multichannel recorder is continuous during the procedure. Potential complications include dysrhythmias, air embolus, thrombosis, and vascular and/or cardiac perforation.

Cardiac Surgical Procedures

The purposes of heart surgery are to correct acquired or congenital anatomic abnormalities, repair or replace defective heart valves, revascularize ischemic myocardium, and improve or assist ventricular function. The hours immediately before the surgical procedure can be a highly stressful period for the patient.

Mental stress can cause myocardial ischemia (inadequate blood supply to the heart) without symptoms of chest pain. Therefore the patient should be monitored from arrival in the OR suite, through induction of anesthesia, and throughout the surgical procedure. Administration of oxygen before induction of anesthesia may be indicated to help reduce stress. Procedures may be performed with or without CPB.

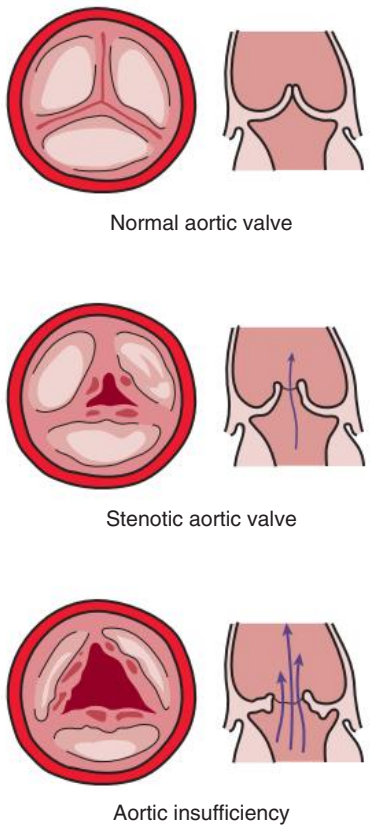
Valvular Heart Disease

Valvular heart disease may arise from a congenital abnormality or can be acquired. Abnormal vibrations or heart murmurs, referred to as S_3 or S_4, may be congenital or the end result of disease such as rheumatic fever or degenerative change.

Valves can become thickened and calcified, resulting in loss of valve substance, narrowing of the orifice, and immobility (Fig. 43.15). They then develop aortic insufficiency, fail to close completely, and permit blood leakage or regurgitation. Failure to open completely is caused by stenosis, which impedes blood flow. A defective valve is reconstructed if possible. If the valve is not repairable or if symptoms return after repair, a prosthetic valve is implanted.

Incisional approaches for valve surgery include median sternotomy, anterolateral thoracotomy, and other modifications of lateral thoracotomy. CPB is used for all valve procedures to create and maintain a bloodless field. Robotic-assisted approaches with the placement of multiple trocars can be performed for select valve replacements such as mitral valve replacement.[2] With the use of high-definition imaging, instrumentation can be maneuvered in tight spaces within a closed chest.

Cardioplegia perfusion and administration can be affected by diseased valves. A continual flow of antegrade cardioplegia is given during aortic valve surgery unless the flow obstructs vision. Cannulation of the ostia can cause ostial stenosis. For mitral valve surgery the antegrade flow is interrupted by the mitral valve retractor and requires the aortic root to be de-aired before the procedure can resume.



• **Fig. 43.15** Aortic valve disease.

Restorative Valve Procedures

Restorative and reparative valve surgery is the preferred procedure for most valve diseases. Reconstruction of the patient's own valve may restore normal valve function. Valvuloplasty and annuloplasty are valve-sparing procedures to maintain structural integrity and ventricular function. In valvuloplasty the leaflets are repaired and calcium deposits removed.

Some surgeons tuck a Raytec into the ventricle under the valve being repaired. Care is taken to account for this sponge and the particulate during the count performed at closure of the heart.

An annuloplasty ring, either flexible or nonflexible, may be used for support and to provide continuity and permanence of repair. Thromboembolism is less of a threat than it is after valve replacement; thus anticoagulant therapy is not indicated postoperatively.

Valve Replacement

A diseased mitral or aortic valve may be excised and replaced. The surgeon selects the most appropriate procedure and approach—repair versus replacement—and then the type and size of prosthesis to be used.

Several factors are used to determine repair versus replacement of the valve with a mechanical or bioprosthetic valve.[1] These include, but are not limited to, age, life expectancy, body surface area, contraindication to long-term anticoagulation, pathology of the valve, general health and lifestyle of the patient, and comorbidities.

The appropriate valve replacement prosthesis is nontoxic to the patient's system and has an effective valve area to accommodate the patient's body size. Several types of prosthetic heart valves are available.[3] They may be mechanical or biologic.

Mechanical Valves

One type of mechanical valve has discs resembling leaflets of human valves. The discs of some are tilted. The metal ring at the base of the cage may be covered with polyester fabric to facilitate suturing. It also encourages tissue ingrowth, an aid to long-term fixation.

All mechanical valves require long-term anticoagulation with warfarin (Coumadin). Tissue valves may require short-term anticoagulation for 3 to 6 months while endothelialization of the annular ring is being undertaken by the body. Some may elect platelet inhibition with aspirin and a platelet inhibitor of choice. However, all tissue valve recipients will require long-term anticoagulation in the presence of atrial dysrhythmias such as atrial fibrillation and atrial flutter.

Biologic Valves

Biologic valves are made from allograft or xenograft (porcine bioprosthesis or bovine pericardial xenograft) donor material. Cryopreserved fresh aortic valve allografts are carefully thawed before use. Glutaraldehyde storage solution is thoroughly rinsed from xenografts with sterile saline before implantation.

Mitral Valve Replacement

Most mitral valve surgery is accomplished through either a medial sternotomy or right thoracotomy. Whichever is used, the pericardium is entered and venous CPB cannulas are placed in the inferior and superior venae cavae. This keeps the surgical site free of blood from the CPB. However, during cardioplegia instillation, blood may inadvertently enter the field. Suction should remain handy.

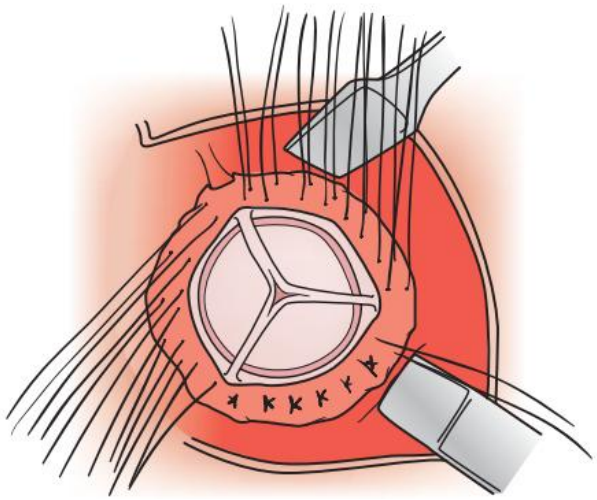
The atrium is opened and the mitral valve is exposed, inspected, and removed by the circumferential excision and severance of muscular attachments to the ventricular wall. The surgeon usually leaves the annulus, chordae tendineae, and papillary muscles intact. Once the valve has been sized by the surgeon and an appropriate valve placed on the field, interrupted nonabsorbable sutures are placed all along the annulus in alternating colors, commonly blue and white. Teflon felt **pledgets** are commonly used as a buttress under the sutures to prevent the annulus from tearing when the prosthetic valve is seated and the sutures are tied.

Once all sutures have been placed, the valve is lowered into the space formerly occupied by the diseased valve and the sutures are tied (Fig. 43.16). After inspecting the newly implanted valve and ensuring it is functioning properly, the atrium is closed while blood is allowed to fill the heart, displacing the room air. This begins the de-airing process.

Temporary pacing wires may be placed on the epicardium of the right ventricle and atrium. These are brought out through the skin and may be attached to an external pulse generator in the event bradycardia or other dysrhythmia requiring pacing is encountered during the immediate postoperative course. These are easily removed with gentle traction when deemed appropriate by the surgeon.

Aortic Valve Replacement

The surgical procedure for aortic valve replacement is basically the same as that described for mitral valve replacement except that the aortic valve is exposed through a transverse incision in the aorta. The surgical site can be kept free from blood by placing a plastic suction tube into a pulmonary vein and directed backward into the left atrium, across the mitral valve, and into the left ventricle.



• **Fig. 43.16** Suturing the annulus of the valve.

Either a mechanical valve or bioprosthesis may be used. Biologic prostheses offer the advantage of a low embolic rate and obviate the need for prolonged anticoagulation therapy. Cryopreserved fresh aortic valve allograft, from either a donor bank or commercially available allograft, may be preferred. The aortic valve may be replaced with the patient's own pulmonary valve (i.e., an autograft known as the Ross procedure).

Transcatheter Aortic Valve Replacement

Many high-risk patients with severe aortic stenosis are not candidates for traditional open heart surgery.[4] A transcatheter aortic valve replacement (TAVR) may be their only option for improving valve function. TAVR is performed under fluoroscopy, using a compressed biologic valve that is introduced via catheter into the stenotic aortic valve. Once in position, a balloon is expanded to secure and deploy the valve.[4] There are three approaches, depending on what is best for the patient.

TransFemoral

The valve is introduced via the femoral artery

TransApical

A small right thoracotomy is made, and the valve is introduced through the apex of the heart.

TransAortic

A mini-sternotomy is made, and the ascending aorta is exposed. The valve is introduced through an aortotomy in the ascending aorta.

Percutaneous Transluminal Balloon Valvuloplasty

An interventional cardiac catheterization procedure, balloon valvuloplasty may be an option to treat valvular stenosis in a high-risk patient who cannot tolerate valve replacement. A catheter with a deflated balloon is inserted under fluoroscopy across a stenosed aortic, pulmonary, tricuspid, or mitral valve. The balloon is repeatedly inflated until the valve is opened.

Coronary Artery Disease

Coronary arteries supplying the myocardium may become stenosed or obstructed, which is referred to as occlusive coronary artery disease or ischemic heart disease. Resultant myocardial ischemia may result in angina or myocardial infarction. Occlusive disease of the coronary arteries characteristically affects vessels in their proximal segments and at the origin of major branches. Significant obstructions can occur in one or all of the coronary arteries simultaneously.

The coronary circulation has four major arteries. The left main coronary artery is the shortest and gives rise to the left anterior descending (LAD) and circumflex (CX) coronary arteries. The right coronary artery (RCA) is the other major coronary artery. The RCA, LAD, and CX arteries also can have major branches arising from them. Revascularization to improve blood supply to the myocardium is possible by surgical intervention in selected patients.

Coronary Artery Bypass Graft

For coronary artery bypass grafting (CABG), single or multiple arterial bypasses are done, depending on the number of vessels affected and the degree of obstruction present. The internal mammary (thoracic) artery is the preferred vascular **conduit** in most patients. Segments of greater saphenous and lesser saphenous veins also are used to bypass coronary artery obstruction. The gastroepiploic, inferior epigastric, and radial arteries also may be used as free grafts. Because the patency rates of cryopreserved saphenous vein and umbilical vein allografts are poor, they are used when no other conduit of choice is available.

The chest is opened by median sternotomy or some other thoracotomy incision for minimal access, and the pericardium is incised. CPB may be used. Most cardiac surgeons wear loupes for magnification while constructing an anastomosis between the graft and the coronary artery. Techniques are influenced by the surgeon's preferred procedure and the extent of grafting.

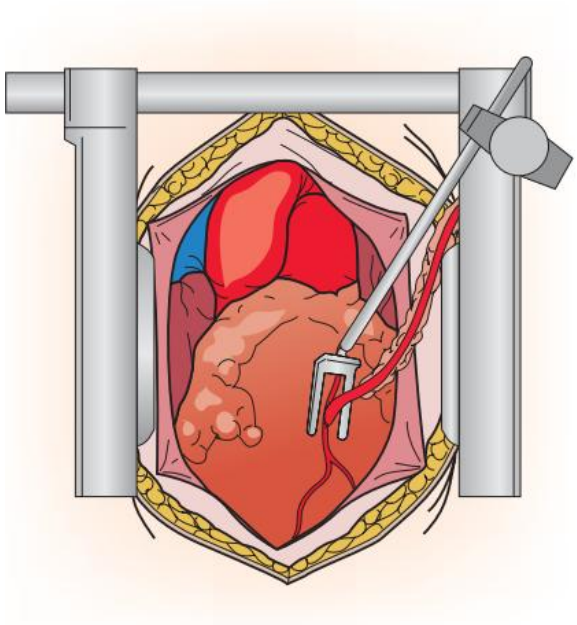
After the conduit or graft is anastomosed, CPB is discontinued (if used); all incisions are closed and checked for leaks. The pericardium may be left open. The patient is hemodynamically stabilized. The wound is closed in the usual manner for sternotomy with closed water-seal chest drainage.

Off-pump CABG procedures are becoming increasingly popular. The use of a stabilizing retractor assists the surgeon by creating a still area at the site of the distal anastomosis (Fig. 43.17). The use of a CO_2 and saline mister-blower helps keep the anastomosis site clear of blood for enhanced vision. Temporary miniature penetrating "bulldog"-style clamps can be inserted into the myocardium and used to occlude the artery by gentle, even compression.

Once the anastomosis is completed, the stabilizer and bulldogs are removed and relocated to the next vessel. The heart is closely monitored for ischemia. CPB is instituted as an emergency measure via the femoral artery and vein if the heart tissue fails to perfuse adequately during the procedure. This approach to coronary artery bypass is especially useful in patients with a calcified ascending aorta where cross-clamping would be contraindicated.

Internal Mammary Artery Conduit

The chest has right and left internal mammary arteries (IMAs). Because of the potential for a long-term patency rate, at least one IMA can be used as a conduit for myocardial revascularization when the proximal stenosis is greater than 70%. The right IMA will reach the RCA. The left IMA can be used for revascularization



• **Fig. 43.17** Stabilizing retractor for "off-pump" cardiac procedures.

of the LAD but can also reach the diagonal vessel (branch of LAD) and the circumflex. Segments of either right, left, or both IMAs also are used as free grafts to bypass other diseased coronary arteries.

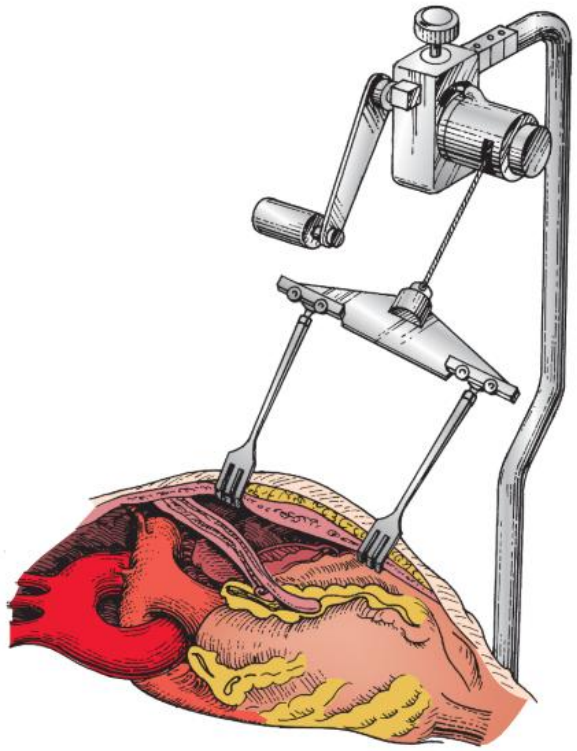
The IMA may become occluded and threadlike caused by what is termed competitive flow, when the intact artery senses an equalized flow in minimally occluded vessels. A significant proximal lesion must be present for the patient to reap the benefits of the IMA conduit. If the chest is reopened at a later date, care is taken not to transect the IMA.

The left IMA is dissected up to its origin (termed "taken down") from the subclavian artery, freeing it from the retrosternal aspect of the chest wall (Fig. 43.18). A small amount of tissue is left around the circumference of the artery. After mobilization, the pericardium is notched or opened to minimize tension and distance to the diseased coronary artery. The goal is to prevent tension on the anastomosis, which can cause stenosis or possibly occlusion. Side-to-side or end-to-side anastomosis is performed primarily between IMA and the LAD coronary artery, distal to the obstruction (Fig. 43.19).

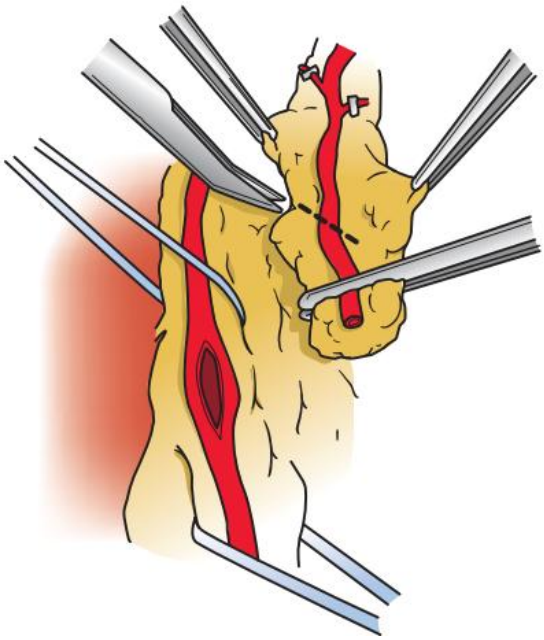
Saphenous Vein Conduit

The procedure for a saphenous vein bypass graft is expedited by two teams: one harvests the greater and lesser saphenous veins for use as conduit, and the other opens the chest and prepares for CPB. Methods for saphenous procurement include the open method (Fig. 43.20) and the endoscopic approach (Fig. 43.21). An adequate length of vein is removed to obtain sufficient graft material. The distal end of each vein segment is identified, and the graft is placed in heparinized normal saline solution after it has been harvested. It is handled gently to avoid trauma to the intima. The vein is reversed to permit a normal direction of blood flow through the venous valves into the coronary artery.

The affected coronary artery is opened distal to the obstruction; the proximal end of the saphenous vein is anastomosed end-to-side to the artery, creating the distal anastomosis, thus bypassing the obstruction. Usually a fine 6-0 or 7-0 monofilament



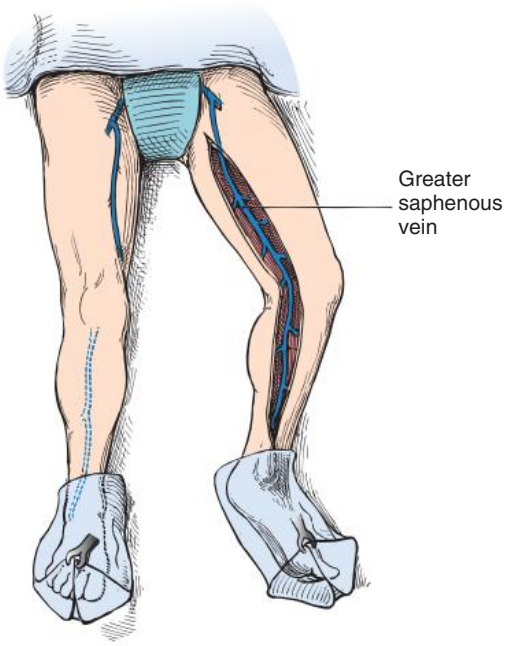
• **Fig. 43.18** Internal mammary artery procurement using mounted self-retaining retractor. (Courtesy Rultract, Inc., Cleveland, OH.)



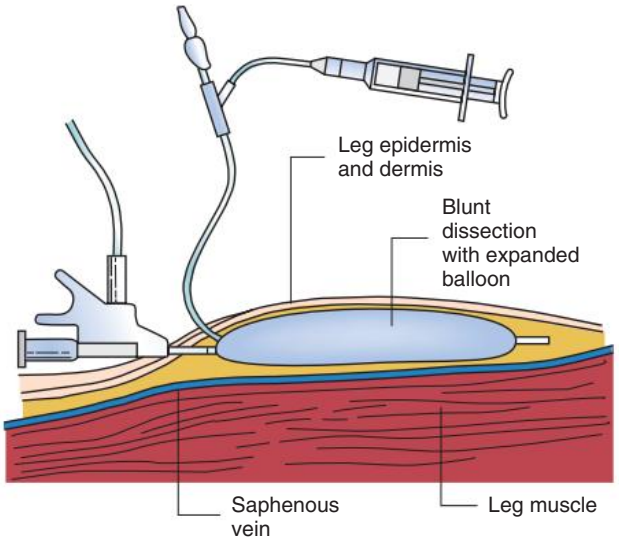
• **Fig. 43.19** End-to-side anastomosis of the internal mammary artery to a diseased coronary artery.

nonabsorbable suture is used. The proximal anastomosis is established by creating a small opening in the aorta with a punch and suturing the distal end of the vein to the aperture (Fig. 43.22).

Saphenous or other vein or artery bypass grafts are completed before the IMA is anastomosed to form a vascular conduit. Manipulation of the heart could stress the arterial anastomosis of the IMA (Fig. 43.23).



• **Fig. 43.20** Open saphenous vein procurement. (From Waldhausen JA, Pierce WS, Campbell DB, editors: *Surgery of the chest,* ed 6, St. Louis, 1996, Mosby.)

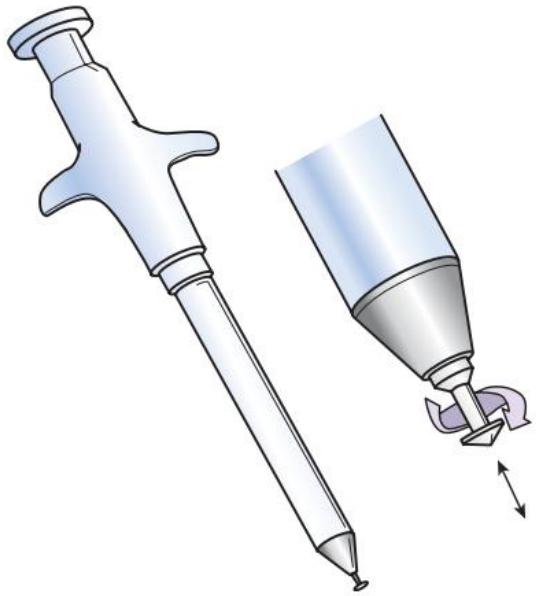


• **Fig. 43.21** Endoscopic saphenous vein procurement.

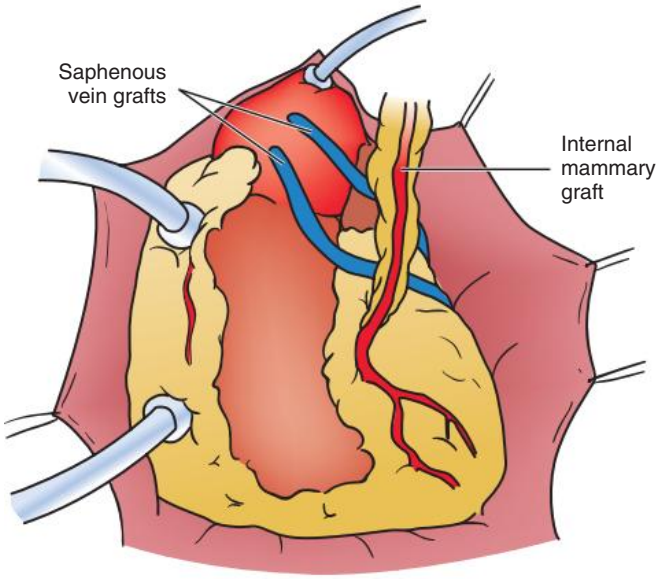
Radial Artery Conduit

An arterial conduit is preferred for most patients, because the patency rate remains higher for a longer period. The radial artery can be harvested either via a single incision or endoscopically. The radial artery arises 1 cm distal to the brachial artery and terminates at the distal aspect in the palmar artery. The harvested segment may measure between 4.7 and 9.9 inches (12 and 25 cm). The end diameters measure between 3 and 5 mm. The procured segment is usually taken from the patient's nondominant hand.

In patients undergoing bypass with radial artery conduit harvest, an Allen test or other test deemed appropriate by the surgeon must be undertaken to ensure adequate perfusion of the hand via the ulnar artery.



• **Fig. 43.22** Aortic punch.



• **Fig. 43.23** Triple conduit bypass. Two saphenous vein grafts with the left internal mammary arterial graft.

Although surgical practices vary, a calcium channel blocker is administered preoperatively to avoid vasospasm of the radial artery during procurement. This is usually continued IV through postoperative day 1, when the patient can be switched to an oral form. Many types of calcium channel blockers are available for use (verapamil [Calan], diltiazem [Cardizem], amlodipine [Norvasc]) or combination calcium channel blocker and angiotensin-converting enzyme (ACE) inhibitor medications may be used (benazepril [Lotrel]).

Coronary Artery Angioplasty

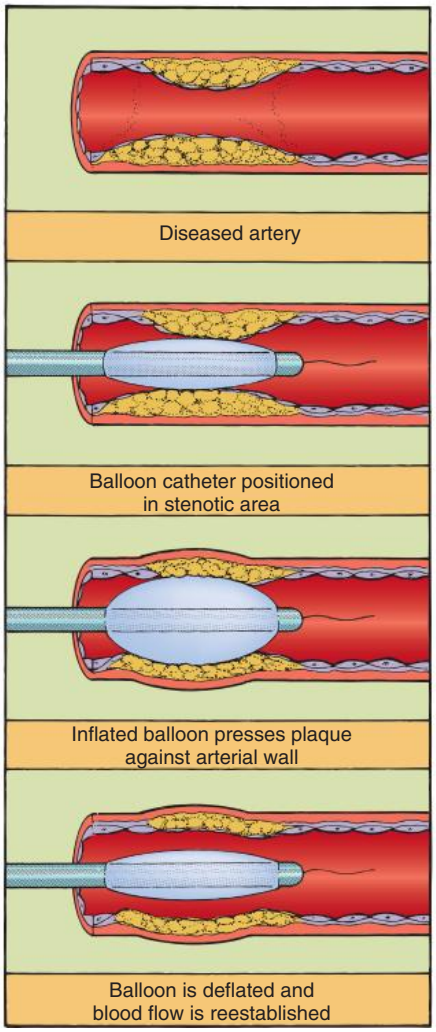
Restoration of perfusion from the left coronary system is possible by direct enlargement of the left main coronary artery lumen in select patients in whom clinical circumstances preclude bypass grafting. A curved incision is made in the lateral aortic wall. Either the posterior or anterior aspect of the left main coronary artery is incised across the stenosis. An autologous onlay pericardial or onlay saphenous vein patch is sutured between the artery and the aortic wall.

Endarterectomy (removal of an organized thrombus and attached endothelium or atherosclerotic fatty plaques from the arterial wall) may be performed in conjunction with left coronary angioplasty or right coronary artery bypass grafting (CABG). Small spatulas, wire loops, miniature abrasive drills, or ultrasonic devices may be used to remove plaque.

Coronary artery angioplasty procedures usually are performed in the cardiac catheterization laboratory (cath lab) or special interventional procedures room in the radiology department. A standby OR team should be available for emergency coronary artery bypass in the event that acute coronary artery obstruction or perforation occurs.

Percutaneous Transluminal Coronary Angioplasty

Percutaneous transluminal coronary angioplasty (PTCA) is performed under fluoroscopy with image intensification. Balloon dilation of the coronary arteries may be the procedure of choice for select patients with significant atherosclerotic narrowing in a major coronary artery (Fig. 43.24). The coronary arteries are



• **Fig. 43.24** Balloon angioplasty. (From Canobbio MM: *Cardiovascular disorders,* St. Louis, 1990, Mosby.)

approached by either percutaneous femoral artery entry or brachial artery cutdown. A balloon-tipped catheter is passed through a guiding catheter into the area of the coronary artery with atherosclerotic material (plaque). The balloon is inflated with a saline-based contrast medium using a syringe or hydraulic pump. The expanded balloon compresses the plaque against the arterial lining and dilates the arterial wall, thus enlarging the lumen.

During the time the balloon is inflated, normal flow of oxygen supplied by the artery to the myocardium is interrupted. Oxygenation distal to the balloon may be maintained with oxygenated perfluorochemical emulsion (Fluosol) flowing through the catheter.

Catheters with ultrasonic devices or tiny drill heads may be used to pulverize atherosclerotic plaque before balloon dilation. Other procedures may be performed as an alternative to or in conjunction with balloon angioplasty.

Laser Angioplasty

An argon laser probe, a neodymium:yttrium aluminum garnet (Nd:YAG) optical fiber, or a pulsed excimer laser may be used for laser angioplasty. An integrated system combines direct laser energy and fiberoptics with a balloon angioplasty catheter. The catheter positions the laser fiber, which then vaporizes the plaque or thrombus obstructing the coronary vessels.

Intracoronary Stent

A stent may be inserted to act as a buttress to keep an artery open. The coronary artery to be stented should be at least 3 mm in diameter. The stent, which is permanently implanted at the site of the stenosis, widens the arterial lumen by compressing atherosclerotic plaque against the arterial wall. The stainless steel mesh or springlike coil stent is tightly wrapped around a balloon catheter. As the balloon is inflated, the stent expands. After the balloon is deflated and removed, the stent remains in place to provide structural support and keep the artery from collapsing.

Transmyocardial Revascularization (TMR)

The myocardium can be revascularized with the creation of a series of channels in an ischemic area of the left ventricle. This procedure is performed through a left thoracotomy incision without the use of CPB. Using a CO_2 or holmium:yttrium aluminum garnet (Ho:YAG) laser, three to five channels are placed in the distal segment of the left ventricle. Hemostasis is usually established within 45 to 60 seconds. This procedure is used when other conventional therapies cannot be used.

Cardiac Dysrhythmias

Some cardiac rhythm disorders are unresponsive to drug therapy. Normally the electrical cardiac impulse begins at the SA node, thus controlling the rhythm of the heart rate. Fibers from the SA node conduct the impulse through the atria into the AV node and then transmit it along the bundle of His into the ventricles, ending in Purkinje fibers.

Occasionally some other part of the heart develops a rhythmic discharge with a rate more rapid than the SA node. This causes tachycardia (a rapid heartbeat). The impulse also may repeatedly reenter the system, most often at the AV node–bundle of His junction (AV junction), causing overstimulation of the heart.

With epicardial and endocardial mapping techniques, the surgeon is able to pinpoint electrical activity causing dysrhythmia. Preoperatively the mapping procedure is done under fluoroscopy. Electrical impulses from electrode catheters, placed in the heart via a femoral vein, activate sites in the heart to reproduce the abnormal rhythm and obtain a direct electrocardiogram. Premature cycles, the origin of electrical signals, and accessory pathways can be pinpointed.

Intraoperative mapping may be needed to correlate preoperative studies or to identify other sites or pathways masked by antidysrhythmia drugs. The origin and site of a dysrhythmia determine the surgical procedure.[5]

Atrial fibrillation (AF) is one of the most common cardiac dysrhythmias, particularly in patients 50 to 60 years of age. Following cardiac surgery, about 30% of patients will convert to this rhythm. Patients with AF are at very high risk for stroke caused by an embolus, congested heart failure, cardiomyopathy, and death.

Drug therapy commonly includes quinidine, procainamide, sotalol, amiodarone, dofetilide, propafenone, beta-blockers, calcium channel blockers, and digoxin. When medical treatments are no longer effective, surgical intervention is necessary. Most patients have left-sided initiating foci near the pulmonary veins, but any of these procedures also can be performed for atrial flutter that is caused by right-sided initiating foci. Ablative treatment near the pulmonary veins causes the risk for pulmonary vein stenosis.

Maze Procedure

The maze procedure, named for the puzzle-like pattern appearance of the incisions introduced by James Cox in 1987, is a cure for AF by interrupting the impulses that cause the dysrhythmias and preserves the contractility of the atria. The procedure requires CPB because both atria are opened and a series of small incisions are made to interrupt the electrical pathways.

The scar tissue that forms as a result of the procedure causes the interruption in the pathways. A mitral valvuloplasty is done in conjunction with the maze procedure to improve cardiac performance.

This method has significant success rates for restoring regular sinus rhythm without the use of a pacemaker. Research is being done to develop a minimal access procedure that would not require CPB using saline and epicardially applied bipolar radiofrequency energy. Patients may experience difficulty in increasing their heart rate on exertion and the potential for prolonged conduction, leading to ineffective left atrial contraction.

Maze III Procedure

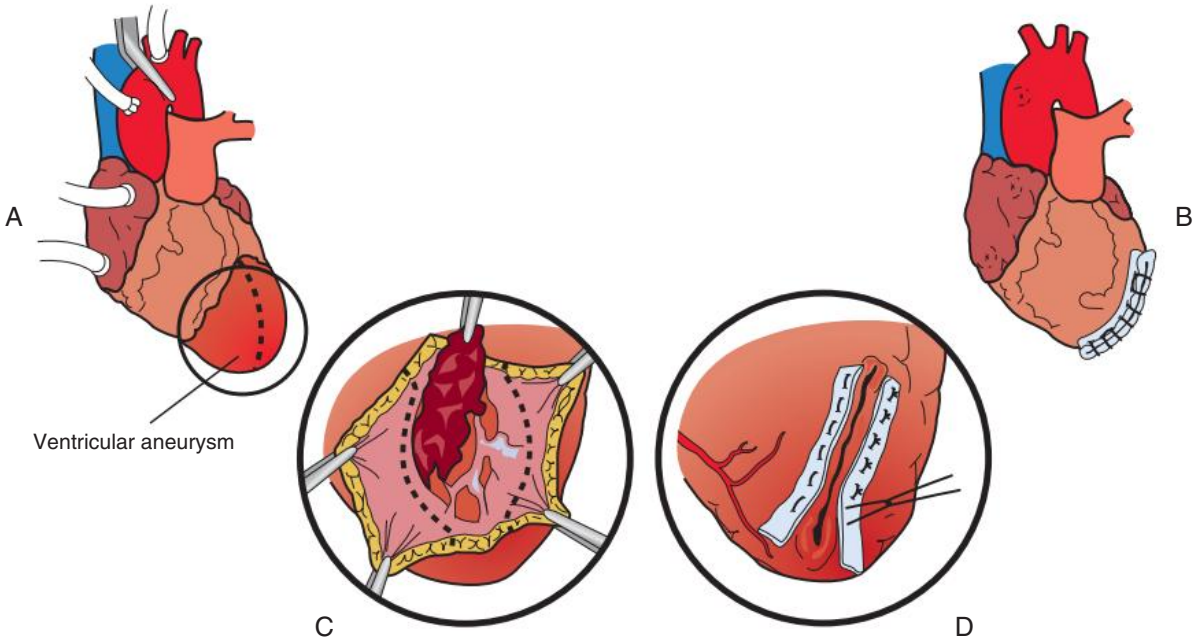
The maze III procedure incorporates similar techniques to the original maze procedure but requires the removal of both atrial appendages, isolation of the pulmonary veins, and application of cryoablation. Minimally invasive procedures are under development.

Mini Maze Procedure

The mini maze procedure uses high-radiofrequency **ablation**. It is similar to the maze III in that it requires isolation of the pulmonary veins altogether or in pairs in conjunction with ablation from the pulmonary veins to the annulus of the mitral valve. This is done without CPB and is highly successful in patients who experience intermittent atrial fibrillation and to a lesser extent in patients with chronic atrial fibrillation.

Radiofrequency Ablation

This treatment for AF involves the use of a surgical probe that creates a series of linear lesions. These lesions encircle the four pulmonary veins and left atrial appendage. The generator supplies



• **Fig. 43.25** Ventricular aneurysm repair. **A,** Aneurysmal sac is incised. **B,** Clot and excess tissue are removed. The circumscribed area is reinforced with suture. **C,** The edges of the trimmed myocardium are approximated and sutured with felt pledgeted suture bolsters. **D,** The closed myocardium is shown with felt pledgets left in place.

temperature-controlled radiofrequency. The surgeon controls the power output.

Cryoablation

This procedure is used to treat the same dysrhythmias as radiofrequency ablation but uses a refrigerant to freeze the affected area to –112° F (–80° C). The maze III procedure can be modified to incorporate cryoablation that requires less aortic clamp time and decreased chest tube drainage postoperatively. A mitral valve procedure is performed in conjunction if necessary.

Ventricular Aneurysm

Atherosclerotic coronary disease predisposes an individual to myocardial infarction. Ventricular aneurysm (a segmental dilation of the ventricular wall) may develop any time from a few weeks to years after infarction. Predominantly occurring in the left ventricular wall, the aneurysm results from ventricular force on an area of nonfunctioning scar tissue.

The thin-walled fibrous aneurysm often contains clots within it. A left ventricular aneurysm usually produces hemodynamic instability manifested by congestive heart failure and ventricular dysrhythmia. The surgeon can excise the aneurysm and reconstruct the ventricle (Fig. 43.25).

The chest is opened by median sternotomy. CPB is established before the adhesion between the aneurysm and pericardium is detached. The ascending aorta is cross-clamped. The aneurysmal sac is opened with a vertical incision, and the area is cleared of thrombus. Fibrotic myocardium is excised circumferentially. Strips of Teflon felt are used as pledgets to prevent tearing of the suture through the ventricle (Fig. 43.26). Before completion of closure, air is removed from the ventricle by suction. The heartbeat is restored, decannulation is performed, and all incisions are closed.

Aneurysmectomy may be done as a single procedure or in conjunction with cardiomyoplasty, valve replacement, coronary artery bypass, or endocardial resection.

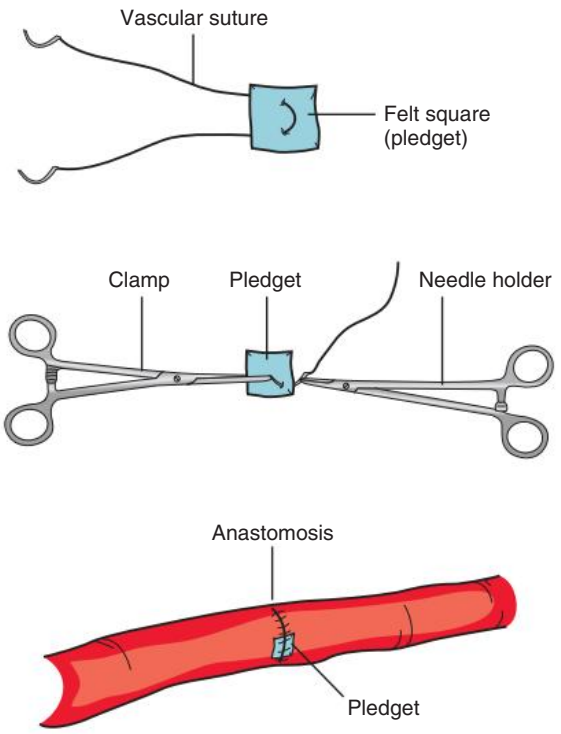
Modified Endoventricular Circular Patch Plasty (Dor Procedure)

Reconstructive surgery of the transmural anterior ventricular wall with a circular patch plasty was introduced by French surgeon Vincent Dor in 1984. This two-layer closure method uses a purse-string suture in the viable inner layer of the myocardium around a scarred aneurysm to minimize the dead area. The dead tissue is excised, and the purse-string is closed to restore the geometry of the ventricle.

Any remaining defect larger than 1.2 inch (3 cm) can be patched with Dacron. The remaining edges are closed with an interrupted mattress stitch over the outside of the patch with pledgeted nonabsorbable sutures to make it more stable. The result is a more normal left ventricular shape and size.

Septal Myectomy

Patients with hypertrophic cardiomyopathy have a thickened septal wall that impedes the outflow tract between the left ventricle and aortic valve. Surgical intervention is needed when medications are no longer effective. A median sternotomy is made, the pericardium is opened, and the heart is prepared for cannulation. After CPB is initiated and cardioplegia given, an incision is made in the ascending aorta. The septal wall can be accessed through the aortic valve. Portions of the septal wall are excised and carefully measured and weighed to confirm the amount of muscle removed. The aorta is then closed with nonabsorbable sutures. No sutures are needed within the ventricle, because the endocardium will heal on its own. In many of these cases, the mitral valve needs repair or replacement, which will be done in conjunction with the myectomy.

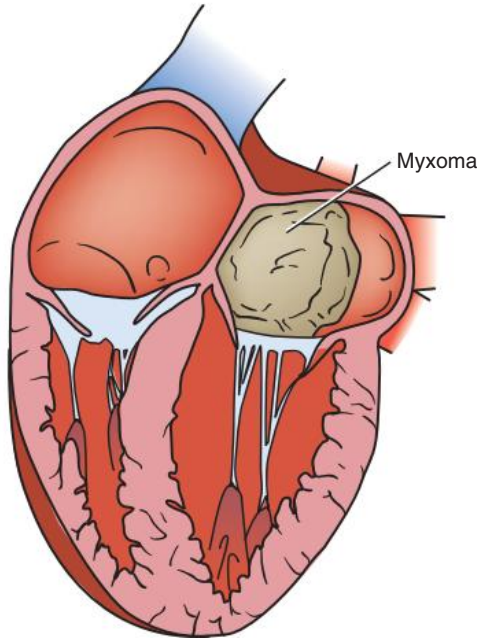


• **Fig. 43.26** Pledgeted suture preparation.

Atrial Myxoma

Atrial myxoma is a primary cardiac tumor resembling a "cluster of grapes" that usually extends from the endocardium inside the atrium via a **pedunculated** stalk (Fig. 43.27). Myxomas are benign and most commonly found in the right atrium but can occur in the left atrium as well as simultaneously in both atria. These benign lesions are dangerous because of their embolic potential and possibility of decreasing the cardiac efficiency. Portions of the myxoma can become dislodged and embolize. If an embolus enters the left atrium, it can lead to a stroke or acute arterial ischemia of a limb or organ.

A myxoma can become enlarged and prolapse into the ventricle, causing incompetence of the tricuspid or mitral valve and leading to heart failure. Removal of a myxoma requires CPB. The entire pedicle stalk must be removed to prevent regrowth.



• **Fig. 43.27** Myxoma: primary cardiac tumor.

Cardiac Transplantation

Cardiac transplantation may be an acceptable option for the patient with limited life expectancy who is incapacitated by end-stage myocardial disease secondary to the following:

- Valvular disease with cardiomyopathy
- Coronary artery disease
- Ischemic cardiomyopathy
- Postmyocardial aneurysm
- Idiopathic cardiomyopathy
- Congenital heart disease
- Cardiac tumor

Cardiac transplantation is discussed further in Chapter 45.

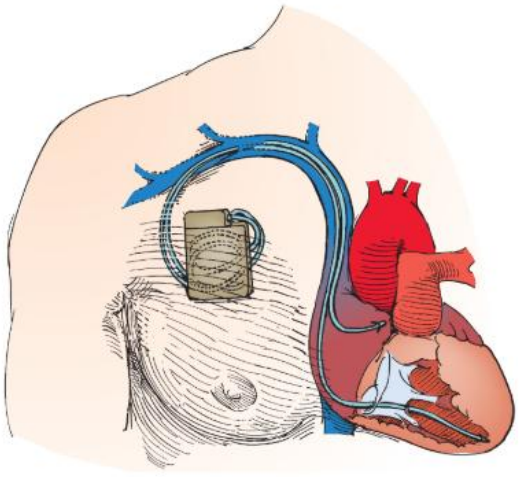
Mechanical Assist Devices

Mechanical assist devices may be indicated for patients with cardiac dysfunction. These devices may be implanted in conjunction with other cardiac surgical procedures or to provide long-term assistance for life-sustaining cardiac function.

Cardiac Pacemaker

The conducting system of the heart may be altered or interrupted at any point by degenerative disease, drugs, or surgical trauma. This may cause syncope, diminished cardiac output, hypotension, dysrhythmias, partial or complete heart block, or sinus bradycardia (sick sinus syndrome). Patients with these conditions may be treated by artificial pacing (i.e., delivery of an electrical impulse by a pacemaker) to correct atrial and ventricular dysrhythmias and interrupt chronic atrial fibrillation.

A pacemaker consists of a pulse generator, which produces electrical impulses, and leads to carry impulses to stimulating electrodes placed in contact with the heart (Fig. 43.28). A pacing system includes electromyocardial conduction.



• **Fig. 43.28** Cardiac pacemaker. (From Waldhausen JA, Pierce WS, Campbell DB, editors: *Surgery of the chest,* ed 6, St. Louis, 1996, Mosby.)

Lithium batteries supply power for 5 to 10 years to the microprocessor of the pulse generator. Platinum alloy or stainless steel electrodes, with leads encased in plastic, may be unipolar or bipolar. Components with nickel alloy can cause reactions in allergic patients. With bipolar systems, electric current flows between two electrodes during pacing; it flows between the electrode tip and the pulse generator in unipolar systems. There are three varieties of pacemakers: (1) single chamber with leads to the right ventricle, (2) dual chamber with leads to the right atrium and right ventricle, and (3) **biventricular** with leads to the right atrium, right ventricle, and the coronary sinus.

A pacemaker may be either a standby ventricular demand type or a physiologic type. Both types are intermittent and noncompetitive with the patient's own pacing system. They monitor the heart's normal activity. The impulse to stimulate the heart is not emitted unless the rate of the heartbeat falls below a preset level. Also known as the R wave–inhibited or QRS-inhibited pacemaker, electrodes of the ventricular demand pacemaker are placed in the ventricle. Stimulating electrodes are placed in the atrium or ventricle, or both, depending on the type of physiologic pacemaker to be used.

Effective external pacing for ventricular standstill led to the development of partially implanted electrode leads connected to an external stimulator for long-term pacing for other conditions. Fully implantable pacemaker systems for long-term use have been available since 1960. An implantable microprocessor generator is hermetically sealed in a metallic container impermeable to body fluids.

Selection of a system depends on the specific pacing requirements of the individual patient. Pacemakers may be temporary or permanent. Endocardial (transvenous) or epicardial (myocardial) electrode leads may be used. Most of these units are programmable to alter pacing function.

Temporary pacing is often necessary before and during permanent-system implantation. Systemic complete heart block and sinus bradycardia are the most frequent indications for permanent-system implantation. A single-chamber ventricular pacemaker may be implanted. The dual-chamber pacemaker, most commonly in the DDD mode (Table 43.1). DDD mode senses and synchronously paces both chambers and triggers or inhibits the response to vary the ventricular rate with the atrial rate. Permanent pacing may be initiated by the following devices.

Endocardial Pacemaker

A transvenous electrode lead is placed in the endocardium and attached to a pulse generator. With the patient under local anesthesia, an incision is made just beneath the clavicle or in the deltopectoral groove, preferably on the side of the chest opposite the patient's dominant hand. The subcutaneous tissue is opened to underlying fascia to create a pocket for the pulse generator.

The lead may be inserted through the cephalic, subclavian, or internal or external jugular vein. Under fluoroscopy, the endocardial electrodes (leads) are advanced via the superior vena cava into the apex of the right ventricle. The leads are attached to the endocardium by one of two ways—passive or active fixation.

In passive fixation, the pacemaking electrode tip has small flexible plastic tines that become attached to the trabeculae of the right ventricle. The endocardium will overgrow these leads, causing a firm attachment.

The electrode used during active fixation has a small threaded tip that is deployed into the endocardium by the surgeon. Atrial leads are directed into the right atrial appendage. The lead is connected to the pulse generator, which in turn is placed into a previously prepared subcutaneous pocket. The incision is primarily closed with or without suction drainage.

Epicardial Electrodes

With the patient under general anesthesia, epicardial electrodes are placed via a transthoracic approach to the myocardium. For an extrapleural parasternal approach, the pericardium is entered by subperichondrial resection of the fifth costal cartilage. Two sew-on or screw-in type of electrodes are implanted 1 cm apart in the myocardium of the right or left ventricle and/or atrium.

After the pacing thresholds are measured from an external source, electrode leads are tunneled under the costal margin to the pulse generator implanted in a subcutaneous pocket in the left upper quadrant of the abdominal wall. Water-seal chest drainage is necessary only if the pleura were entered.

Precautions with Pacemakers

A trauma or emergency patient may arrive in the OR with a pacemaker in place. A chest x-ray should be done to determine whether the leads are intact. If the manufacturer of the pacemaker is unknown, most have a marker that is visible on x-ray to provide the company name. If the function of the pacemaker is questionable,

blood work should be done and a complete medication history taken. Some cardiac drugs and electrolyte imbalance can interfere with contractility. A special magnet can be positioned over the pacer pocket to cause the device to default at 60 to 80 beats/min in a fixed synchronous pattern. If the patient goes into cardiac arrest, the defibrillator pads should not be placed over the pacemaker pocket. The pads should be positioned on the anterior and posterior chest.

Use of a monopolar electrosurgical unit (ESU) is usually avoided during placement of a pacemaker or when a surgical procedure is performed on a patient with a pacemaker. Electromagnetic interference may affect the pulse generator, depending on the type of pacemaker. If it is necessary to use a monopolar ESU, the current should be kept as far away from the pulse generator as possible. The return electrode should be placed on the thigh area, not near the chest. Bipolar ESU may be a safer alternative because the current does not pass through the patient's body to a return electrode.

A pacing system analyzer measures the amount of energy in milliamperes (mA) needed to stimulate the heart. It is used to locate the area of the myocardium where the least amount of energy will be needed (generally 0.4 to 0.8 mA) and to test functioning of the electrode and pulse generator before placement. Telemetric communication capabilities of some pacemakers allow the surgeon to obtain direct evidence of battery output.

The patient with a pacemaker requires adequate follow-up care. He or she should carry identification containing the serial number, model, rate, manufacturer's name, and date of insertion. The circulating nurse records this information in the patient's medical record, along with the time of insertion. Patients with demand or radiofrequency units should be warned to avoid proximity to electromagnetic devices, such as magnetic resonance imaging (MRI) machines, because magnetic interference will interfere with the pacemaker function.

Battery depletion is the most common indication for replacement of the pulse generator. The old generator is removed from the subcutaneous pocket. A new one is connected to the electrode and inserted into the pocket. Occasionally, electrode problems and/or erosion of or infection around the generator require surgical intervention.

Cardioverter-Defibrillator

The automatic implantable cardioverter-defibrillator (ICD) has the capability of recognizing potential life-threatening episodes of ventricular tachycardia or fibrillation. The system has a pair of sensing electrodes to monitor changes in the heart rate, cycle length, and waveform (Fig. 43.29). After the onset of ventricular tachycardia, two defibrillating electrodes deliver a synchronized shock to terminate it. The electrical conduction pattern of the heart is converted to a more normal pattern.

Newer models are capable of pacing, as well as defibrillating. Supplied sterile, the pulse generator of the device is powered by lithium batteries hermetically sealed in a titanium case. The device may be implanted in addition to endocardial resection or other ablation or instead of a surgical procedure for dysrhythmia. Placement of this device is similar to procedures described for implantation of cardiac pacemakers. If the ICD malfunctions and delivers more shocks than necessary, a magnet can be placed over the unit to stop the discharges without interrupting the pacing activity.

The wavelength of the ESU or magnetic field of MRI can deprogram the ICD and cause the device to discharge aberrant electric current into the myocardium. A specialized electromagnetic wand can be placed over the chest to deactivate the device for subsequent surgical procedures requiring the use of electrosurgery. The same electromagnetic wand can be used to reactivate and reprogram the ICD. ICDs are not affected by household appliances, such as microwave ovens, computer terminals, or television sets.

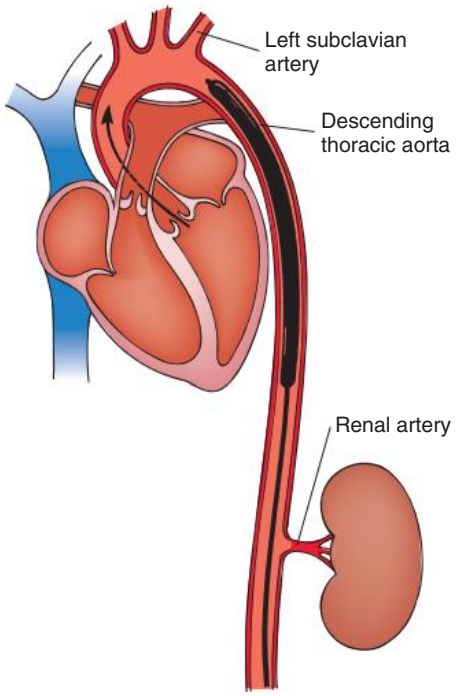
Intraaortic Balloon Pump

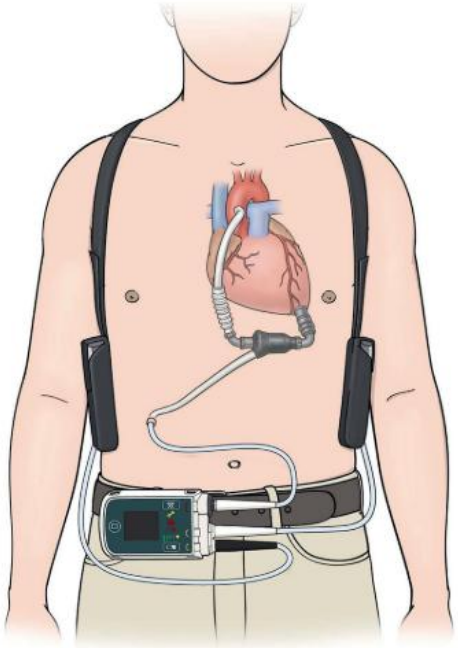
An intraaortic balloon pump (IABP) is a left ventricular supportive device used to assist a patient with prolonged myocardial ischemia, reversible left ventricular failure, or cardiogenic shock. The IABP can be inserted in the OR in conjunction with an open-heart procedure for circulatory support during weaning from CPB. Because the IABP can be inserted percutaneously via the femoral artery, it can be inserted in an interventional area such as the cardiac catheterization laboratory or the ICU when necessary. An IABP reduces left ventricular workload and increases delivery of oxygen to the myocardium, thereby increasing cardiac output and systemic perfusion. An IABP cannot be effective without partial ventricular function.

The cylindrical balloon is inserted into the descending thoracic aorta, just below the left subclavian artery, by way of a femoral artery (Fig. 43.30). The balloon catheter may be inserted percutaneously or by direct vision, or it can be inserted via a prosthetic arterial graft anastomosed end-to-side to the femoral artery. After insertion, the balloon catheter is connected to a pump console.

The IABP uses principles of counterpulsation. In contrast with systemic arteries, coronary arteries are constricted during systole and fill during diastole. Therefore inflating the balloon during diastole increases coronary perfusion, aiding contractility and oxygen transport. When the balloon is inflated, the blood volume displaced increases coronary artery pressure. When the balloon deflates during systole, the resistance against which the ventricle pumps is decreased. Balloons vary in size to provide 20, 30, or 40 mL of volume displacement, thus giving a maximum assist without total aortic occlusion. When the balloon is placed and



• **Fig. 43.30** Intraaortic balloon catheter positioned in descending thoracic aorta, above renal artery and below left subclavian artery, via femoral artery.



• **Fig. 43.31** HeartMate ventricular assist device. (Reprinted with the permission of Thoratec Corporation, Pleasanton, CA.)

the position is verified by chest x-ray, the complete system is vented of air and filled with either helium or carbon dioxide for balloon inflation, depending on the type of counterpulsator. The ratio of ventricular assist is determined by the individual patient's hemodynamic status.

The pump can be regulated automatically, triggered by an electrocardiogram signal, or operated manually. To prevent potential thrombi, pumping should be continuous. Intraaortic balloons are made of antithrombotic material. The manufacturer's instructions for use should be followed. Pumps are equipped with sensors (e.g., alarm and automatic shut-off) to minimize danger.

Weaning from the IABP is usually gradual, as tolerated by the patient. Lower extremity pulses are checked during and periodically after balloon catheter removal to assess circulation in the foot on the side of the catheter insertion and to check for the presence of clots. Complications associated with an IABP include distal extremity ischemia, compartment syndrome, thrombus or emboli, gas embolism, arterial or aortic perforation, bleeding, and infection.

Ventricular Assist Device

A powered ventricular assist device (VAD) can be used to wean patients from CPB when the IABP, drugs, and/or cardiac pacing are ineffective, to support circulation after postinfarction cardiogenic shock or traumatic myocardial contusion and provide a temporary bridge for support before transplantation (Fig. 43.31). The VAD has been a significant bridge to transplantation and is useful for cardiac support until a suitable donor is available. The mechanical device maintains systemic and myocardial perfusion while promoting metabolic and hemodynamic recovery of a reversibly damaged myocardium.

The VAD does not depend on cardiac contractility or electrical conduction. It acts as an artificial ventricle. The VAD consists of a flexible polyurethane blood sac, a flexible diaphragm, and a pump assembly enclosed within a rigid polysulfone housing. Inlet and outlet valves maintain unidirectional blood flow. The VAD is attached to the patient via inflow and outflow cannulas. Support can be to the left, right, or both ventricles:

- *Left ventricular assistance (LVA):* Blood is withdrawn from the left atrium into a left ventricular assist device (LVAD) and returned to the ascending aorta.[6] The polyurethane inflow cannula can be inserted into either the left atrium or the left ventricle. The outflow cannula has a segment of woven polyester that is anastomosed end-to-side to the thoracic aorta.
- *Right ventricular assistance (RVA):* Blood is withdrawn from the right atrium into the right ventricular assist device (RVAD) and is returned to the pulmonary artery. The inflow cannula is placed in the right atrium. The outflow cannula is anastomosed end-to-side to the main pulmonary artery.
- *Biventricular assistance (BVA):* Both an LVAD and an RVAD can be used to support both ventricles simultaneously. The cannulas exit the pericardial sac below the costal margin. They are connected to parts of the VAD after removal of all air. Depending on the intended duration of support, the housing is exteriorized or implanted.
- *Extracorporeal VAD:* The extracorporeal VAD is used for short-term ventricular assistance and is externally powered pneumatically with compressed air or electrically with centrifugal force. The housing rests on the patient's chest, with the inflow and outflow cannulas passing through the chest wall. The power source is attached to the air-inlet port or pump head. The skin is approximated, or the chest is left open and covered with sterile material sutured to the wound edges. Then the chest is covered with a sterile occlusive dressing. The patient returns to the OR for removal of the device and chest closure or heart transplantation, usually within 10 days.

- *Implantable VAD:* The implantable VAD is for long-term use and is an electrically activated pump implanted in the left upper quadrant of the abdomen. The internal battery pack and control unit in the housing are connected to an external battery pack. The cannulas pass through the diaphragm.

The rate of pumping and movement of the diaphragm inside the VAD are programmed by the power console. Another type of LVAD is mounted on a catheter connected to a pump and external motor. The catheter, inserted via the femoral artery or by transthoracic or retroperitoneal approach, draws blood out of the left ventricle and returns it to the descending aorta.[6]

Extracorporeal Membrane Oxygenator

An extracorporeal membrane oxygenator (ECMO) is used as a resuscitative device for patients who have potentially reversible respiratory and/or cardiac failure. It is also commonly used to prolong extracorporeal circulation when the patient is in distress after removal from CPB.

Artificial Heart

Clinical trials are in process to test an artificial heart that can be permanently implanted to maintain circulation in the patient with irreparable myocardial damage or end-stage cardiac disease who does not meet the criteria for cardiac transplantation. A total artificial heart also could be used as temporary support while the patient is awaiting a transplant.

Artificial Heart History

In 1982, William DeVries implanted the first total artificial heart into patient Barney Clark, who lived for 112 days with the device. In 1984, DeVries implanted an artificial heart into a second patient, William Schroeder, who lived 620 days. The Jarvik-7 was an air-driven, double-chambered device that replaced the ventricles. Connector cuffs were sutured to the atria, pulmonary artery, and aorta. These cuffs attached to rims of openings on the device. Power was supplied to the pumping chamber through percutaneous tubes to an external source of compressed air. The patient was essentially tethered to a machine. Many complications, such as emboli, hemorrhage, and infection, were associated with the device.

Recent Advances in Artificial Heart Technology

The German Heart Institute Berlin developed a pediatric bridge to transplant approved by the U.S. Food and Drug Administration (FDA) in 2011. The Berlin Heart EXCOR works with the patient's failing heart by supporting the right and/or left side of the heart. The device is powered by an air pump that is not implanted in the child's body but is connected to cannulas in the heart. The sizes range from 10 to 60-mL capacity. The pulsatile chambers are maintained outside the body, where they can be continually assessed for blood quality and the presence of clots. EXCOR is contraindicated in babies who either cannot receive anticoagulants or must be examined by MRI. More information can be found at www.berlinheart.com.

Abiomed developed the AbioCor, a fully implantable artificial heart that has been granted permission by the FDA for use in clinical trials on humans since 2001. It is a softball-size self-contained unit with internal rechargeable batteries that can run independently for 30 minutes at a time. The implantable component of the device weighs around 2 lbs and is made of titanium and plastic. There are no external wires; however, an external power pack passes energy through the skin to an internal coil. The external power pack weighs 4 lbs and is recharged every 4 hours.

The AbioCor is able to provide complete circulatory support with normal tissue perfusion and no hemolysis, according to current studies. Criteria for use of the AbioCor include biventricular failure without viable treatment alternatives and imminent death within 30 days. The patient's diseased heart is removed with the exception of small atrial attachments.

The first patient to receive the AbioCor implant was Robert Tools, age 59. The implantation was performed in July 2001 at Jewish Hospital in Louisville, Kentucky, by Laman Gray Jr. and Robert Dowling. Mr. Tools lived for 5 months with the device. The second recipient, Tom Christerson, age 71, had the device implanted in September 2001 at the same facility and lived for 512 days with the device. He lived at home and had the opportunity to celebrate his 55th wedding anniversary and the birth of his first great-grandchild. Additional patients have had the device implanted at several heart centers in the United States since, with some success.

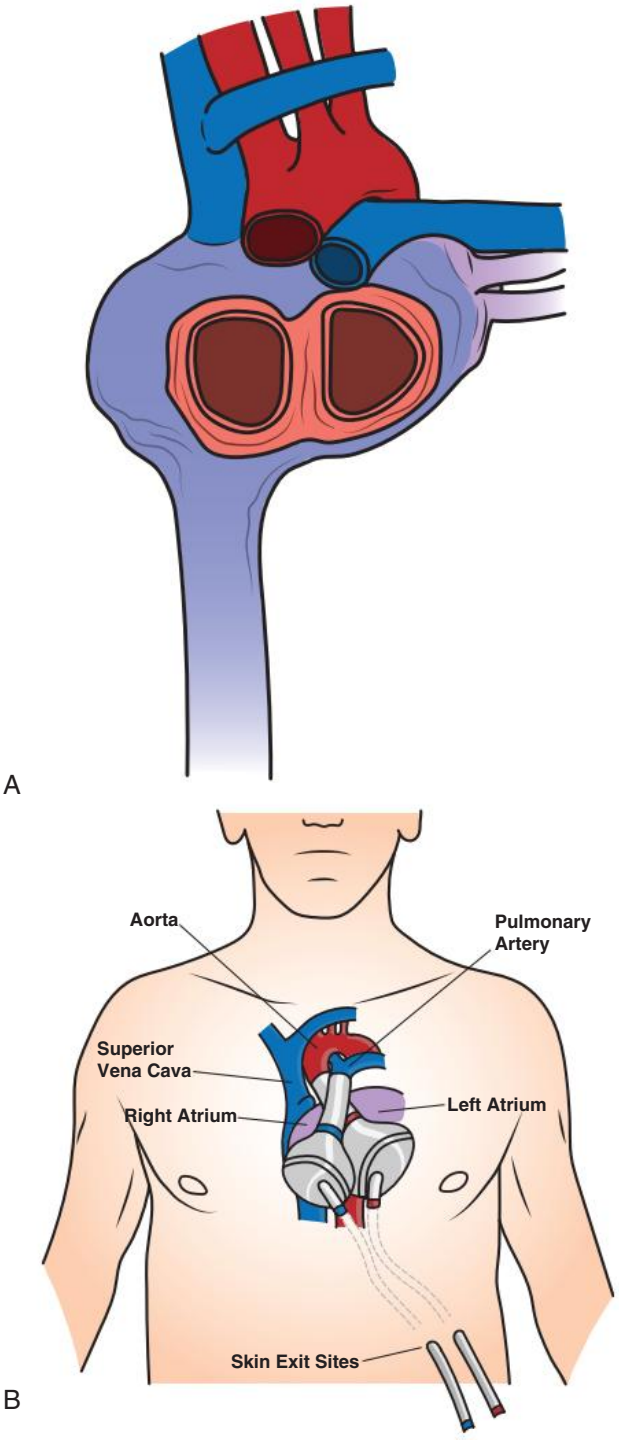
Patients in biventricular failure who need a heart transplant can have a SynCardia total artificial heart (TAH) as an immediate replacement bridge to transplant. The TAH replaces both ventricles and all four valves (Fig. 43.32). The atria remain intact. The SynCardia TAH 70 cc is the most commonly used bridge to transplant. Since FDA approval, the TAH has been placed in over 1700 patients. Some patients had replacement TAH implanted for adjustments to the system. The longest use by one patient was close to 4.5 years before his heart transplant was available.

Patient selection for TAH includes being a current transplant candidate, appropriate anticoagulation, and physiologic space in the chest (sternum to vertebrae) to accommodate the TAH device. The 160-g weight TAH device moves 9.5 L of blood through each ventricle and responds to resting needs or increases during exercise when muscular activity increases. The heart pump rate does not increase, but can increase ventricular blood capacity by 30% to meet the body's needs. The improvement in blood flow to major organs improves the outcomes of health, leading to better outcomes as a transplant candidate.

The mechanism is powered by lithium ion batteries that are recharged easily with any available electrical outlet or the lighter system in a car. The two replacement ventricles each contain a diaphragm that responds to a pneumatic air power shift provided by the power pack. The tubing to the power device exits the patient's body via the midabdomen. Patients are able to ambulate when stable after placement of the TAH. Any change in performance of the device sounds an alarm and flashes a light.

A clinical study started in 2015 with patients permits humanitarian or compassionate use for patients who are not transplant candidates. This study has permitted an improved quality of life for patients with a short life expectancy. These patients are able to go home with a portable power supply encased in a shoulder bag or backpack. The hope is to use the TAH as a permanent replacement in the future for the failed native heart.

A smaller 50-cc model is available for smaller patients. The criteria for the clinical investigation are age 10 to 79 years with functional atria. Body size and coagulation studies are some of the criteria for use of the 50-cc TAH and are similar to those used for the larger 70-cc TAH, already FDA approved. More information about the SynCardia total artificial heart can be found at www.syncardia.com.



• **Fig. 43.32** **A,** SynCardia total artificial heart attaches to the intact atria with connection rings after removal of both ventricles and all four valves. The superior cardiac anatomy (arterial and venous) remains intact. **B,** SynCardia artificial heart biventricular device in place.

Complications of Cardiac Surgery

Prevention of complications is a collaborative effort of the surgeon, anesthesiologist, scrub person, and circulating nurse. The care continuum continues through the patient's stay in the ICU and later in the stepdown area. Careful monitoring and management of BP are critical throughout the perioperative care period. Aggressive preoperative evaluation is necessary to screen for patients who are at high risk.

The most common complication of cardiac surgery with or without CBP is stroke. In a patient with atherosclerosis of the coronary arteries the arterial supply of the brain is usually affected. Air embolus is a common complication during valve procedures. Meticulous de-airing of the heart is done by the surgeon before removal of the aortic cross-clamp in an attempt to prevent air embolus.

Low BP (50 to 60 mm Hg) during bypass can lead to ischemic cerebrovascular accidents of the brain. Hypertensive episodes can lead to hemorrhagic brain insults. Calcium deposits and atheroma that can line the intima of the aorta can embolize during the application and removal of the aortic cross-clamp. The surgeon inspects and palpates the aorta to find a section amenable to cross-clamping. There is no guarantee that plaque will not be dislodged by manipulation of the instrument.

Excessive bleeding can result in cardiogenic shock and alteration of the body's clotting mechanism. Factors that influence clotting include preoperative use of antiplatelet agents, occult liver disease, disruption of an anastomosis caused by hypertension or technical malfunction of a suture line, prolonged use of CPB, and ineffective use of protamine for reversal of heparin.

Mediastinal and/or pleural chest tubes are placed to monitor the amount of drainage and, if excessive, may warrant a return to the OR for exploration or **redo**.

Postoperative myocardial infarctions (MIs) are infrequent; however, an MI can lead to cardiogenic shock. Postoperative MI can be caused by a kink or acute thrombosis in the newly placed bypass conduit or an air embolus. Acute restrictive pericarditis can obstruct blood flow in a new graft, causing myocardial ischemia.

Organ failure is always a concern with cardiac surgery and CPB. Organ failure can affect any organ system, but is most commonly seen in the kidneys. Low BP caused by an ineffective pump prevents the kidneys from functioning.

Acute tubular necrosis (ATN) can result from atherosclerosis of the renal arterial system, leading to kidney failure. Patients may need hemodialysis for a short time or for life depending on the extent of renal damage. Some patients, who continue to have adequate urine output, may have only a transient rise in their blood urea nitrogen (BUN) and creatinine levels with quick return to normal without the assistance of hemodialysis.

Acute respiratory distress syndrome (ARDS) and other respiratory disorders complicate the postoperative outcomes of some patients undergoing cardiac surgery. Preoperative evaluation, especially in smokers, is essential to try to predict and prevent the incidence of postoperative pulmonary disorders.

The bowel and liver are occasionally affected by the surgical experience. Acute liver failure can be first noticed with postoperative blood work. A rise in liver function studies (aspartate aminotransferase [AST], alanine aminotransferase [ALT], bilirubin, alkaline phosphatase) can lead to coagulopathies. Bowel that becomes ischemic during bypass can become necrotic in the postoperative course and lead to profound sepsis and death.

Wound infections of the sternum can also lead to horrific sepsis and are managed surgically. The sepsis can result in a prolonged hospital stay or even death. Removing the sternum (sternectomy) is usually a procedure performed by a multidisciplinary team of both cardiac and plastic surgeons. Once the sternum is removed, the plastic surgeon creates a vascularized pedicle flap from the pectoralis muscles or omentum to create a tissue cover for the

defect left by the missing sternum. The skin is closed over the flap. The ample blood supply of the muscles and omentum assist with the evacuation of any remaining pathogens and promote wound healing.

Cardiac tamponade occurs when blood and fluids build up around the heart. When blood collects in the pericardium and is not adequately evacuated by the drains, it can collect and begin to compress and compromise the function of the heart. This life-threatening event is first observed when there are increasing right atrial and right ventricular pressures. It is also reflected in a drop of more than 10 mm Hg in systolic blood pressure during the patient's inspiration (pulsus paradoxus). If left untreated, cardiac tamponade can lead to hypotension and fatal dysrhythmia.

Electrolyte imbalance in magnesium, potassium, and, to a lesser extent, calcium, can lead to serious cardiac dysrhythmias such as sinus bradycardia, supraventricular tachycardia (SVT), ventricular tachycardia (VT), atrial fibrillation, atrial flutter, and ventricular fibrillation (VF). High levels of potassium will cause a fatal dysrhythmia if not medically corrected with medications such as glucose or insulin, furosemide (Lasix) or sodium polystyrene (Kayexalate), or hemodialysis.

Cardiogenic shock may be precipitated by coronary air embolism, pulmonary embolism, myocardial contusion, mechanical venous obstruction, or hypothermia. Precautions are taken intraoperatively to avoid postoperative cardiogenic and/or hemorrhagic shock. Excessive bleeding can result from stress to the clotting mechanism.

Cardiac surgery can be a lifesaving procedure if carefully managed by the entire perioperative team. Attention to sterile technique and patient monitoring is especially critical.

Vascular Surgery

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter the learner will be able to:

- Identify the pertinent anatomy of the peripheral vascular system.
- Describe the potential complications associated with peripheral vascular disease.
- Describe care of the patient with peripheral vascular disease.
- List the differences in aneurysms and their treatment.
- Discuss the vascular access options for hemodialysis.

KEY TERMS AND DEFINITIONS

Aneurysm Abnormal out-pouching or bulging of an artery.
Anticoagulation Alteration in the cellular activity associated with clotting.
Dissecting aneurysm Occurs when the intima separates from the media. A false passage fills with blood, causing further separation of intima and media.
Embolize Material (i.e., fat, plaque, vegetation, or clot) in a blood vessel becomes bloodborne with the potential for lodging in smaller vascular tributaries.
Endarterectomy Removal of clot or other material from an artery.
Hemangioma Vascular lesions classified as tumors or malformations.
Hemodialysis Vascular system is accessed for the purpose of removing chemicals and other solutes from the blood.
Iatrogenic Condition inadvertently caused by the medical or surgical treatment performed by a physician.
Interstices Spaces in a woven surface or between the strands of a braided suture.
Mycotic aneurysm Bacterial vegetation embolizes from the valve of the heart to the arteries, where it implants and grows, causing the weakened artery to distend and rupture.
Pseudoaneurysm (false aneurysm) Injury to all three layers of the arterial wall that permits blood to accumulate in the connective tissue.
Thrombose Blood within a vascular structure clots and occludes the lumen.
True aneurysm Progressive dilation of an artery.

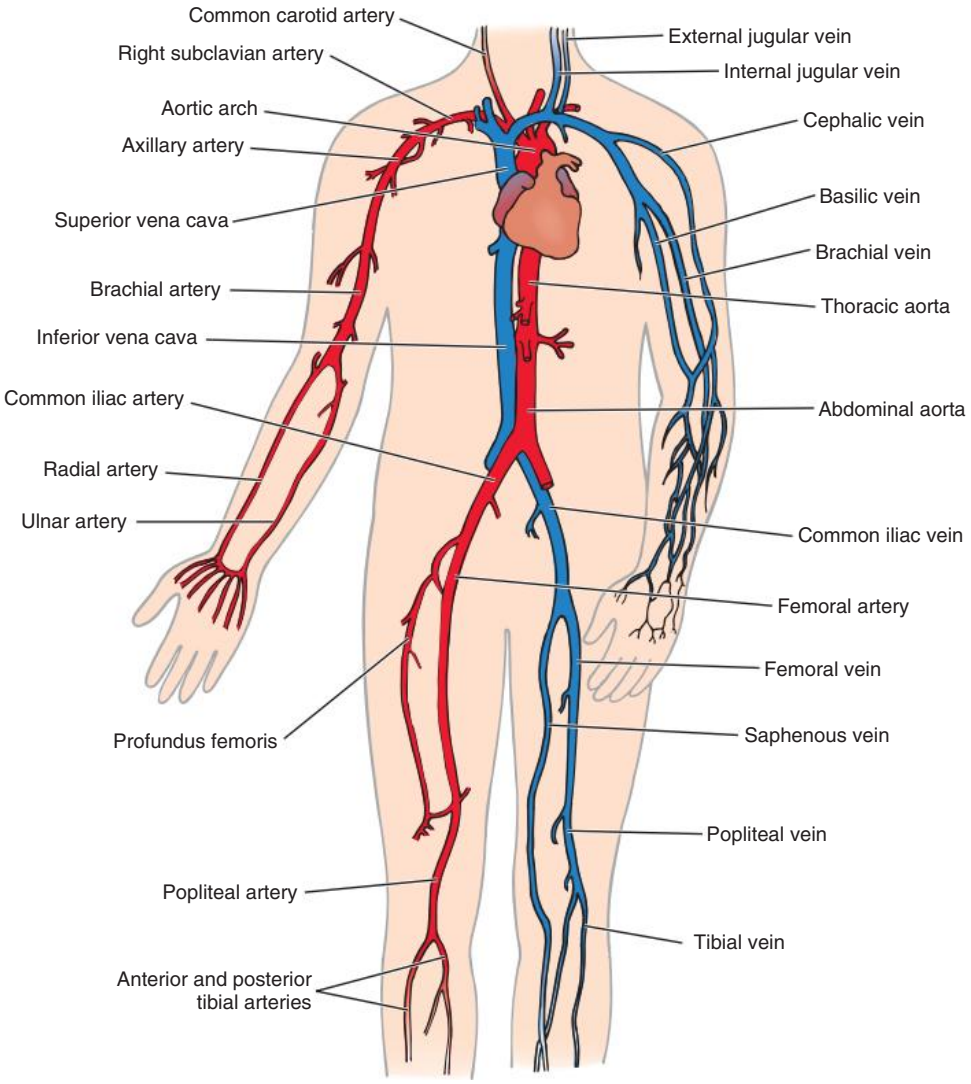
Anatomy and Physiology of the Vascular System

Vessels in the thorax, abdomen, extremities, and extracranial cerebrovascular area constitute the circulatory system (Fig. 44.1). The ascending aorta, which originates from the left ventricle, carries oxygenated blood from the heart to the arteries. The major arteries leading to the head and upper extremities—the brachiocephalic trunk, left common carotid, and subclavian arteries—branch off from the aortic arch in the middle mediastinum above the heart. The thoracic aorta then descends through the posterior mediastinum at the left side of the vertebral column.

Passing through the diaphragm, the abdominal aorta descends to the level of the fourth lumbar vertebra, where it bifurcates (i.e., divides) to form the common iliac arteries that lead to the lower extremities. Arteries from the abdominal aorta carry blood to the kidneys and the abdominal and pelvic organs. The femoral artery, which originates from the iliac artery, is the main artery in each leg.

Oxygenated blood flows from the arterial system through the capillary network and returns deoxygenated to the heart via the venous system (Fig. 44.2). The superior and inferior venae cavae enter the right atrium. The superior vena cava, formed by the union of the two brachiocephalic veins, returns deoxygenated venous blood from the head, neck, upper extremities, and chest. The inferior vena cava, which begins at the level of the fifth lumbar vertebra, returns blood from the lower extremities, pelvis, and abdominal organs. There are two exceptions to this oxygenation/deoxygenation pattern, as follows:

1. The pulmonary arteries carry deoxygenated blood to the lungs, and the pulmonary veins carry oxygenated blood to the heart.



• **Fig. 44.1** Circulatory System. Arteries (and the heart) are shown as red vessels. Veins are shown as blue vessels.

2. In fetal umbilical circulation, one vein carries oxygenated blood and two arteries carry mixed blood. These three vessels, surrounded by Wharton's jelly, traverse the umbilical cord to the placenta.

Innervation of the arteries and veins is controlled by the efferent vasomotor fibers of the autonomic nervous system. The nerve fibers enter the vessel adventitia (i.e., covering) along the same route as the blood supply. Stimulation of these nerves can cause vasoconstriction that shunts blood to larger organ groups, such as the skin or gastrointestinal tract. Some medications cause vasodilation, which relaxes the vessels and slows heart rate to decrease intraluminal pressure.

The vessels are lined with endothelial cells, which when intact do not support platelet aggregation. This property is interrupted when a vessel is injured, and a clot is allowed to form. The endothelial lining also secretes factors that resist clotting, stimulate tissue repair, and synthesize clotting factors.

Arterial Anatomy

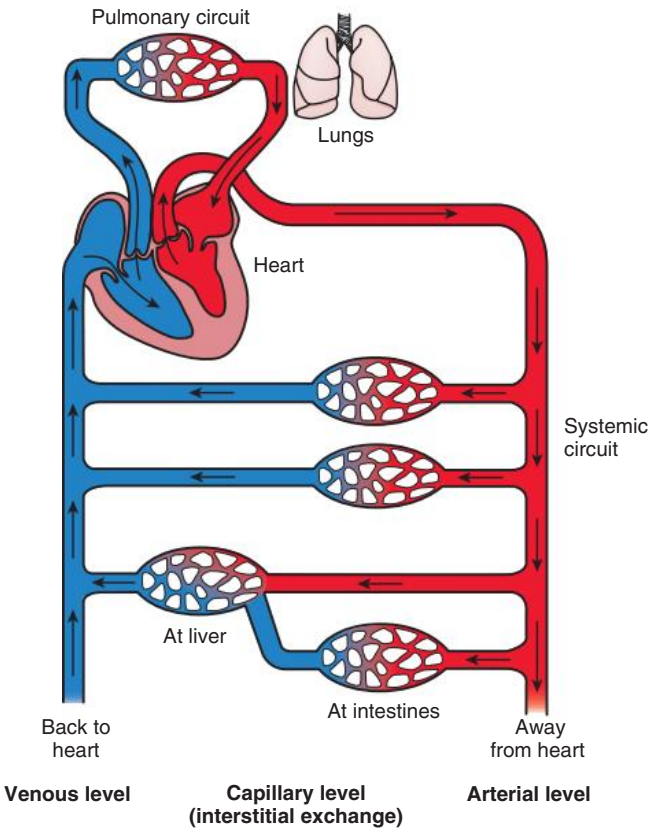
Arteries are elastic and constrict in response to hemorrhage. The arterial walls are made up of three layers separated by internal and external elastic membranes (Fig. 44.3). The innermost layer is the intima (tunica intima), a single layer of endothelial cells on a thin matrix of hyaluronic acid, collagen, and elastic fibers. The middle layer is the media (tunica media, or yellow fibrous). It is the thickest of the layers and is composed of a combination of smooth muscle fibers, yellow collagen, and some elastic fibers. The medial layer gives the arterial wall the flexibility and strength to withstand higher internal pressure.

The outermost layer is the adventitia (tunica adventitia, or white fibrous connective tissue). It is the thinnest layer but provides most of the external support for the arterial wall and resistance to overexpansion.

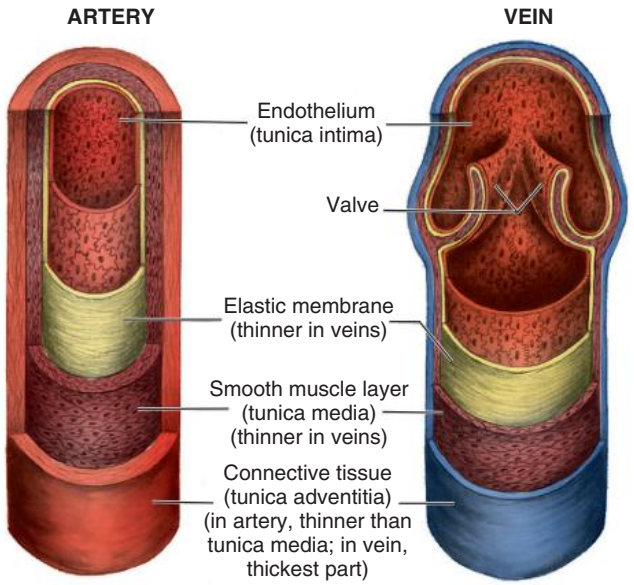
The tissues of the adventitia and the outer third of the media are nourished by a series of capillaries called the vasa vasorum. The rest of the medial layer and the intimal layer are nourished by diffusion from the luminal flow. Terminal arteries, referred to as arterioles, end at the level of the capillary beds in the tissues.

Venous Anatomy

Venous walls are structured in three layers. The innermost layer, the intima, is composed of endothelial cells that produce coagulation



• **Fig. 44.2** Circulatory system to the capillary level.



• **Fig. 44.3** Cross-section of an artery and a vein showing the three layers: tunica intima, tunica media, and tunica adventitia.

factors. The middle layer, or media, is much thinner in the deep venous system and may even be hard to identify microscopically. The superficial veins have a thicker medial layer composed mainly of smooth muscle fibers. This provides some resistance and response to intraluminal pressure changes. The external layer, or the venous adventitia, is composed of loose connective tissue (see Fig. 44.2). Because of lower flow pressure, larger veins have internal semilunar valves to maintain the direction of the blood flow.

The muscular component of the lower extremities provides force during contraction of large muscle groups, which facilitates venous return from the larger peripheral sinusoids. The cerebral veins are an exception; they have no valves. Veins are less elastic than arteries and tend to ooze instead of contract in response to hemorrhage.

Venous anatomy has three structural components: superficial veins, deep veins, and perforators (also known as communicating veins) (Fig. 44.4). The venous structure and flow of the lower extremities are examples of this system. At the tissue level the origin of the venous system at the capillary bed is referred to as venules. The venous drainage of deoxygenated blood from the superficial veins returns through the perforators to the deep veins during muscular contraction. The deoxygenated blood then passes from the deep veins to the inferior vena cava.

Capillary Anatomy

Capillary beds are the vascular nutrition and waste exchange points of the arterial and venous systems. Capillaries are the diameter of a red blood cell and form a network throughout body tissues. Structurally they are a single epithelial cell layer thick, which facilitates the exchange of oxygen and carbon dioxide at the tissue level. They are semipermeable to water and crystalloids but are impermeable to larger molecules such as proteins. Oxygenated blood enters the capillary bed via the arterial system, and deoxygenated blood passively drains into the venous system.

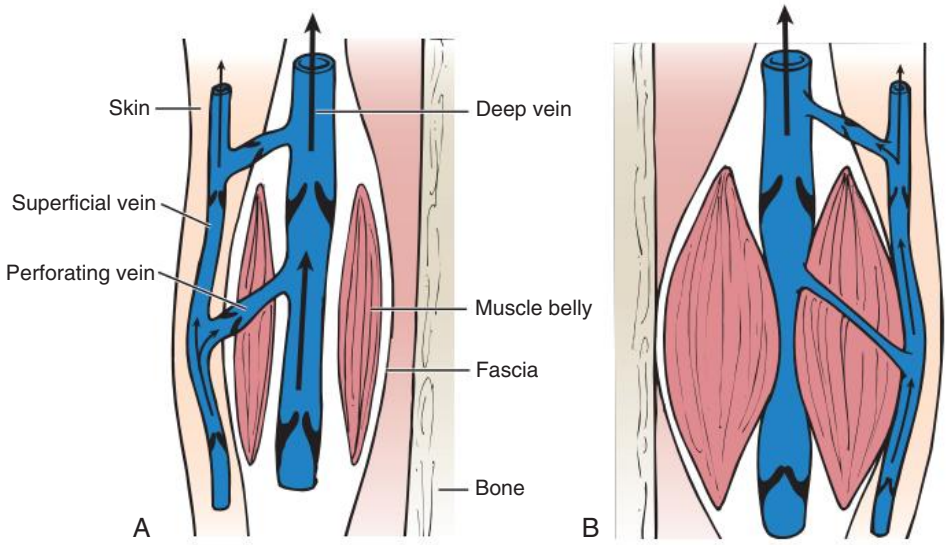
There are no fibrous or muscular layers of the vessels at this level. Lymphatic vessels passively exchange lipids, debris, fluids, proteins, antibodies, and other nutrients at this level in response to skeletal muscle contraction. This fluid is filtered by the lymphatics and is transported through the thoracic duct to the vena cava. The lymphatic vessels are structurally very pliable and have valves to maintain a unidirectional flow.

Vascular Pathology

Vascular diseases that cause occlusion or stenosis are usually acquired diseases. Inadequate arterial blood supply causes ischemia in tissues and complete organ systems. If left untreated, this can lead to thrombus, embolus, ulceration, necrosis, or gangrene. Vessels are repaired, reconstructed, or replaced to improve peripheral (systemic) circulation.

Atherosclerosis is the most common arterial disease. It is a diffuse disease and begins as a disruption of the intima of a large artery. Cholesterol enters the media to stimulate muscle growth, and platelets accumulate around the disruption of the endothelial intima to form plaque or a thrombus. Often this process becomes localized around vessel orifices and branches (i.e., at bifurcations). The disease may produce stenosis (narrowing) and subsequent occlusion or ectasia (dilation) and aneurysm. The most common procedures are performed to revascularize a lower extremity for limb salvage, repair an aortoiliac aneurysm, and improve cerebral blood flow through the carotid arteries.

Atherosclerosis is the principal factor in transient ischemic attacks (TIAs, or "mini strokes"), cerebrovascular accidents (strokes, or "brain attacks"), myocardial infarctions (heart attacks), and aortic stenosis. Risk factors include familial history, a high level of serum cholesterol, smoking, and hypertension (Box 44.1).



• **Fig. 44.4** Structural Components of Deep Venous Anatomy in Lower Extremity. **A,** Relaxed state. **B,** With muscle contraction, the perforating veins are squeezed closed.

- Diabetes
- Familial predisposition
- Habitual long periods of standing
- High-fat diet causing high serum cholesterol
- Hypertension
- Obesity
- Repeated pregnancies
- Sedentary lifestyle
- Smoking
- Stress

Venous stasis disease or obstruction of venous return can cause hemodynamic imbalances that affect distal structures. Arterial blood enters the area, but cannot return through the venous system. Superior vena cava (SVC) syndrome is one example. Patients with compression on the SVC caused by benign or malignant tumors or mediastinal fibrosis have serious venous drainage obstruction of the head and upper extremities. SVC can be caused by venous thrombosis associated with pacer wires or central venous catheters. Patients experience visual disturbances and dyspnea.

Relief of the obstruction by conservative medical management is not always successful. SVC syndrome can be a surgical emergency. Endovascular treatment is usually the best choice. In select patients a surgical bypass may be necessary.

Hemangiomas are tangled masses of malformed blood vessels. They can be found anywhere in the body. These vascular dysmorphic structures are congenital and are classified as (1) low-flow venous/lymphatic or (2) high-flow arterial or combined venous-arterial.[1] Low-flow hemangiomas are soft and compressible and appear bluish. They can cause disfigurement and an aching discomfort. The size ranges from small to large. Larger venous hemangiomas can expel clots, bleed, and lead to multisystem organ failure based on the location. If located on an organ, the treatment must be surgical.

Low-flow lymphatic masses are referred to as lymphangiomas.[1] Deeper lymphangiomas can lead to cystic hygromas of the neck. The treatment can be sclerotherapy or excisional surgery. Common postoperative complications include seroma formation and infection.[1]

High-flow arterial or arteriovenous hemangiomas are very aggressive and are not cured despite surgical intervention. They appear as purple masses anywhere on the body or on internal organs.[1] Fistulas form around arterial feeder vessels and establish new pathways continually. Growth of the hemangioma is stimulated by puberty, pregnancy, or physical trauma.[1] The mass becomes pulsatile, and a bruit can be heard with a Doppler. Loss of a limb can be caused by a mixed hemangioma that impairs circulation and mobility.[1] Treatment is aimed at the origin of the arterial feeders. This area may require repeated arterial embolization with ethanol, cyanoacrylate, or liquid vinyl alcohol polymer. High-flow hemangiomas may require life-long treatment.[1]

Diagnostic Procedures

Preoperative assessment of cardiac risk is critically important in planning the care of a patient who requires major vascular surgery. Peripheral arterial and venous diseases are assessed by auscultation, palpation, and observation.

Table 44.1 compares the assessment factors of peripheral arterial and venous obstructive diseases in an extremity. Peripheral vascular laboratories, which are similar to cardiac catheterization laboratories, have been established in many health care facilities to perform noninvasive and invasive studies before and after surgical intervention. Interventional radiologists perform many of the diagnostic tests. X-ray studies, scans, imaging, ultrasound, and Doppler assessment reveal most pathologic conditions.

Computed tomography (CT) and magnetic resonance imaging (MRI) are noninvasive techniques of choice to confirm a diagnosis of aortic aneurysm, thrombus, or atherosclerotic plaque in arterial walls, especially in the abdominal and carotid circulation. CT scans are a good way to assess the sizes and stages of vessel occlusions. They can be performed with or without a contrast medium and very quickly in emergency situations. CT scans are somewhat expensive and expose the patient to x-rays.

TABLE 44.1 Comparison of Peripheral Arterial and Venous Obstructive Diseases in an Extremity

Assessment of Extremity	Arterial Obstructive Disease	Venous Obstructive Disease
Color	Dusky, blue, gray, mottled, pallor distal to obstruction	Red, purple, brown hemosiderin spots, brawny
Temperature	Cool, cold	Warm, hot
Visual and palpable characteristics	Dry, shiny, flaking skin; vessels not obvious Lack of hair on affected part Thick nails	Moist, peeling skin Vessels may be tortuous and inflamed Thickened tissue Hair present on affected part Normal nails
Sensation	Numbness, tingling, pain during exercise (intermittent claudication) Pain at rest in severe disease Increased pain when exposed to cold Pain can be acute and severe	Aching, throbbing, tightness, feeling of heaviness; muscles feel fatigued Pain decreased by motion or elevation of legs Feels worse at end of day
Mobility	Painful range of motion; limited flexion and extension caused by avascular necrosis at the tissue level	Painful range of motion; limited flexion and extension caused by congestive edema in joints
Size	Not enlarged, average for body build	Swollen, edematous
Integrity of surface layer	Peeling; infarcted; painful, deep, serous, oozing ulcers with defined edges on or between toes	Stasis ulceration; open, draining, shallow ulcers with irregular borders
Pulses	Weak or absent	Present
Condition of digits	Mottled, blackened, fragile, painful; can become gangrenous	Edematous, reddened, painful; can become gangrenous

MRI is useful for evaluating a three-dimensional image of the vessel being studied. This method is contraindicated for patients with stainless steel pacemakers, vena cava filters, or vessel clips, but many patients can benefit from its use. Nonmagnetic materials are not contraindicated. MRI is more expensive than CT scans and takes longer to perform.

Carotid phonoangiography and oculoplethysmography (OPG) are techniques to obtain cerebral blood flow measurements to localize obstructions in the vessels of the head and neck. OPG is contraindicated in patients with intraocular lens implants.

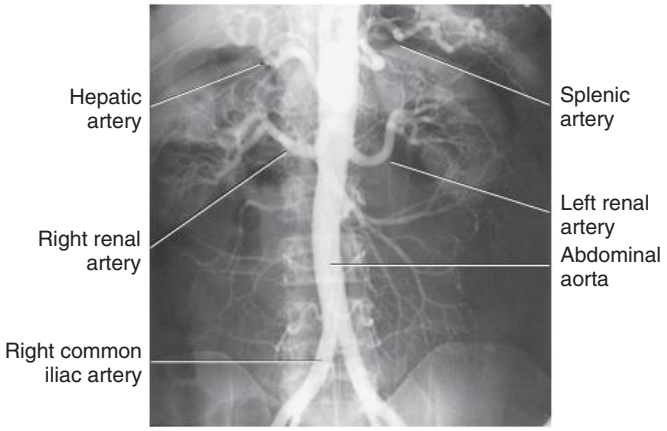
Pulse volume recording (PVR) or photoplethysmography is used to measure systolic pressure in the extremities and digital arterial systems. This test is affected by artifacts and patient positioning. A diagnosis of deep vein thrombosis (DVT) may be made by phleborheography (PRG), a plethysmographic technique that records the rhythmic changes in venous volume in the legs; these changes are associated with respiration. PRG is not useful for small thrombi or for deep iliac or femoral veins, and the process is time consuming and expensive.

Ultrasonography is a major diagnostic tool for measuring segmental arterial pressures and venous patency in the extremities; it also may be used for abdominal circulation. Doppler color-coded flow imaging and transcranial Doppler imaging are replacing carotid phonoangiography and OPG in the evaluation of carotid circulation. High-resolution, B-mode ultrasound provides real-time images of venous systems in the upper and lower extremities.

Saphenous and cephalic vein mapping accurately measures vein diameter, location, and quality to determine preoperatively if the vein is suitable for use as an arterial conduit in arterial reconstruction. Ultrasound also detects venous thrombosis. With a pulse Doppler blood flow detector, longitudinal and/or transverse cross-sectional scans are obtained and the images are recorded by oscilloscope. A computer-generated print of the image on the screen provides a permanent record of the arteriograph or venograph.

Intraoperative assessment of shunt performance or vessel patency or stenosis, as well as identification of an arteriovenous fistula (AVF), is easily performed with a sterile Doppler probe (Fig. 44.5). An audible signal is transduced and is similar to the sounds transmitted by a Geiger counter.

• **Fig. 44.5** Doppler box and probe.



• **Fig. 44.6** Normal abdominal aortogram.

Invasive Procedures

Selective angiography permits the x-ray study of a particular segment of the vascular system. Aortography visualizes the aorta (Fig. 44.6). Arteriography shows the patency of an artery or a branch of the aorta and its collateral circulation.

Phlebography detects DVT, and a venogram visualizes the veins. An angiogram requires the injection of a nontoxic contrast medium. The pain associated with injection of intravascular contrast material can be intense. The procedure may be performed under continuous epidural anesthesia or general anesthesia.

Angioscopy is an endoscopic technique used to visualize the interior of vessels. A small (1.5 to 3-mm), flexible fiberoptic angioscope is coupled to a camera, which allows the view from the angioscope to be seen on a monitor. The lining and structures within the blood vessels are visualized as the scope is advanced within each vessel. For many patients, angioscopy is an alternative preoperative diagnostic technique to angiography and may be used to evaluate the effectiveness of therapy intraoperatively. It can reveal retained atherosclerotic plaque or thrombi and suture lines.

Intravascular ultrasonic scanning of the coronary or peripheral vasculature uses a miniaturized ultrasonic probe at the end of a 3.5-Fr catheter. The probe is introduced over a guidewire. The probe is irrigated with heparinized saline as it is introduced into the vessel percutaneously. Images of the entire circumference are obtained and viewed on a monitor to determine the thickness of the vessel wall and the distribution of plaque within the wall. This technique may be performed percutaneously or during a surgical procedure. This device is single use and not reprocessed. This device is not recommended for use on cerebral vessels.

Special Features of Vascular Surgery

Circulation within the peripheral vascular system affects the brain, internal organs, and extremities. An expanding body of knowledge relating to vascular physiology and the development of the art of vascular surgery has improved the quality of life for many patients with peripheral vascular diseases. Circulatory problems may affect any part of the body, but this discussion focuses on the most common pathologic conditions amenable to vascular procedures performed by vascular surgeons and interventional radiologists. Current surgical trends include open procedures and endovascular techniques.

Vascular injury can occur during invasive diagnostic tests, intravascular monitoring, or therapeutic procedures. **Iatrogenic** arterial injuries, those resulting from an unexpected outcome of a procedure, can cause loss of function or even death from ischemia, hemorrhage, or embolus. The patient must be carefully observed and monitored for signs of complications during and after vascular procedures. Infection is a devastating postoperative complication that must be avoided through strict adherence to aseptic and sterile techniques. Other considerations include the following:

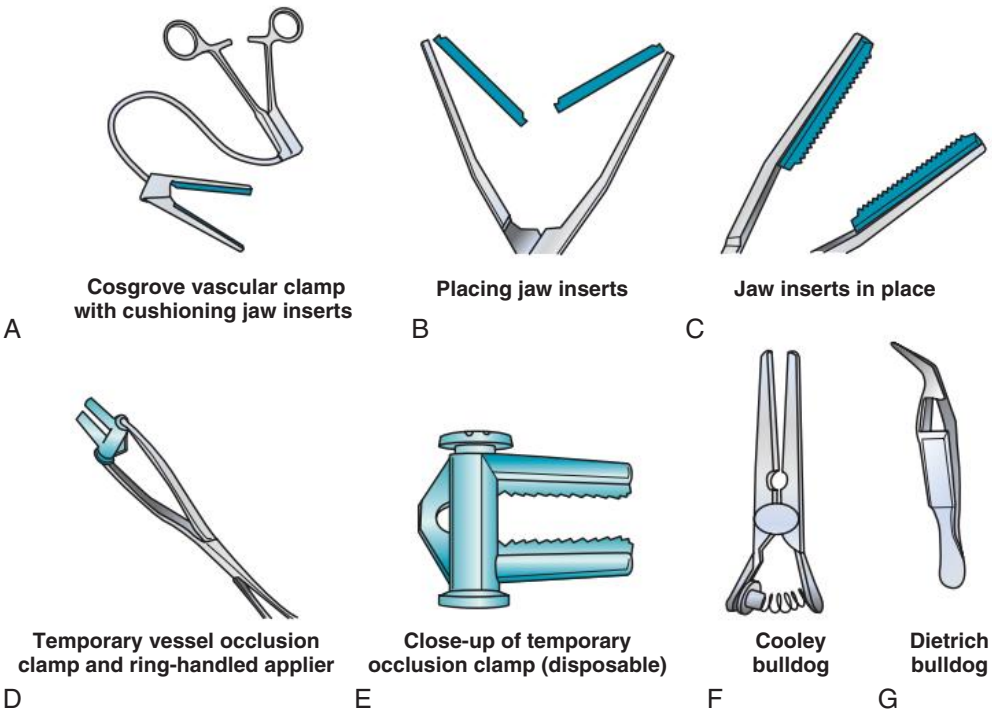
- A thorough understanding of the principles of general surgery should be combined with special training in vascular surgical techniques. Speed and accuracy are imperative.
- Local or monitored anesthesia care (MAC) is usually preferred for most conservative interventional procedures. General anesthesia or regional block is used for longer or more extensive procedures.
- Skin preparation is performed very gently. Vascular pathology (i.e., carotid stenosis, aneurysms, or venous thrombosis) should never be rubbed or pressed during the prep because plaque or clots could **embolize**, causing serious limb or brain damage. Aneurysms could rupture.
- Temperature regulation may be a problem during long procedures or when multiple blood transfusions are given. Warmed fluids can be administered via rapid infusing pumps. Forced-air warming blankets provide a normothermic temperature.

  Intentional hypothermia can be used to preserve the spinal cord during aortic surgery. The low temperatures decrease the metabolic needs of the cord by minimizing the effects of temporary ischemia during cross-clamping of the aorta.
- During anastomosis of vessels, meticulous care is exercised to avoid the danger of postoperative thrombosis and stenosis. To prevent undue trauma to vessels, an assortment of curved and angled scissors, noncrushing vascular clamps, and forceps specifically designed for vascular surgery is included in the instrument setup (Fig. 44.7). Umbilical tape (also called hernia tape) or synthetic vessel loops are used for retraction and vessel control (Fig. 44.8). An operating microscope may be used for anastomosis of vessels. Appropriate instrumentation for microsurgery is made available.

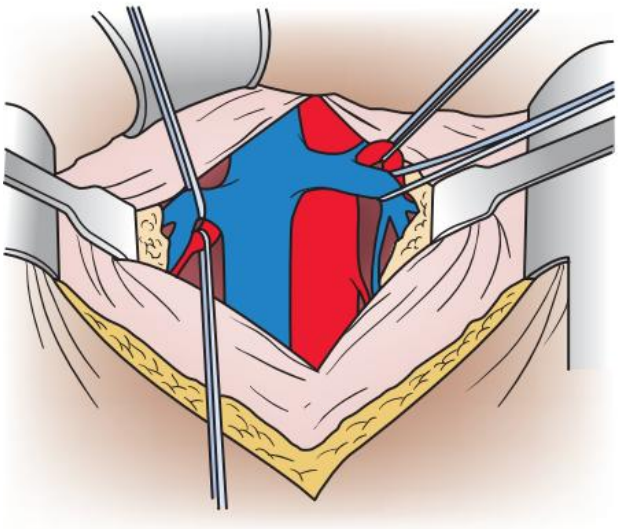
  Synthetic nonabsorbable monofilament suture materials are preferred because they are strong and pass through vessel walls and grafts easily with minimal trauma and tissue reaction. Uncoated braided suture has **interstices** (spaces) that cause trauma by abrasion and can harbor microorganisms. Swaged needles also minimize trauma. A larger swaged suture-to-needle ratio is advantageous to avoid leakage. Holes made in graft materials by the needle are occluded by the larger suture. Double-armed needle sutures are often used for vessel anastomosis.

  Structurally the surgeon may use a triangulating technique in which three vessel edges are gently straightened to create a straight sutured angle with three separate sutures instead of suturing a circular stitch with one suture that could stricture.
- Heparinized solution is available for use as an anticoagulant irrigation. Preoperatively, heparin (5000 units) may be given subcutaneously (SQ) for DVT prophylaxis 1 hour before the surgical procedure.[2] Intraoperatively the optimal dose is 70 to 100 units/kg of body weight if given intravenously (IV) for immediate systemic effect. Thromboelastography may be used intraoperatively to monitor the effects of heparin administration.

  Sensitivity to bovine sources of heparin can result in heparin-induced thrombocytopenia (HIT), also known as white clot



• **Fig. 44.7** Specialty vascular instruments.



• **Fig. 44.8** Vessel loops in place for retraction of arteries and venous structures.

syndrome. Clots composed of fibrin and platelets form after 4 to 15 days of heparin therapy. A severe decrease in the platelet count predisposes the patient to thrombosis and acute arterial occlusion.

- Patients with preoperative **anticoagulation** with warfarin for known blood coagulation pathology are at risk for extreme blood loss. Temporary reversal of the therapeutic anticoagulation for the duration of an emergent surgical procedure is accomplished by the administration of fresh frozen platelets (FFP). Onset of FFP action is immediate and easily amenable to postoperative anticoagulation as necessary. The activity of FFP is short term.

Less urgent surgical procedures for the anticoagulated patient can be performed with minimal blood loss after the administration of vitamin K. Studies have shown that 1 mg of IV vitamin K reversed the effects of therapeutic anticoagulation within 27 hours of administration. SQ vitamin K injections are absorbed at an unpredictable rate and are rarely used. Low-dose vitamin K does not interfere with postoperative therapeutic anticoagulation regimens.

- Before closure at the end of the procedure, protamine sulfate, a heparin antagonist, is given to reverse the anticoagulant effect; 1 mg of protamine is given to counteract 100 units of heparin. Protamine is derived from fish semen and testicular tissue and may elicit a sensitivity reaction in patients who are allergic to fish. Patients with type 1 diabetes who take NPH insulin also may be predisposed to a sensitivity reaction to protamine. Some men who have had a vasectomy may exhibit allergic or hypersensitivity reactions.
- Hemostatic agents can be used independently or in combination (Box 44.2). Care is taken not to permit hemostatic materials to be suctioned into the blood-salvage or cell-saving device. These products can be hazardous if permitted to enter the patient's vascular system. Containers and delivery devices for thrombin should be carefully labeled with concentration and dosage to prevent accidental injection.
- A vasodilator such as papaverine is used to relax the smooth muscle of the vessel. This prevents endothelial damage during intraluminal irrigation. Vasopressors should be available. Some surgeons use 1% lidocaine without epinephrine.
- Blood is lost by the flushing of clots and debris. Blood loss should be calculated, and blood should be available for replacement if the hematocrit level falls below 26%.

During procedures on the great vessels, blood may be salvaged from the thoracic or abdominal cavity for autotransfusion. An autologous blood salvage machine (cell saver) may be used to collect the patient's own blood for autotransfusion.

• BOX 44.2 Hemostatic Agents Used in Vascular Surgery

- Absorbable gelatin sponge (Gelfoam) can be used dry or dipped in saline. According to the manufacturer, the patient may have an antigenic reaction when the sponge is soaked in thrombin. The sponge can be applied to the site and removed after 20 seconds or left in the wound; it is absorbed after 4 to 6 weeks. Gelfoam should never remain in a closed cavity, because it greatly increases in size and can cause pressure on tissues. Because it may provide a favorable microbiologic growth medium, it is not used in the presence of infection. It is derived from porcine gelatin and has more of a mechanical than a chemical hemostatic property.
- Absorbable collagen (e.g., Avitene, Hemopad, Helistat)—either in powder, foam, woven, or nonwoven form—induces platelet adhesion and results in the formation of fibrin. It provides both a chemical and a mechanical hemostasis. Because it may provide a favorable microbiologic growth medium, it is not used in the presence of infection. The long-term effects of an in situ collagen hemostat are unknown, but animal studies indicate that it absorbs. It is of bovine origin and can be moistened, but it works better when dry.
- Oxidized cellulose (Surgicel, Oxycel) is applied dry over a bleeding site for hemostasis. Although a single layer can be left in the wound and absorbed, it is preferred that a large wad be removed because it may interfere with healing or cause pressure. It chemically destroys thrombin and is not used concurrently with it. Because it may provide a favorable microbiologic growth medium, it is not used in the presence of infection. It has some bactericidal properties against gram-positive and gram-negative microorganisms. The mode of action is mechanical hemostasis when applied to an area of bleeding.
- Fibrin glue is applied by simultaneously placing a combination of cryoprecipitate, bovine thrombin, and/or calcium chloride on the bleeding tissue surface to form a fibrin patch.
- Topical thrombin should be available. Preparations from bovine origin are contraindicated in patients who are sensitive or allergic to these products. Thrombin is never injected.

Care is taken not to aspirate hemostatic materials or other debris into the blood suction-salvage device. A separate suction tip for blood salvage should be labeled and not used for suction of irrigation solutions.

Blood should be warmed before transfusion to help prevent inadvertent hypothermia. Consideration is given to the patient who does not want a blood transfusion. Patients undergoing nonemergent procedures should be given the option of donating autologous blood in advance of the procedure.

- For DVT prophylaxis, antiembolic stockings or sequential compression devices should be worn by the patient during and after the surgical procedure, in addition to therapeutic anticoagulant therapy.
- For vascular monitoring, Doppler ultrasound, pulse volume recorder, and/or intravascular imaging techniques are used intraoperatively to monitor hemodynamic changes and assess blood flow after peripheral vascular reconstruction. A pulmonary artery catheter (e.g., Swan-Ganz) is usually inserted to monitor pulmonary artery pressures during and after the procedure.

The most serious immediate postoperative complications are thrombus and hemorrhage. The patient may need to return to the OR for immediate correction of these problems. Long-term complications include infection and graft failure by occlusion.

Vascular Grafts

Biologic or synthetic prosthetic vascular grafts are required to bypass a vascular obstruction or reconstruct vessels. These substitute conduits for blood flow vary in length, diameter, and configuration to meet the requirements of each situation. A graft may be straight or bifurcated into a Y shape. Pieces of biologic or synthetic material may be cut to size for use as patch grafts.

The American National Standards Institute (ANSI) has established requirements for product characteristics and the labeling of textile and nontextile synthetic grafts, vascular allografts, and vascular xenografts. Grafts sterilized in see-through containers or packages permit the surgeon to select the appropriate size after exposure of the surgical site. Manufacturers' instructions for use and handling are strictly followed.

Biologic Vascular Grafts

Autografts, allografts, and xenografts have been used for arterial or venous conduits, but autologous grafts have a higher success rate. Allografts and xenografts have a higher failure rate.

Arterial Conduit

Autologous arteries are procured for coronary artery bypass grafting. The radial, gastroepiploic, or internal mammary arteries are commonly used. Arterial grafts do not **thrombose** and occlude as readily as do venous grafts.

Venous Conduit

An autologous vein is a suitable graft conduit because it is lined with endothelial cells that inhibit clotting. These cells produce fibrinolytic substances and the plasminogen factor essential to maintain patency. The saphenous vein is commonly used for an autologous arterial bypass or vein graft. If the saphenous vein is not suitable, the basilic or cephalic veins of the arm are sometimes used. A vein graft is used as a conduit in one of the following three ways:

1. *In situ conduit/bypass:* To revascularize a lower extremity, the saphenous vein is exposed at the proximal and distal aspects but is left in place. The surgeon performs a venotomy at each end of the vein, inserts a valvulotome and/or a disposable valve cutter, and disrupts the internal valves. The occluded artery to be bypassed is ligated distally and proximally and then anastomosed proximally and distally to the saphenous vein. This technique reverses blood flow in the vein and reestablishes the flow of oxygenated blood beyond the level of arterial occlusion. Decreased manipulation and not excising the length of vein minimizes endothelial trauma and preserves antithrombogenic properties. The vasa vasorum and neurovascular components of the vessel remain intact.
2. *Nonreversed vein graft:* Renal and mesenteric revascularization also can be accomplished by grafting nonreversed segments of the saphenous vein.
3. *Reversed vein graft:* When a segment of saphenous vein is harvested for placement in the arterial system, the vein is reversed from its normal anatomic position so the valves will not obstruct arterial blood flow. Intact valves are used to keep the blood flow unidirectional after anastomosis. Endothelial integrity is maintained by gentle dissection and handling. The surgeon exposes the surgical site while the first assistant, resident, or another surgeon—working at a separate sterile table supplied with fine vascular instruments, ties, and vascular clips—prepares the vein for grafting.

Magnification loupes are worn to check for imperfections in the vein and tie off leaking perforators. The valves may be cut, especially in small-diameter segments. The vein is flushed with sterile, cold solution (commonly heparinized Plasma-Lyte with

papaverine hydrochloride) and immersed in this solution until the recipient site is prepared.

The saphenous vein decreases in diameter as it courses distally. A size discrepancy may cause difficulty at the anastomosis attachment sites.

Synthetic Vascular Prostheses

Various forms of synthetic materials are used to construct arterial vascular prostheses. Certain materials are more suitable than others for specific applications. The surgeon selects the most appropriate graft for each patient. Rejection and tissue reaction are minimized if Dacron or Teflon is used.

Knitted Polyester

Knitted polyester (Dacron) grafts are porous enough to allow the ingrowth of fibrous tissue into the interstices. They also are porous enough to allow blood to seep through the material and are therefore preclotted before insertion. Preclotting causes the wall of the graft to become impervious to blood by filling the interstices with fibrin. For the preclotting process the surgeon withdraws blood from the patient at the surgical site before anticoagulation therapy. The scrub person places the blood in a sterile basin containing the graft material. The blood saturates the lumen and all surfaces of the graft. The fabric-fibrin conduit later becomes firmly placed in tissue and provides a hypothrombogenic flow surface.

Filamentous Velour

Knitted velour construction of polyester grafts has uniform porosity for easy preclotting and ensures rapid tissue ingrowth. These types of grafts may be crimped or noncrimped, with velour inside and/or outside. One type, the exoskeleton (EXS) prosthesis, has a spiral polypropylene support fused to the outer surface of noncrimped velour. This graft was developed specifically for use across the knee joint. Another type, in which amikacin is bonded to knitted filamentous velour polyester with a bovine collagen matrix, provides an antibiotic in the prosthetic wall. This type of construction also renders the porous graft impervious to leaks, which eliminates the need for preclotting.

Bonded albumin also reduces porosity and potential thrombosis. Older style porous grafts required bonding. This was achieved by "baking on" autologous plasma. A porous graft was soaked in the patient's plasma or in allogeneic albumin and was then steam sterilized. This thermal process altered the fibrin and protein elements in plasma.

Woven Polyester

The weave of woven polyester (Dacron) grafts is tight enough to be leakproof; therefore these grafts do not require preclotting. However, the more inflexible construction limits their use for aortic replacement or the bypass of large-caliber arteries.

Polytetrafluoroethylene

The microporous wall of polytetrafluoroethylene (PTFE) serves as a lattice framework into which cells grow to become a microthin lining for contact with blood. These prostheses (Gore-Tex) do not require preclotting. Vascular grafts that are constructed of expanded and reinforced PTFE maintain dimensional stability. Configuration may be straight, tapered, or bifurcated. It may be supported by external rings to resist compression.

During the surgical procedure the inside lumen of the graft may be seeded with the patient's own endothelial cells to sustain patency. The graft may be bonded with an antibiotic before implantation to prevent infection.

Composite Vein Grafts

A composite graft of autogenous vein and synthetic, usually PTFE, may be the surgeon's choice as a substitute for an insufficient length of saphenous vein. The prosthetic graft is anastomosed to a segment of reversed or in situ autogenous vein. The prosthetic graft is cut to match the diameter of the vein.

Conservative Interventional Techniques

Peripheral vascular disease is often managed by a team of collaborating vascular surgeons, cardiologists, and radiologists. Multifaceted care encompasses invasive interventional procedures to treat occlusive disease conservatively. Endovascular procedures are considered minimally invasive conservative management. Vascular instruments and supplies for an open surgical procedure should be immediately available in the event a vessel is perforated or injured during any of the conservative interventional techniques. A perforation may be closed with sutures; a patch graft, in situ conduit, or synthetic prosthesis may be required.

Percutaneous Transluminal Angioplasty

Severe ischemia or incapacitating claudication (pain in a limb) resulting from localized or segmental stenosis or occlusive disease can be conservatively treated by recanalization to restore the lumen in the obstructed vessel.

Atherosclerosis in the iliac, femoral, and popliteal arteries is the most common indication for percutaneous transluminal angioplasty (PTA). Cardiac stents can be placed for coronary artery blockages. Stenosis in the renal arteries also can be treated. Stenotic renal arteries cause hypertension.

PTA is performed under local anesthesia and fluoroscopy, often in the interventional radiology department by a radiologist, in the angiography or cardiac catheterization laboratory by a cardiologist, or in the OR by a surgeon.

The area over the target vessel is anesthetized by local infiltration. In the Seldinger technique the artery is punctured percutaneously with a large-bore needle and a guidewire is introduced through the lumen of the needle. The needle is withdrawn and a plastic dilator sheath is advanced over the guidewire into the vessel. The guidewire is removed once the dilator sheath is seated in the vessel. Care is taken to secure the guidewire on the sterile instrument table in case it is needed again. The endovascular device is passed through the dilator sheath for the performance of several types of percutaneous intravascular procedures. The sheath can be peeled back and removed once the endovascular device is in place. Various techniques are used to dilate a stenotic lesion or displace or ablate a plaque by endovascular methods.

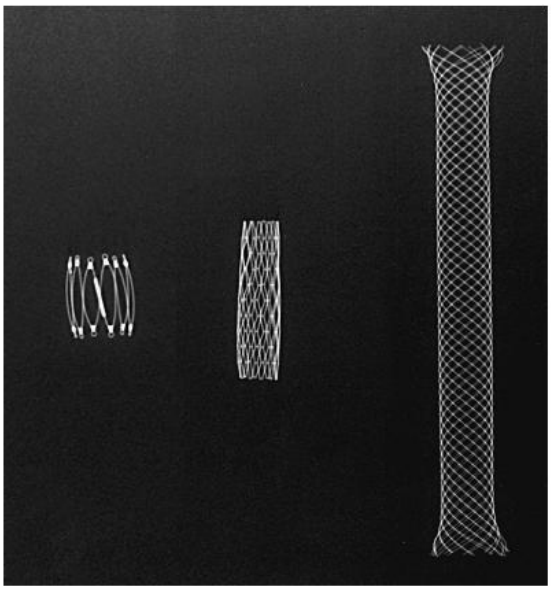
Balloon Angioplasty

A Gruentzig or other type of balloon dilation endovascular catheter is passed over the guidewire and positioned across the lesion. Catheters of several diameters with balloons of various widths and lengths are available. Determination of the appropriate balloon size and length is made on the basis of angiogram findings. When the balloon is inflated with a saline-based contrast medium, atheromatous material is compressed and displaced against the arterial wall. It remolds and cracks, splitting the plaque and intima (inner lining) and stretching the media (middle layer) and adventitia

(outer layer), thus dilating the lumen of a stenosis or recanalizing an occlusion. The balloon is repeatedly inflated and deflated until the lumen is dilated. Balloon angioplasty is done before expanding a stent in the dilated lumen to maintain patency.

Intraluminal Stent

A prosthetic stent may be placed along the vessel wall to maintain patency after endovascular balloon dilation. The Palmaz stent, for example, is a stainless steel mesh tube mounted coaxially on a balloon angioplasty catheter. After the stent is positioned in the artery the balloon is inflated to expand the stent. The stent remains in place when the balloon is deflated and removed. Stents made of titanium, polypropylene, or other materials either operate in a similar manner or are self-expanding (Fig. 44.9).



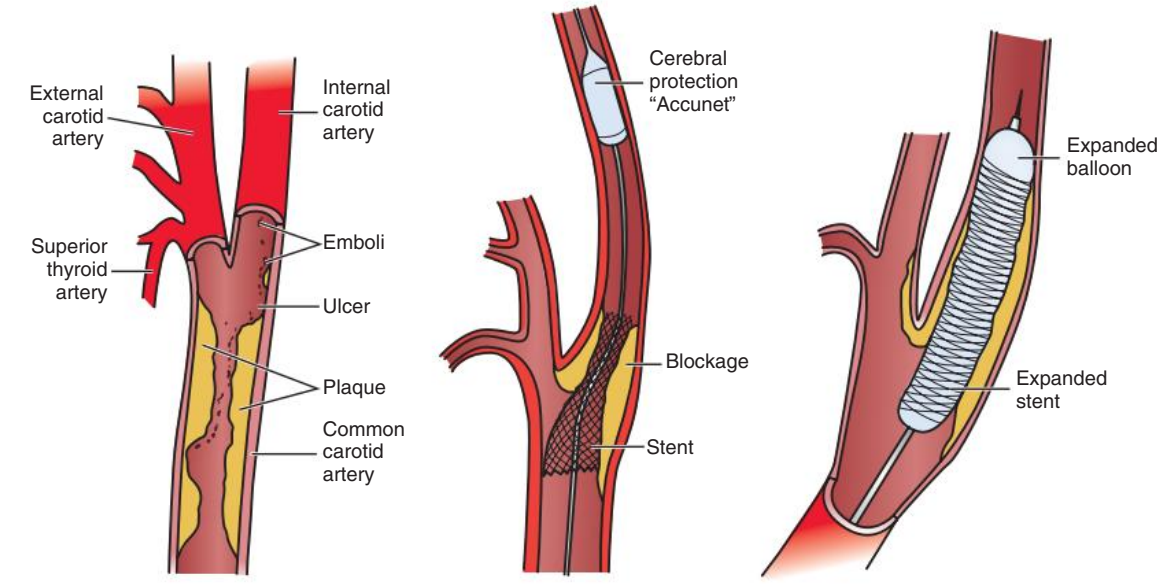
• **Fig. 44.9** Examples of intraluminal vascular stents.

A specialized method of performing carotid stenting uses a cerebroprotective guidewire and netlike sheath to prevent migration of particulate to the brain (Fig. 44.10). The protective net is positioned before the stent is inserted and deployed. Carotid stents are not always as effective as stents used in other vessels. The postoperative complications such as ischemic stroke are shown in studies to be higher in endovascular patients than in those who had conventional open endarterectomy.

Laser Angioplasty

With laser angioplasty a laser fiber is introduced into an occluded artery to destroy plaque or thrombi. The laser usually is used to supplement balloon angioplasty. The procedure may be done percutaneously or as an open surgical procedure via an angioscope. Several different types of laser probes are available. The physician selects the most appropriate probe on the basis of the location and size of the artery and the determination of the degree of calcification in plaque or other cause of obstruction. The delivery system determines the mechanism of action, as follows:

- *Thermal laser:* A thermal laser uses argon or neodymium:yttrium aluminum garnet (Nd:YAG) laser energy to heat the tip of a metal probe at the end of a fiberoptic catheter to a temperature between 392° F and 752° F (200° C and 400° C). Plaque is vaporized as the tip is moved through the obstruction. This "hot-tip" technique may cause some damage to vessel walls. The laser fiber may be positioned within a balloon to destroy the thrombus selectively or seal the arterial wall while the vessel is dilated. A temperature between 203° F and 230° F (95° C and 110° C) in the surrounding tissues dries and disintegrates the thrombus. The combination of pressure from the inflated balloon and diffuse laser energy adheres the loose flaps of arterial tissue back onto the arterial wall; this process is known as *arterial welding.*
- *Photothermal laser:* A photothermal laser uses contact Nd:YAG laser energy. A sapphire-tipped probe or catheter heats plaque by a photopic effect at the point of contact for vaporization of



• **Fig. 44.10** Carotid stent placement.

plaque. This is followed by rapid cooling to prevent damage to the intima.

- *Photochemical laser:* A photochemical laser uses an excimer laser with pulsed energy or a tunable dye laser to destroy plaque with minimal generation of heat. With the athermal action of a "cold laser," the intima is not damaged. Heavily calcified plaque cannot be ablated by an excimer laser.
- *Photoablation:* An excimer laser with a special catheter can vaporize plaque by advancing the catheter into the plaque and ablating it with short bursts. The plaque is reduced to tiny particles and absorbed by the surrounding tissue. The use of the excimer laser prevents widespread thermal tissue damage and subsequent stenosis of the vessel.

Intravascular Ultrasonic Energy

An ultrasonic probe on the tip of a catheter can be used to recanalize occluded or stenosed peripheral vessels.

Atherectomy

In an atherectomy, catheter-mounted instruments are used for transluminal removal of atherosclerotic plaque. A high-speed rotating cam, burr, or side cutter is positioned under fluoroscopic guidance. The plaque is pulverized and retrieved to restore the patency of the vessel. These instruments may be used intraoperatively.

Thrombectomy and Embolectomy

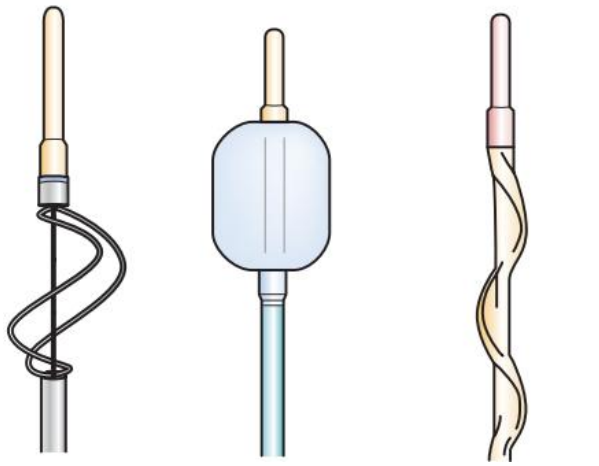
For a thrombectomy and embolectomy a local anesthetic is infiltrated percutaneously. A 2 to 7-Fr Fogarty catheter is inserted proximally and advanced into a vessel distally beyond a soft thrombotic obstruction. The catheter stylet is removed. The balloon on the tip is then inflated with 0.05 to 2 mL injectable heparinized saline solution according to the size of the balloon diameter. The amount of solution that can be safely used to inflate the balloon is listed on the inflation port. The balloon diameters range between 4 and 14 mm. As the catheter is withdrawn, thrombotic or embolic material is removed to restore blood flow to an extremity. Complications of catheter treatment include perforation of the vessel leading to a fistula formation that may need surgical repair.[2,3]

This procedure may be performed with fluoroscopy to selectively cannulate vessels. Different types and sizes of catheters and balloons may be used when the blockage is in a native vessel or an artificial graft (Fig. 44.11). Care is taken to use latex-free catheters when a patient is sensitive to latex products.

Chronic venous insufficiency can develop with repeated venous thrombosis. This is more common in males than females. If the thrombus forms in the deep veins of the leg, valves can be destroyed, resulting in 30% recurrence within a year. The risk for forming venous stasis ulcers is high.[2]

Closure Devices

Arterial closure devices are commonly used to close percutaneous puncture sites in place of manual compression.[4,5] Closure devices come in a variety of sizes and can be specific for an area such as the femoral artery. Various size sheaths contain hemostatic agents or devices. A closure device may deploy suture, sealants, clips, a plug, or a disc. Complications include device failure, infection, and thrombosis.



• **Fig. 44.11** Fogarty embolectomy catheter tips in close-up view.

Thrombolytic Therapy

In thrombolytic therapy, streptokinase, urokinase, or tissue-type plasminogen activator (t-PA) may be administered by local bolus infusion or x-ray–directed catheter into the occluded vessel or directly injected into the thrombus over a period of 12 to 24 hours. Most clots break up within 24 hours. The patient is given IV sedation and local infiltration anesthesia. As the thrombolytic drug enters the vessel the patient will feel a systemic warm feeling. An x-ray contrast medium will be used to monitor the position of the clot. Streptokinase is contraindicated in patients with a streptococcal infection.[3]

The thrombolytic drugs activate plasminogen and cause liquefaction of fibrin, thus dissolving the clot or loosening it for removal by a balloon catheter. Thrombolytic therapy may be used in conjunction with angioplasty or infused intraoperatively, especially in tibial vessels, for lower limb salvage.

Streptokinase

Treatment for DVT, pulmonary embolus, or another clotted vessel is facilitated by the use of streptokinase. Streptokinase is derived from a form of beta-hemolytic streptococci and has an indirect effect that breaks down fibrin. It may not be effective for patients who have antibodies against streptococcus infections. Clots more than 1 week old are not treated with this drug.

The maximum effectiveness of streptokinase is evident within 10 minutes. Reversal of the anticoagulant effect can be accomplished by administering cryoprecipitate or fresh frozen plasma. Some patients have a sensitivity reaction that can progress to anaphylaxis. Pretreatment with antihistamines and steroids may be indicated.

Urokinase

Urokinase is administered directly into the clot with a catheter in an interventional procedure room equipped with x-ray and fluoroscopy capabilities. Care is taken not to damage the endothelial lining of the vessel. Urokinase causes fewer sensitivity reactions than streptokinase, but it is expensive to produce. It is derived from fetal kidney cells and urine, and it is reconstituted with sterile water without a bacteriostatic agent.

Tissue-Type Plasminogen Activator

More recent advances in thrombolytic therapy include t-PA, a chemical that occurs naturally as a secretion of the endothelial cell lining of vessels. However, there is a risk for bleeding when t-PA is used.

Vascular Surgical Procedures

If conservative therapy is unsuccessful or contraindicated, an open surgical procedure may be indicated.

Arterial Bypass

Occlusive disease or trauma may cause arterial blockage, or arterial injury may indirectly occur near the site of a fracture. The vessel lumen located above and below the lesion is usually normal. Vascular reconstruction is performed in an attempt to restore normal circulation. The surgeon selects an appropriate method to bypass the obstruction, as follows:

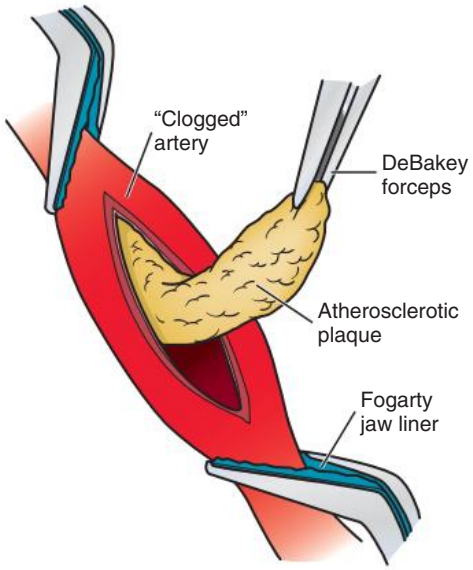
- The involved segment may be excised and the ends anastomosed if they can be approximated without tension.
- If direct anastomosis is impossible, the involved segment is excised, and an autograft or synthetic prosthetic graft is used as a replacement.
- The lesion can be bypassed using the long saphenous vein from one thigh as a vein graft, or a synthetic prosthetic graft may be used. The ends of the graft are anastomosed to the artery proximal and distal to the lesion. The obstructed segment of the artery is not resected.
- The lesion can be bypassed by interposing a prosthetic graft through the subcutaneous tissues between a patent artery and the artery distal to the lesion; this procedure is known as an extraanatomic bypass. For example, in a femoral-femoral bypass the graft is placed from the femoral artery of the unaffected leg to the femoral artery of the ischemic leg. In an axillofemoral bypass the graft is placed from the axillary artery to the femoral artery of the ischemic leg.

Femoropopliteal Bypass

The femoral artery is most prone to obstruction by occlusive vascular disease in a lower extremity. A femoropopliteal bypass, the most commonly performed bypass procedure in an extremity, may be the procedure of choice for severe ischemic disease and limb salvage (Fig. 44.12).

The patient is placed in the supine position on the OR bed with the thigh of the affected leg slightly abducted and the knee flexed and supported. The entire extremity is prepped and draped to allow adequate exposure. Incisions are made over the femoral and popliteal arteries to expose them and explore the area before bypassing the obstruction in the femoral artery. An autogenous in situ saphenous vein graft, PTFE or noncrimped velour graft, or composite graft may be used.

Anastomoses may be visualized with an angioscope. During the surgical procedure, pulsations of the proximal and distal popliteal artery, as well as pulsations in the foot, are checked with a sterile Doppler pulse detector. A skin marker may be used to mark the location of the distal pulses for quick assessment.

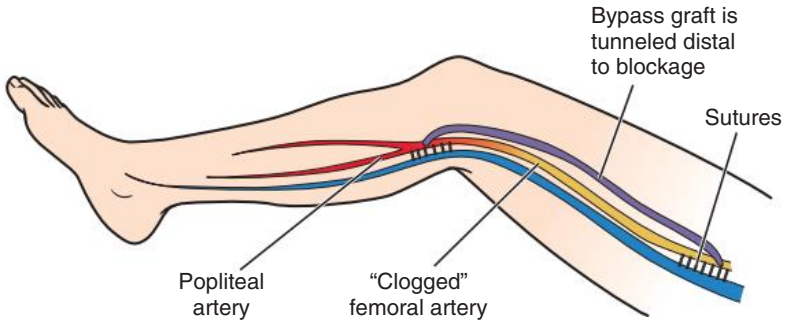


• **Fig. 44.13** Endarterectomy. Removing atherosclerotic plaque from an artery with Fogarty clamps in place.

Endarterectomy

Atherosclerotic plaque may cause localized stenosis in the major peripheral arteries. An **endarterectomy** involves the excision of the diseased endothelial lining of the artery and the occluding atheromatous deposits; this leaves a smooth lining (Fig. 44.13). Loosely attached plaque may be removed by dissection in the media with wire-loop strippers, spatulas, and/or catheters.

A long-segment endarterectomy may be facilitated in the iliac, femoral, and popliteal arteries with a powered Hall oscillating endarterectomy valvulotome or other high-speed drill, to pulverize plaque as described for atherectomy. A saphenous vein or patch graft may be used to close the arteriotomy site. Plaque also



• **Fig. 44.12** Femoropopliteal bypass graft.

can be vaporized from femoral and carotid arteries with a laser. Subsequent inflammation and fibrosis are minimal, and healing is rapid.

Carotid Endarterectomy

One of the most common vascular procedures, a carotid endarterectomy, is performed to prevent a brain attack (stroke) in a patient with severe carotid artery insufficiency.[6] Atherosclerotic plaque at the bifurcation of the common carotid and/or in the internal and external carotid arteries causes localized stenosis or ulceration that impedes cerebral blood flow. Endarterectomy is indicated when this stenosis causes TIAs.

This procedure can be performed with the patient under superficial and deep regional cervical block, or a general anesthesia may be preferred to preserve metabolic demands. The patient should be continuously monitored by electroencephalogram (EEG) or computerized EEG topographic brain mapping (CETBM) to assess cerebral circulation and neurologic deficits.

The patient is placed in the supine position with the head turned away from the affected side. The head is placed in a donut, and a small roll is placed behind the shoulders to hyperextend the neck. Care must be taken not to place undue extension on the neck because such pressure may occlude vertebral arterial blood flow. The skin is prepped without causing excessive pressure or massage over the carotid artery, which could dislodge the plaque and cause an embolic event in the brain.

An oblique, 4-inch incision is made over the lateral neck on the affected side. The subcutaneous tissue, the platysma muscle, and the anterior border of the sternocleidomastoid muscle are incised. Retraction of the sternocleidomastoid muscle and jugular vein allows exposure of the common carotid artery and its internal and external branches.

After systemic heparinization administered by the anesthesia provider, angled vascular instruments are used to clamp above and below the occluded area. In certain instances an intraluminal shunt is inserted in the artery above and below the clamp to bypass blood flow to the brain while the artery is opened and the plaque is removed. Many surgeons routinely use a shunt, whereas other surgeons prefer an alternative means of cerebral protection, such as deliberate production of mild to moderate hypertension or hypercapnia. Cerebral protection during carotid cross-clamping is a primary concern to prevent serious postoperative neurologic complications.

An arteriotomy (incision in an artery) is made in the common carotid artery below the plaque and is extended upward; in the internal and external carotid arteries it begins above the plaque and extends downward. The plaque is dissected free with a swivel-knife or elevator and is removed in its entirety. In addition, most of the underlying media layer is removed. A headlight and magnifying loupes are worn by the surgeon to enhance visibility during dissection and closure of the arteriotomy. To check blood flow a Doppler pulse detector is used after the artery is closed.

A PTFE or saphenous vein patch graft angioplasty or bypass grafting is occasionally necessary if an adequate lumen cannot be established. Bilateral endarterectomies may be indicated for severe bilateral occlusion, but the surgical procedures are performed at least a week apart. Complete occlusion is not amenable to surgical treatment because the pressure in the restored artery can be greater than the distal tissue can tolerate, causing severe damage.

Aneurysmectomy

An **aneurysm** is a localized abnormal dilation in an artery that results from the mechanical pressure of blood on a vessel wall that has been weakened by biochemical alterations. There are three types of aneurysms—pseudoaneurysms, true aneurysms, and dissecting aneurysms.

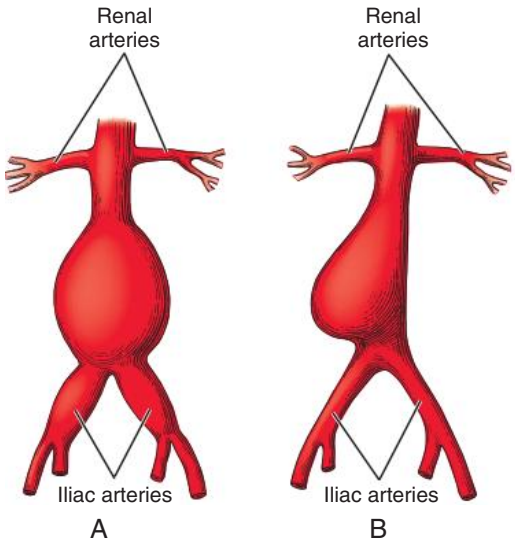
A pseudoaneurysm is usually caused by a break in the integrity of the vessel wall. The integrity can be breached by iatrogenic treatment during vascular procedures such as passing a stent or embolectomy. The pressure from inside the vessel causes all of the layers of the vessel to separate and bulge. This can happen in any artery and requires an open surgical repair.

A **true aneurysm** does not separate all the layers of the arterial wall. The aneurysmal bulge forms in the media layer. These can take two forms—saccular or fusiform. A fusiform aneurysm is a uniform circumferential dilation. Less common is a saccular aneurysm, a saclike outpouching in the media of the vessel wall (Fig. 44.14).

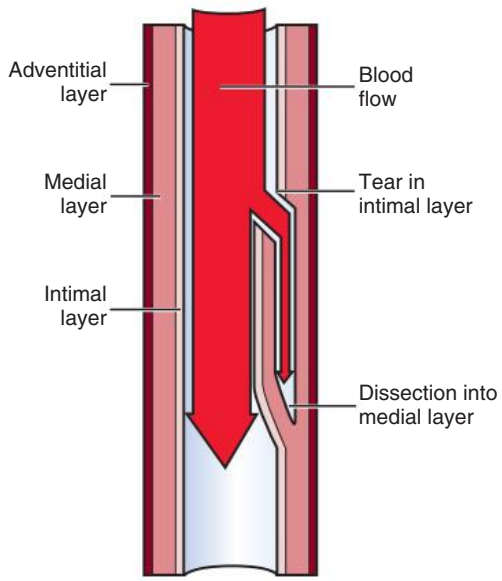
An infection of the lining of the heart (bacterial endocarditis) can predispose the patient to the formation of a **mycotic aneurysm**. The microorganisms form vegetations on the leaflets of the heart valves that are ejected into the arterial circulation. The vegetations attach to a normal or diseased artery wall, causing an aneurysm to form and expand. Mycotic aneurysms can occur in true or pseudoaneurysms, particularly at a point of bifurcation. Most mycotic aneurysms are found in the aorta, but they can occur in the femoral, carotid, cerebral, or brachial arteries. Multiple sites have been found in the same patient and can persist despite surgical treatment.

A **dissecting aneurysm** creates a false passage for blood between the intima and the media. The dissection can extend the full length of the aorta, causing damage to the vascular attachments of major organs such as the bowel and kidneys. Cystic medial necrosis causes a dissecting aneurysm, usually in the thoracic aorta, in which the media separates from the intima (Fig. 44.15).

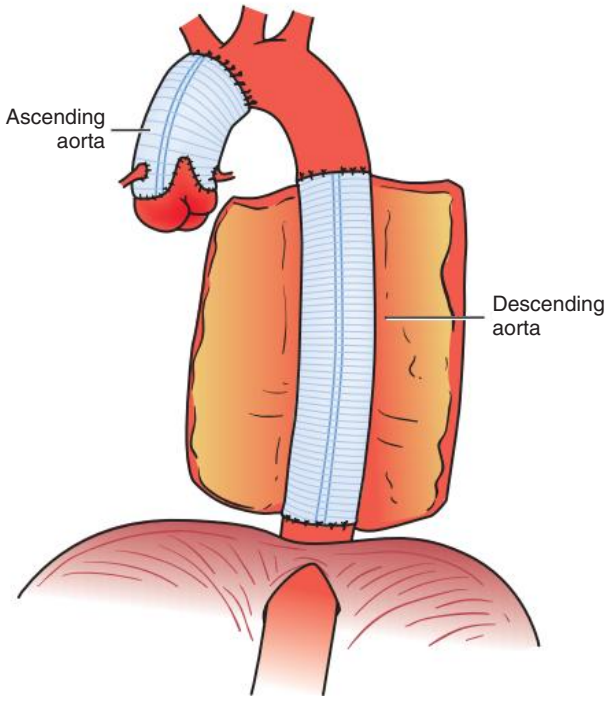
Thoracic dissection requires a thoracotomy and replacement of the diseased portion of the aorta. Fig. 44.16 depicts the repaired ascending and descending aorta using synthetic graft material.



• **Fig. 44.14** Abdominal Aortic Aneurysm between Renal and Iliac Arteries. **A,** Fusiform (circumferential) type. **B,** Saccular (saclike) type.



• **Fig. 44.15** Arterial Dissection. The intimal layer tears, and a false passage develops and fills with blood.



• **Fig. 44.16** Graft Examples for Thoracic Aorta. Thoracic ascending and thoracic descending repairs.

Atherosclerosis is the most common cause of a true aneurysm, but trauma also may be a factor. The abdominal aorta, thoracic aorta, aortic arch, and popliteal arteries are the vessels most often affected. Diagnostic evaluation combines a physical examination, laboratory findings, and the results of ultrasonography, CT scan, MRI, and aortography and/or angiography.

The location and extent of the lesion determine the operability of the aneurysm and the type of reconstruction.[7] For example, cross-clamping of the descending thoracic aorta to remove an aneurysm will impair blood supply to the spinal cord. Preservation methods must be used.

Repair in the arch or ascending aorta can impair cerebral and coronary perfusion. Descending and abdominal aortic aneurysms affect blood flow through the visceral, mesenteric, and renal arteries. Vital structures must be protected during aneurysmectomy.

A ruptured aneurysm is a surgical emergency and precludes further evaluation. A transbrachial or transfemoral occluding balloon catheter may be placed in the aorta to prevent an exsanguinating hemorrhage. The surgical procedure is performed immediately. With a ruptured abdominal aortic aneurysm (AAA), the patient has a mortality rate of 94%.

Open Resection of an Abdominal Aortic Aneurysm

An AAA usually develops between the renal and iliac arteries (infrarenal), although it can occur anywhere along its course. An abdominal aneurysmectomy may be a lifesaving procedure. Serious hazards, including massive hemorrhage, ischemic organs, and injury to ureters and other nearby structures, are associated with the procedure. Renal failure is a potential complication. Modern techniques have greatly reduced elective AAA open resection 30-day mortality to between 2% to 4%. Survivors of the procedure enjoy the same life expectancy as do other patients with comparable atherosclerotic disease. Early detection is key. Resection at 1.8 to 1.9 inch (4.5 to 5 cm) is usually successful.

Constant monitoring of cardiac function with a Swan-Ganz pulmonary artery catheter is used in these high-risk patients. Patients in an unstable condition may require frequent blood gas determinations. Central venous pressure monitoring is a guide for regulating fluid replacement. Blood must be available for transfusion. Autotransfusion may be used if massive hemorrhage is encountered, such as with a ruptured AAA. An indwelling Foley catheter is inserted preoperatively, and urinary output is monitored by the anesthesia provider. Mannitol can be infused before aortic cross-clamping to prevent ischemic renal failure. Prolonged cross-clamping can lead to spinal cord or bowel ischemia.

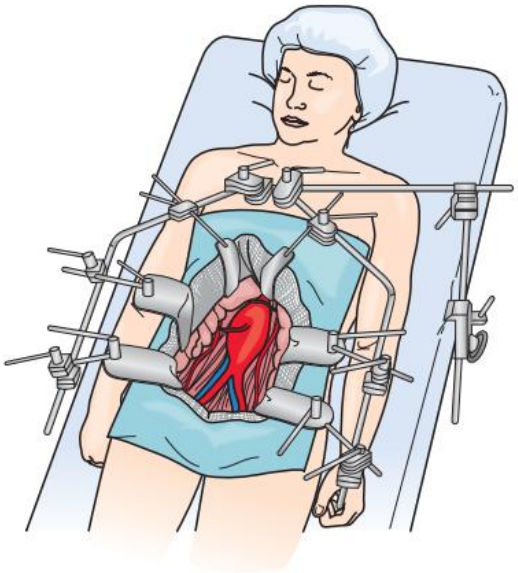
Somatosensory evoked potential (SSEP) monitoring measures primarily dorsal column (sensory) function and minimal anterior cord (motor) function. A time clock should be used to measure the amount of time the aorta is clamped.

Blood flow in the extremities should be checked immediately preoperatively and postoperatively to detect embolic or occlusive problems. Marking the location of the posterior tibial and dorsalis pedis pulses with a marking pen enables rapid location of the appropriate site when they need to be checked intraoperatively. An audible Doppler device generally is used.

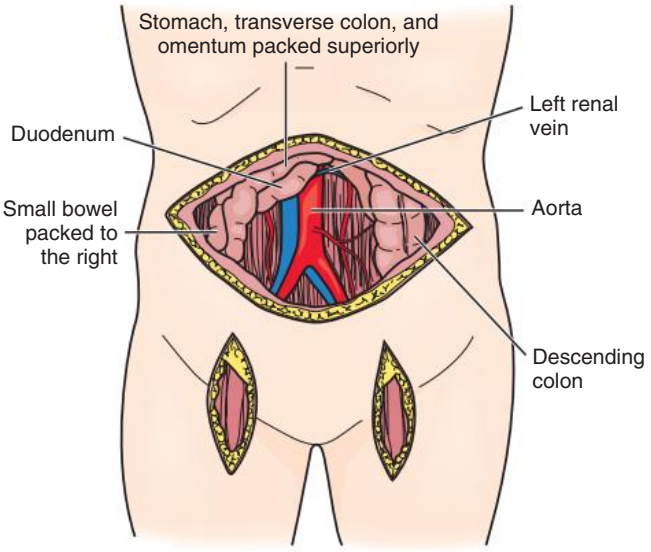
In an open AAA a long midline incision from the xyphoid process to the pubis is used. During surgery for an AAA the abdomen is thoroughly explored, the small intestinal mesentery is mobilized, and the posterior peritoneum overlying the aorta is incised to expose the aneurysm. A bed-mounted, self-retaining abdominal retractor and blades helps provide needed exposure (Fig. 44.17).

The small intestine and ascending colon are delivered outside the abdomen to increase exposure and prevent injury. Warm moist tapes, moist radiopaque towels, Silastic sheeting, or a Lahey (bowel) bag may be used to protect these structures. The incisions will extend into the anterior thighs for exploration of the femoral arteries.

Although the situation may be urgent or emergent, care is taken to account for Silastic sheeting, towels, Lahey bags, and other items used in the abdomen. If counts are aborted because of the patient's condition, documentation in the patient's permanent record should include that the count was not performed, as well



• **Fig. 44.17** Abdominal aorta exposure for resection.



• **Fig. 44.18** Incisions used for aortic aneurysms that involve the femoral arteries.

as the reason for not performing it. The count should not be listed as incorrect. An abdominal x-ray should be obtained as the patient's condition permits. If known items are packed into the patient for later removal, the numbers and types of items should be documented on the patient's record and reported in the hand-off report to the postanesthesia care unit (PACU).

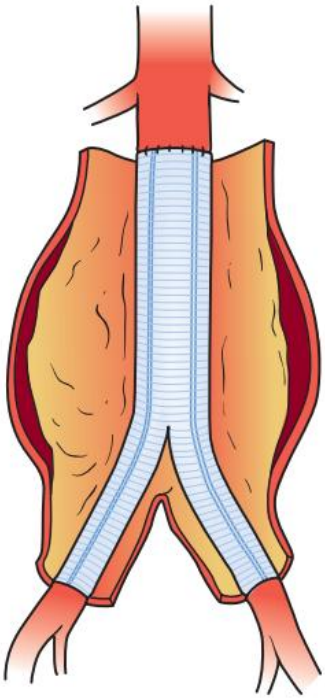
An extended posterior retroperitoneal approach may be preferred, especially in a patient who is obese or has had previous abdominal surgery. The patient is placed in the right lateral position with the left side up. An oblique flank incision is extended along the superior margin of the twelfth rib, which may be resected. The entire abdominal aorta and left renal artery are exposed by opening the retroperitoneum without needing to enter the pleural or peritoneal cavities.

The kidney, ureter, and peritoneal sac are reflected anteromedially and packed with moist tapes. Exposure is maintained with self-retaining and handheld retractors. If access to the iliac or femoral arteries is required, the patient's hips are rotated to a semiprone position, and longitudinal incisions are made in the bilateral groins (Fig. 44.18).

Before occlusion of the aorta, blood is drawn if needed for preclotting the graft. Heparin is injected by the anesthesia provider for anticoagulation. Aortic clamps are placed proximal to the aneurysm, and the iliac arteries are clamped distally. The distal aortic stump or iliac arteries may be closed with staples. If the aneurysmal wall is opened, clots and loose intraluminal debris are removed. A tube graft is used if the aneurysm is confined to the aorta. More commonly, a bifurcated graft is sutured in place above the aneurysm and to the common iliac or femoral arteries distally (Fig. 44.19).

Branches of other arteries are anastomosed to the graft as necessary, depending on the segment of aorta being replaced. The graft is commonly placed inside the aneurysm (open inclusion method), and the sac is closed over the graft. With the less commonly used closed exclusion method, the graft is placed beside the unopened aneurysm sac.

Living tissue, either the aneurysm sac or the mesentery, must cover the prosthesis to prevent contact of the prosthesis with the intestines; otherwise a fistula can develop. After the aortic clamps are released, the anastomoses are checked for leakage. The incision

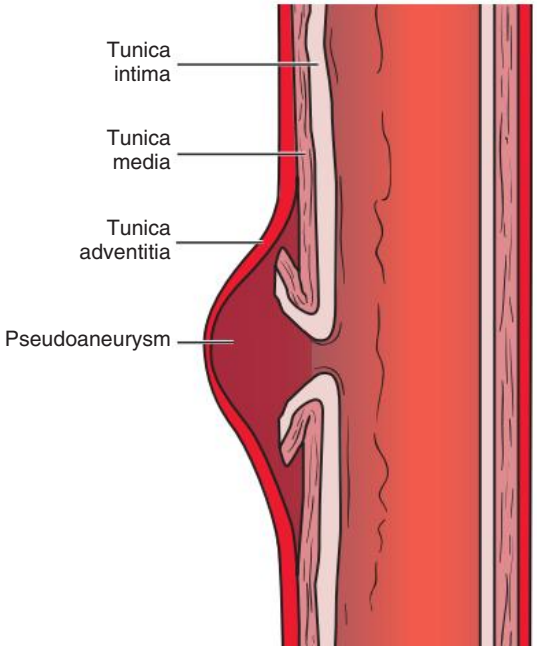


• **Fig. 44.19** Abdominal Aortic Graft Example. The abdominal aorta and bilateral femoral arteries have been repaired with synthetic graft material.

is usually closed with nonabsorbable sutures; retention sutures are commonly used to support a long midline abdominal incision.

Pseudoaneurysm

Injury to the arterial layers causes blood to accumulate in the local connective tissue surrounding the vessel, forming an enlarging bulge that can rupture and hemorrhage. **Pseudoaneurysm**, sometimes referred to as a false aneurysm, commonly arises from an iatrogenic source. One example, is an arterial intravascular procedure such as cardiac catheterization. The most common site is the femoral artery. Pseudoaneurysm differs from true aneurysm because it is caused by an outside source rather than vascular pathology (Fig. 44.20).



• **Fig. 44.20** Pseudoaneurysm. The endothelial (tunica intima) and the muscular (tunica media) layers separate, causing a bulge in the outer connective tissue layer of the artery.

Repair of a pseudoaneurysm is performed in the OR and may require the use of a small patch of natural or synthetic graft. Some success has been achieved with localized thrombin injection under ultrasound guidance. Complications include embolization and compression of nerves and tissues in the area.

Endovascular Repair of Abdominal Aortic Aneurysm

Endovascular AAA repair has the same indications as an open repair. The risk for rupture increases as the diameter of the aneurysm expands, especially if the diameter exceeds 0.5 cm per year. Not all AAAs can be repaired via the endovascular route. Anatomic criteria include having an adequate length of aorta between the renal arteries, the iliac arteries, and the aneurysmal bulge. The anatomic diameter of the aorta cannot exceed 28 mm, or the graft will not work.

Endovascular grafts can be modular or one piece with limbs that extend into the iliac arteries[7] (Fig. 44.21). The procedure is done by performing bilateral femoral cut-downs and placing guidewires cephalad into the aorta through the femoral artery on the ipsilateral (closest) side.

Aortograms are performed using full-strength contrast medium and a power injector. For a modular aortic stent the first limb and body of the graft are placed up the guidewire using C-arm guidance and deployed into position. It is pulled caudad into position in the ipsilateral iliac artery and expanded with a balloon filled with half-strength contrast medium to seat the anchors. The second limb is introduced via the contralateral femoral artery and deployed. A unibody design with both limbs attached is positioned in the same manner; however, both distal limbs are seated into the iliac arteries at the same time and expanded.

Advantages of endovascular repair include smaller incisions, less blood loss, and shorter hospital stay. Disadvantages include the possibility of converting to an open method if a complication arises, lack of long-term evaluation of the procedure in humans, endo leak, embolism, and renal artery occlusion.[8] Graft-related complications can lead to the need for additional procedures. Morbidity and mortality rates for open and endovascular AAA repair are comparable.

Standby instrumentation for an open procedure is a must. Blood salvage devices should be used. Doppler and warming/cooling devices should be used as needed throughout the procedure. The team should exercise all precautions for blood and radiation exposure. The guidewires and graft deployment devices are very long and require an extended sterile table setup.

Embolectomy

An embolus is a mass of undissolved matter carried by the bloodstream until it lodges in a blood vessel and occludes it. An embolus may be an air bubble, fat globule, blood clot, clump of bacteria, piece of tissue, or foreign body. The occlusion of a blood vessel by an embolus causes various symptoms depending on the size and location. The occlusion of a vessel in the brain, lungs, or heart can cause rapid and sudden death.

Surgical intervention is the primary treatment for an embolus unless contraindicated. Select patients may be treated with heparin, vasodilators, and perhaps sympathetic blocks. Renal or mesenteric emboli are usually treated by surgical embolectomy or bypass grafting. With an embolectomy the affected blood vessel is incised and the embolus is removed.

Pulmonary Embolus

The occlusion of a pulmonary artery or one of its branches usually occurs with emboli that originate from veins in the lower extremities or pelvis. Emboli pass up the inferior vena cava to the right side of the heart and are ejected from the right ventricle into the pulmonary artery. A pulmonary embolism may be diagnosed by lung scans, pulmonary angiograms, and phlebograms.

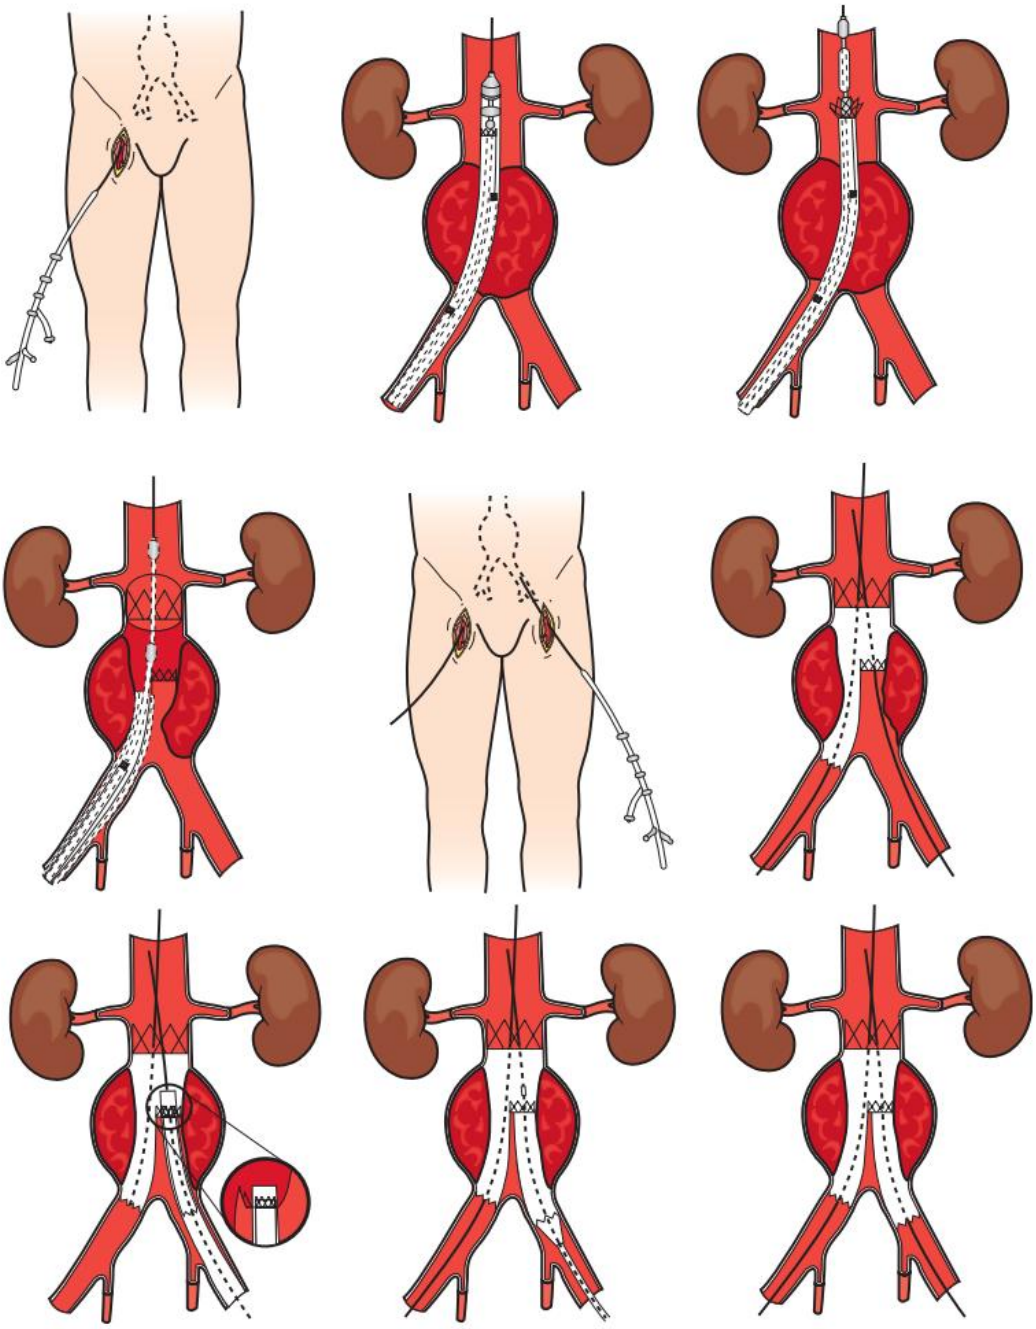
Pulmonary Embolectomy

A massive pulmonary embolism can cause irreversible cardiac arrest or profound refractory hypotension and hypoxemia. If portable cardiopulmonary bypass equipment is available, cannulas can be inserted at the patient's bedside or in the emergency department or intensive care unit. The patient is then transported to the OR. A median sternotomy is performed to establish total cardiopulmonary bypass and allow access to the pulmonary artery.

Large pulmonary emboli are removed by manual extraction (Trendelenburg's operation), the passage of forceps into both the right and left pulmonary arteries, the passage of balloon catheters into pulmonary arterial segments, and squeezing both lungs to force peripheral thrombi through a pulmonary arteriotomy.[3] The incision can be extended for vena cava ligation to prevent recurrent embolization.

Pulmonary Thromboendarterectomy

Chronic pulmonary thromboembolic disease may develop from failure to resolve a massive pulmonary embolus, repeated embolic episodes, or a combination of both. The removal of obstructions in the main pulmonary arteries by thromboendarterectomy improves right cardiac hemodynamics. The procedure is performed with the patient under induced hypothermia and cardiopulmonary bypass; thrombi are removed from the upper, middle, and lower branches of the right pulmonary artery and then from the left pulmonary artery.



• **Fig. 44.21** Endovascular repair (ipsilateral and contralateral) of abdominal aortic aneurysm with a modular endograft.

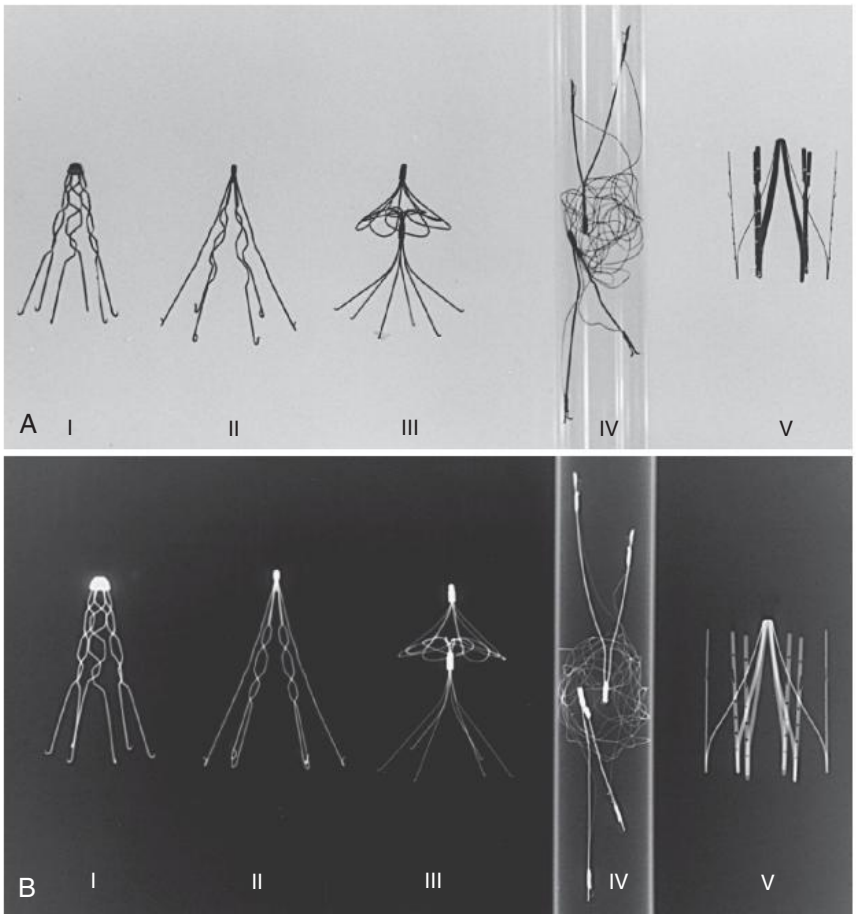
Vena Cava Filter

Venous stasis in the deep veins of the lower extremities and pelvis can cause clotting and the potential for embolization via the vena cava through the right atrium to the lungs. Patient conditions that require prophylactic protection from venous embolization are described in Box 44.3. A specialized endovascular filter can be placed via the right jugular or femoral vein under fluoroscopic visualization into the vena cava to prevent emboli from traveling to the lungs (Fig. 44.22). The filter is seated above or below the renal arteries depending on the location of the venous thrombus. The ideal filter should have the following characteristics:

- Low cost
- Lifetime of device is not time limited

• BOX 44.3 Patient Conditions That Require Prophylactic Protection from Venous Embolization

- Anticoagulants are contraindicated
- History of pulmonary embolus
- Closed-head injury
- Paralytic spinal cord injury and immobility
- Pelvic fractures
- Long-bone fractures
- Poor cardiovascular reserve
- Malignancies that cause hypercoagulation



• **Fig. 44.22** Vena Cava Filters. *Left to right:* Kimray-Greenfield, Titanium Greenfield, Simon-Nitinol, Gianturco Bird's Nest, Vena Tech. **A,** Actual filters. **B,** Radiographic images.

- High filtration without flow interruption
- Low access site thrombosis
- Small-caliber percutaneous insertion and deployment devices
- Repositioned or removed easily
- Secure fixation to vessel wall
- MRI friendly (nonmagnetic)

Vena cava filters are classified as permanent or temporary. Permanent titanium filters are designed to endothelialize to the vessel wall in as soon as 12 days. A clot that is ensnared in the filter eventually dissolves. The Greenfield filter is a permanent implant that traps and holds clots of 3 mm or larger. If preferred, it can be placed through the femoral vein over a guidewire to the level of L2-L3.

The permanent Mobin-Uddin umbrella filter or Greenfield filter is a cone-shaped titanium filter that measures 4.6 cm from apex to base and is ejected and fixed in position below the renal veins and above the point of juncture of the iliac veins. Hook-like prongs anchor the device in the correct orientation to collect clots.

Angiography may be performed during the vena cava filter placement procedure, and the appropriate contrast medium should be readily available. For a high-risk patient a filter may be placed at the completion of a diagnostic angiogram. A patient with an enlarged, dilated caval lumen 0.3 mm in diameter caused by right heart failure may require placement of a filter in each iliac artery.

The Filcard or Amplatz temporary vena cava filter can be repositioned or removed. Bard has designed the Recovery Filter, which can be removed using the Recovery Cone system for retrieval of the vena cava device. The Gunther Tulip vena cava filter manufactured by Cook allows percutaneous insertion and retrieval from 10 to 14 days after insertion and may be useful for either permanent or temporary prophylaxis against pulmonary embolism. Temporary filters can be placed through the brachial or femoral arteries. Prolonged placement may result in unsuccessful retrieval.

A titanium filter does not interfere with CT scans or MRI, but the radiologist should be informed of its presence before any imaging procedure is performed. Older stainless steel models cause distortion on imaging scans and are not safe during MRI because of the magnetic qualities and superheating of the metal. Patients with vena cava filters should be instructed to carry wallet cards with the make and model of filter implanted. After filter placement the patient usually begins anticoagulant therapy.

Complications include lower extremity edema, which may indicate an obstruction in the filter that requires prompt medical thrombolytic attention.[9] Other potential complications include premature deployment of the device or migration toward the right atrium. If the device cannot be repositioned by endovascular methods, an open surgical procedure may be performed.

If a vena cava filter cannot be placed, the blood flow within the vena cava may be partially interrupted or plicated with specialized Moretz clips using an open abdominal retroperitoneal approach. This allows blood to return to the right ventricle of the heart without passage of the emboli to the lungs.

Venous Stasis Disease

When the valves of the veins fail to function normally, increased back pressure of blood causes the veins to become dilated, tortuous, or elongated. These are known as varicose veins. Pain and secondary complications, such as thrombophlebitis and venous stasis ulcers, may follow. It is believed there is a familial tendency toward varicosities caused by incompetent valves, which afflicts both males and females. Habitual long periods of standing, repeated pregnancies, and obesity are other predisposing factors.

A procedure may be performed to bypass a venous obstruction, such as iliac-venous occlusion or femoropopliteal occlusion. Venous valve repair (valvuloplasty) or venous valve transposition may be performed to correct femoral valvular incompetence and severe venous stasis and to salvage the saphenous vein. The perforator or superficial femoral veins may be ligated for severe venous stasis with marked fibrosis and ulcerations. Injection-compression sclerotherapy to treat varicose veins may be preferred to surgical treatment.

Ligation and Stripping of Varicose Veins

For ligation and stripping of varicose veins in a leg the saphenous vein is excised in toto with the aid of a semiflexible stripping device; this procedure begins at the ankle. Additional incisions are made along the course of the vein to ligate perforator branches as the stripper is moved upward toward the groin. Perforators and branches are occluded with ligating clips and transected. At the groin an incision is made over the palpated stripper, and the vein is ligated at the saphenofemoral junction.

Preoperatively the surgeon may mark areas of varicosity for incision with the patient standing at the bedside. Some surgeons use indelible markers. During the skin prep, care is taken not to wash away the markings and not to massage areas of potential thrombus accumulation. After closure of the incisions and the application of dressings, the full length of the leg is wrapped in cotton elastic bandages for compression.

Fasciotomy

Decompression by fasciotomy is the treatment of choice for the prevention of compartment syndrome after acute ischemia in the upper or lower extremity. Vascular compromise can occur after a penetrating or crush injury. Release of the overlying fascia may be indicated for clinical evidence of increased pressure, such as pain, edema, pallor, and diminished sensation.

Epidural Spinal Electrical Stimulation

Epidural spinal electrical stimulation (ESES) may be used to improve nutritional blood flow in patients with severe lower limb ischemia. This can lead to the healing of ischemic ulcers. ESES uses a microscope connected to a television camera, television monitor, and video recorder. Intravital capillary microscopy is performed before and after ESES to measure red blood cell velocity in skin capillaries. With the patient in a sitting position, the dorsum of the foot is placed over the microscope. Fluorescein dye is injected IV, and the time for perfusion of the capillaries is measured. With the patient under local anesthesia and x-ray control, an epidural electrode is placed parallel to the spinal column. After stimulation of the electrode, perfusion in the foot is tested again.

Vascular Shunts

Normal circulation can be altered to increase or decrease blood flow to a specific organ, either temporarily or permanently. A vascular anastomosis or prosthetic device may be used to establish a route for the diversion of blood flow. For example, vascular isolation of the liver can be achieved with an atrial caval shunt. This shunt permits continuous venous return to the ventricle to sustain cardiac output during the repair of traumatized suprahepatic or retrohepatic vena cava and/or hepatic veins. A straight tube or inflatable balloon catheter may be inserted to establish the shunt.

Portosystemic Shunts

A shunt between the portal and systemic venous systems is definitive treatment for esophageal varices complicated by portal hypertension. This surgical procedure may be only palliative. Many patients have progressive liver disease that eventually leads to liver and right-sided heart failure. Shunting does not repair an already damaged liver but can prevent further hemorrhage. Portal hypertension is an increase in portal venous pressure and is caused by the obstruction to intrahepatic blood flow as a result of cirrhosis, hepatitis, or thrombosis. The increased pressure results in venous dilation that causes esophageal varices. The patient also may have ascites. The purpose of the surgical procedure is to reduce portal hypertension and/or portal venous blood flow. The surgeon selects the most appropriate type of shunt to achieve the purpose.

Distal Splenorenal Shunt

Known as the Warren shunt, this procedure involves anastomosis between the splenic vein and the left renal vein. The hilum of the spleen and the tail of the pancreas are exposed through a left subcostal incision. The splenic vein is completely dissected from the pancreas to its bifurcation at the splenic hilum. This technical maneuver preserves portal profusion but eliminates collateral circulation to control bleeding from gastric and esophageal varices by decompression. The splenoportal system must be patent, and there must be adequate distance between the splenic and renal veins for the anastomosis.

An autogenous jugular or external iliac vein graft may be interposed to ensure a tension-free splenorenal anastomosis. A splenectomy may be performed. Other modifications may be made to meet specific patient circumstances.

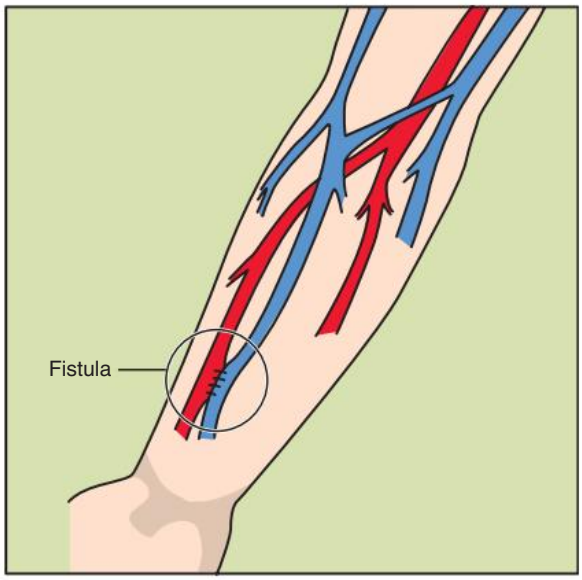
Mesocaval Shunt

A mesocaval shunt is an option if a splenic vein is too small for a successful splenorenal shunt. A superior mesenteric inferior vena caval shunt is well tolerated by young patients. With a mesocaval shunt the side of the superior mesenteric vein may be anastomosed to the proximal end of the divided inferior vena cava. An interposition autologous vein or synthetic H-graft also may be used to create a shunt between the inferior vena cava and the superior mesenteric vein.

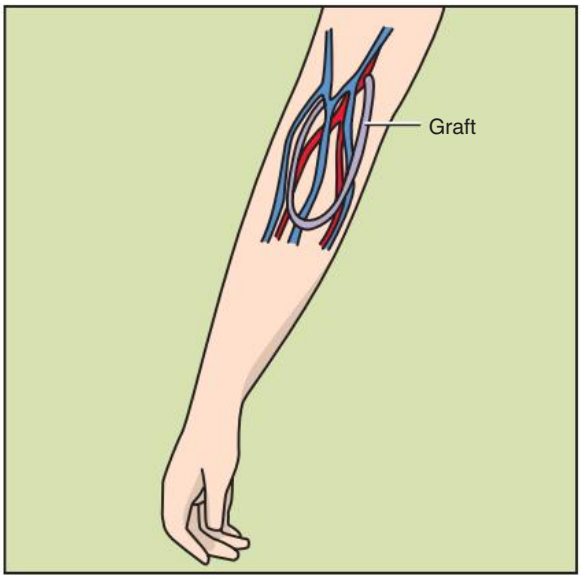
Portacaval Shunt

A portacaval shunt may be performed with end-to-side or side-to-side anastomosis between the portal vein and inferior vena cava, or with an interposition H-graft inserted between the portal vein and inferior vena cava. A ringed PTFE graft may be used, or an autologous graft may be obtained from an internal jugular or saphenous vein. The shunt relieves hypertension by bypassing the obstruction and diverting the return flow of blood to the liver from the portal vein, thus decompressing esophageal varices.

Depending on the type of portosystemic shunt planned by the surgeon, either a subcostal or transabdominal incision may be used. Two suction setups should be available to evacuate the



• **Fig. 44.23** Internal arteriovenous dialysis fistula.



• **Fig. 44.24** Internal dialysis graft.

copious amounts of ascitic fluid that can be anticipated when the peritoneum is opened. Both abdominal and vascular setups are prepared.

Pressure within the portal vein is measured with a manometer, via a cannulated branch of the superior mesenteric vein, at the beginning and at the conclusion of the surgical procedure. Because of venous distention and the vascularity of the surgical area, hemorrhage is a major intraoperative hazard. Care is taken to avoid injury to adjacent structures, including the hepatic artery and the common bile duct.

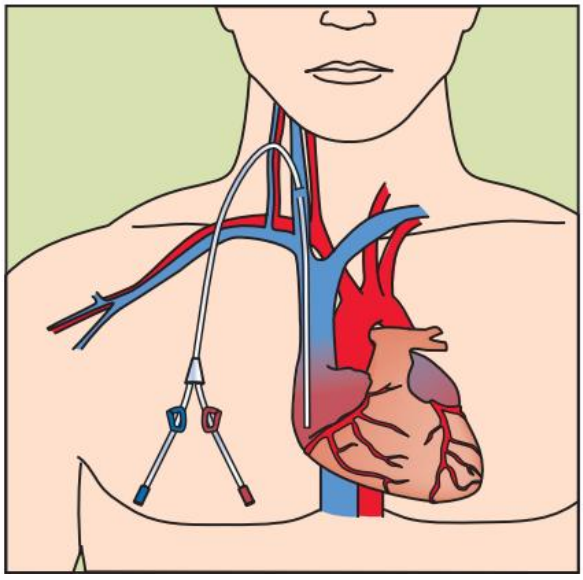
Arteriovenous Shunts and Fistulas

With arteriovenous shunts and fistulas, blood flow from an artery to a vein is established directly and without going through the capillary network. Access to the vascular system through an arteriovenous shunt or fistula is necessary for a patient who is suffering from end-stage renal disease and who is being maintained on long-term chronic **hemodialysis**.

With the patient under local anesthesia the endogenous Cimino-Brescia arteriovenous fistula is established internally at the wrist by anastomosis between the radial artery and cephalic vein (Fig. 44.23). This method has the longest functional life of dialysis methods with fewer infections and thrombotic events. This method takes 3 to 4 months to mature before the fistula can be used for dialysis. Creation of a fistula is contraindicated in diabetic patients and patients with peripheral vascular disease.

If the vessels of the wrist and arm are inadequate, a synthetic PTFE graft may be interposed between the artery and vein (Fig. 44.24). A loop fistula may be created with a graft from the brachial artery to the cephalic or basilic vein in the antecubital fossa or from the brachial artery to the axillary vein in the upper arm. A graft access must mature for 3 to 6 weeks before use. The incidence of thrombosis is high.

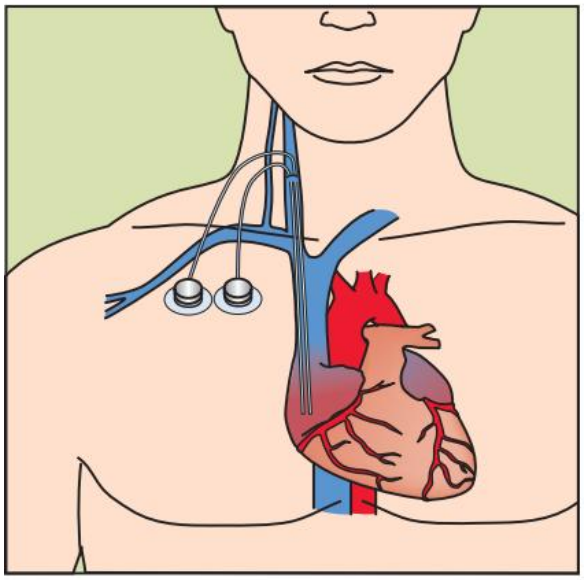
Enzymatically treated bovine carotid artery xenografts are used occasionally to create arteriovenous shunts or fistulas. Thrombosis and infection are the most common complications. Using a Fogarty balloon catheter, a thrombectomy may reestablish patency. Total explantation of the graft is necessary in the event of a generalized infection.



• **Fig. 44.25** External dialysis catheter.

An external double-lumen dialysis catheter with inflow and outflow tubing that is inserted in the jugular vein to the right atrium can be used for hemodialysis (Fig. 44.25). This type of access is easily inserted and can be used immediately after placement. There is no pain associated with connecting as with percutaneous puncture to access a subcutaneous graft or fistula. Care is taken because these catheters are easily infected and thrombosed. The average usefulness of a catheter is 3 to 6 months. They can be replaced quickly when a problem occurs.

A hemodialysis double-port valve system can be implanted in the anterior chest with two catheters into the right jugular vein to the right atrium (Fig. 44.26). If the right jugular cannot be used, the catheters are passed through the right subclavian vein instead. Placement of the port valves should be planned for patient comfort and tissue stability at 10 or 15 mm beneath the surface of the skin. Pockets are created under the skin in an area that is not compressed by clothing or shoulder straps of handbags.



• **Fig. 44.26** Internal dialysis port system.

The exit valve is place laterally and the return valve is placed medially. Standardized placement helps prevent errors during cannulation of the valves during dialysis.

Vascular Anastomosis

The operating microscope is needed for microvascular anastomosis of small vessels to revascularize tissue. Patency of the anastomosis depends on factors related to blood flow, coagulation, and vessel spasm. The vessels must be approximated without trapping adventitia in the lumen. Collagen fibers, tissue thromboplastin, and other thrombogenic factors in the adventitia predispose the patient to rapid platelet aggregation that may cause thrombus formation. Interrupted sutures are placed through the full thickness of the vessel wall (i.e., adventitia, media, and intima).

Veins are technically more difficult to anastomose than are arteries, because their walls are thinner and have less substantial muscularis. Anastomoses may be end-to-end or side-to-side. An interpositional vein graft may be needed to add length or to bridge a gap between the ends of either an artery or a vein. A patent artery should pulsate distal to the anastomosis. Although this procedure is used most commonly for tissue transplantation (e.g., vascularized free flaps or replants such as severed digits), the peripheral vascular surgeon may be needed to assist with vascular problems that require microvascular techniques.

Laser-assisted vascular anastomosis, also referred to as vascular tissue welding, fuses medium-size (6 to 8-mm) vessels together to form an anastomosis. The adventitial surface is less thrombogenic than it is after suturing and heals faster with less scar tissue. The argon laser is used for this technique. It may be used to create an arteriovenous shunt at the wrist for hemodialysis, to reattach severed limbs, and to repair damaged vessels.

Limb Salvage

Amputation of a lower extremity may be required for peripheral vascular disease or lymphedema with lymphangitis. All efforts are made to salvage the limb; amputation is the last resort. Ischemia can cause debilitating pain, skin ulcers, and gangrene, often secondary to smoking or diabetes. Revascularization by the techniques described in this chapter may save the patient from the emotional trauma of amputation. This is a prime objective of the peripheral vascular surgeon.

Organ Procurement and Transplantation

CHAPTER OUTLINE

CHAPTER OBJECTIVES

After studying this chapter, the learner will be able to:

- List the criteria for validating brain death.
- Describe the testing performed on tissue before it is suitable for transplantation.
- Discuss the role of the host procurement facility.
- Discuss the psychologic effect of a transplant on the donor and recipient families.

KEY TERMS AND DEFINITIONS

Apnea The absence of breathing.
Benching The sterile process of preparing an organ or tissue for transport to a receiving facility for transplant.
Benching table A sterile field established away from the primary sterile field for the preparation of an organ or tissue for transplant.
Brain death No brain function and no reflexes.
Donor Person, living or dead who gives an organ or tissue to another person.
En bloc Multiple organs are procured from a donor with vascular and other communications intact.
Procurement The process of surgical removal of an organ or tissue from a donor.
Recipient The person who receives tissue or an organ from another person.
Transplant The process of taking tissue or an organ from one person and surgically placing it into another person.

Types of Transplants

Transplantation is the transfer of an organ or tissue from one person to another or from one body part to another. Concentrated efforts continue in search of compensation for or suitable replacements for deficient tissues and organs. The indication for organ transplantation is irreversible functional failure of the organ. The goals of transplantation include changing appearance, restoring function, or improving quality of life. (More information is available at www.unos.org and www.organdonor.gov.)

Certain tissues and whole organs can be transplanted and grafted to restore bodily function. The type of **transplant** selected depends on the purpose of the graft, anatomic function, and availability of the tissue or organ. The types of biologic transplants are listed in Box 45.1.

Tissue Transplantation

Some tissues can function normally even after being moved from one area of the patient's body to another (autologous) or after being obtained from another human **donor** (allogenous), as follows:

- Skin grafts provide a protective surface covering, initially acquiring and then eventually losing vascular connection with the host.
- Corneal grafts replace nonfunctioning corneal tissue.
- Bone grafts afford temporary structural supports and a pattern for regrowth of the host's bone; the grafts are then resorbed.
- Ossicles and the tympanic membrane in the ear can be transplanted to restore bone-conduction hearing loss.
- Cartilage restores contour in a defect of cartilaginous facial structures.
- Blood vessel grafts bypass or replace diseased or obstructed segments of vessels.
- Bone marrow restores hematologic and immunologic functions.
- Heart valves replace stenosed or diseased valves.

Tissue transplants can be either autografts or allografts. Xenograft (from another species) transplants are in the research phases. The American Association of Tissue Banks sets standards for retrieving, processing, storing, and labeling tissues and for donor criteria for allografts (Box 45.2). Tissue for transplantation is procured from suitable cadaver (nonliving or brain dead) donors, either heartbeating or nonheartbeating, or from a living donor. Table 45.1 details the **procurement** parameters for tissue allografts. (Additional information is available from the National Institute of Transplantation at the United Network for Organ Sharing at www.unos.org.)

• BOX 45.1 Types of Biologic Transplants

- *Allografts:* Tissue grafted between different or genetically dissimilar individuals of the same species.
- *Autografts:* Tissue grafted in the same person from one part of the body to another. The donor is also the recipient.
- *Bioengineered grafts:* Biologic tissue is combined with synthetic material for implantation.
- *Heterotopic transplant:* Transplant to an anatomically abnormal location in the host. Heterotopic grafts may function normally in the unnatural site.
- *Isografts:* Tissues grafted between genetically identical donor and recipient, as between identical twins.
- *Orthotopic transplant:* Transplant to an anatomically natural recipient site.
- *Xenografts:* Tissues grafted between two dissimilar species; may be used when allograft material is unavailable or a temporary replacement is necessary.

• BOX 45.2 Donor Selection Criteria for Tissue Allografts

- Negative for viral, bacterial, and fungal infection or disease
- Negative for sexually transmitted disease
- Negative for neurologic disease
- Negative for autoimmune disease
- Negative for metabolic bone disease
- Negative for malignant disease or suspected malignant neoplasm
- Negative for disease of unknown origin
- Negative for death of unknown origin
- Negative for use of systemic medication
- Negative for parenteral drug use
- Negative for exposure to toxic substances
- Not ventilator dependent for more than 7 days before brain death
- Not immobile or bedfast for more than 7 days before brain death
- Normothermic 98.6° F (37° C) for more than 7 days before brain death

Potential donors are screened to avoid the transmission of infection or disease. Cultures are taken at the time of procurement for microbiologic and serologic testing. Tissue is not transplanted until negative test results are obtained; tissue is discarded if the test result is positive. Living bone donors are tested for human immunodeficiency virus (HIV) immediately after donation and again after 90 days because seroconversion can be delayed. Recipients also should be tested and should be negative for HIV and hepatitis B virus (HBV). A baseline is essential to establish that the patient was not infected by the act of grafting. Patients with HIV or HBV are not barred from receiving an allograft, but baseline data can help rule out causes for rejection or infection. Incidences of graft failure and superinfection are high in patients who are immunocompromised with HIV.

Banked tissues are labeled with the donor's name and identification number, pertinent medical history, the pathology report of the donor, final culture and serology reports of donors, type and site of donation, date and time of procurement, and method of procurement and preservation.

Bone Marrow Transplantation

Bone marrow transplantation is essentially a tissue transplant. However, because this type of transplantation is fraught with the hazards of rejection, bone marrow is procured and transplanted with a protocol similar to that of solid organ procurement and transplantation. Bone marrow is transplanted only after conventional treatments have failed to replenish depleted bone marrow cells. The marrow given via infusion restores hematologic and immunologic functions. Indications for treatment are acute myelodysplastic syndrome, lymphoblastic leukemia, myelogenous leukemia, aplastic anemia, and certain other blood diseases.

Bone marrow transplantation is the only cure for severe combined immunodeficiency disease—a genetic disorder in which a child lacks adequate immune defenses to fight infections. Bone marrow transplants also are given to victims of severe radiation exposure. Contraindications to transplantation are renal or cardiac diseases.

With bone marrow transplantation, blood type and human leukocyte antigen (HLA) compatibility are essential. A bone marrow transplant may be one of the following three types:

1. *Autologous:* The donor is the **recipient**. Stem cells are collected from the patient with leukemia that is in remission, cryopreserved, and stored to be infused during a subsequent relapse.
2. *Allogeneic:* The donor is HLA-compatible with the recipient. Marrow is procured for immediate infusion into the recipient.
   a. A syngeneic donor, an identical twin, is preferred.
   b. A genotypically compatible sibling or parent has the identical tissue type.
   c. An unrelated allogeneic donor must be HLA-compatible. Graft-versus-host disease (GVHD) is unique to allogeneic bone marrow transplantation. With GVHD, donor T cells immunologically attach to recipient cells and cause tissue damage at the site of antigen localization.
3. *T cell–depleted marrow:* For prevention of GVHD, mature T lymphocytes are removed from donor marrow before infusion into the recipient.

Before transplantation, the recipient is given a high-dose regimen of immunosuppressive chemotherapy to eradicate leukemic, lymphoid, and bone marrow cells, thereby inducing marrow depression. The recipient also receives total body irradiation (TBI) to penetrate the areas resistant to the drugs. During this period of pretransplant preparation, the patient is placed in reverse isolation, preferably in a laminar airflow clean or sterile (germ-free) environment. The patient is closely monitored for the side effects of immunosuppressive chemotherapy and TBI.

After pretransplant protocols have been completed, the donor is hospitalized before the scheduled transplantation. In the OR, with the patient under general or spinal anesthesia, 500 to 700 mL of bone marrow is aspirated at multiple sites from the iliac crests; the sternum also may be used. The marrow is filtered, heparinized, and placed in sterile containers for infusion. The donor is watched for bleeding and may need blood and fluid replacement.

Marrow is infused into the recipient intravenously (IV) or via a Hickman or Broviac catheter over several hours. During this time, the patient is constantly attended and closely monitored for adverse reactions. By an unknown process, the marrow migrates into the marrow cavities of the bones. For 10 to 30 days after transplantation, the recipient may receive daily transfusions of lymphocytes, platelets, and granulocytes, preferably taken from the donor, to counteract the predictable side effects of pretransplant immunosuppressive therapy (mainly hemorrhage and infection).

If the marrow is not from an identical twin, blood is irradiated before transfusion to destroy the lymphocytes. Mature blood cells

TABLE 45.1 Tissue/Allograft Procurement Parameters *NOTE: Tissues are evaluated by condition. Age is not a barrier. For additional information see www.organdonor.gov*

Donor Tissue	Physiologic Status of Donor	Time between Procurement and Grafting	Other Considerations
Cornea			
	Nonheartbeating cadaver donor	Procured 6-8 hours postmortem at room temperature.	Corneas are not perfused tissue. Heartbeating status is unimportant. Tissue may be procured in morgue or setting other than OR, under sterile conditions.
		Procured 48 hours postmortem if donor has been refrigerated at 39.2° F (4° C).	Corneas are usually used fresh rather than in cryopreserved state.
		Transplanted fresh 7-10 days after procurement.	Corneal tissue is not commonly cryopreserved.
		Cryopreserved cornea may be stored for 1 year.	
Skin			
	Nonheartbeating cadaver donor	Procured 6-8 hours postmortem at room temperature.	At least 75% of skin surface should be free of abrasions, scars, and deformities to qualify as donor.
		Procured within 24 hours postmortem if refrigerated at 39.2° F (4° C).	Skin is procured before bone and is taken only from below nipples to knees on ventral surface and from scapulae to popliteal area on dorsal surface. Tissue is taken to the depth of dermal layer (split thickness). A 70-kg donor can provide 7-8 ft^2 of skin.
		Cryopreserved skin can be stored for 5 years at -238° F (-150° C).	Newly procured skin is stored at 39.2° F (4° C) in preservation medium for a maximum of 24 hours. Cryopreserved skin is thawed at room temperature not to exceed 59° F (15° C) for use on recipient.
			Allograft skin is commonly used as a biologic dressing in combination with autograft skin. The recipient autograft is meshed 6:1 and then covered by allograft that has been meshed 2:1. Allograft skin is temporary and is replaced on the recipient every 48-72 hours until natural reepithelialization at the autograft site begins.
Iliac Crest			
	Nonheartbeating cadaver donor	Procured within 12 hours postmortem at room temperature.	Bone is procured after the recovery of any other internal organs and skin. Preferably, bone is procured under sterile conditions; however, it may be procured under clean conditions in a setting such as the morgue and secondarily sterilized by ethylene oxide followed by aeration. Sterile bone can be freeze-dried and stored at room temperature.
		Procured within 24 hours postmortem if refrigerated at 39.2° F (4° C). Cryopreserved bone can be stored for 3 years at –112° F (–80° C).	
Joints and Long Bone			
	Nonheartbeating cadaver donor	Procured within 12 hours postmortem at room temperature	Bone is procured after the recovery of any other internal organs and skin. Preferably, bone is procured under sterile conditions; however, it may be procured under clean conditions in a setting such as the morgue and secondarily sterilized by ethylene oxide followed by aeration. Sterile bone can be freeze-dried and stored at room temperature.
		Procured within 24 hours postmortem if refrigerated at 39.2° F (4° C). Cryopreserved bone can be stored for 3 years at –112° F (–80° C).	Joints are not used as joints per se but are cut into pieces to fit a defect. Living nonrelated donor femoral head can be salvaged during total joint arthroplasty procedure and processed for use as bone plug or ground bone grafting tissue.
	Living nonrelated donor (femoral head or rib)		
Heart Valves			
	Nonheartbeating cadaver donor	Cryopreserved valves can be used within 1-2 years.	Size match is important.

and platelets are unaffected by the irradiation process. Daily marrow aspirations and complete blood counts are performed on the host. The success or failure of transplantation is usually decided after 10 to 20 days, when the new marrow begins to function.

Organ Transplantation

Organ transplantation can be a lifesaving treatment for some end-stage diseases. Although tissue grafts are commonplace, transplantation of functional, whole, vital organs presents physiologic, philosophic, and ethical dilemmas. A biologically related donor (referred to as a living related donor) makes a supreme sacrifice to become an organ donor; therefore cadavers are the primary source of organs for transplant. Organ donation is the ultimate gift of life and is given by the donor to the recipient. Transplantation can restore the recipient to near-normal physiologic status.

Ethical concerns cross religious and cultural boundaries. Table 45.2 gives examples of religious and cultural groups and their positions about organ donation and transplantation. Some traditionalist beliefs do not support donation because the body of the dead should not be altered in any way. Modernist beliefs have transcended many old ways by pointing out that the body is not needed for passage into the afterlife. Information about religious and cultural views about donation can be found at www.organdonor.gov and www.lifebanc.org.

Kidney transplantation was initially the most successful and principal clinical application of organ transplantation. If a kidney graft fails, the patient may survive by returning to hemodialysis indefinitely before receiving another transplant. This option does not exist for transplants of the heart, liver, pancreas, or lungs. No practical prolonged artificial support exists for these organs in the event of an allograft failure.

Transplantation of each organ involves unique technical and physiologic problems, but the major barriers and causes of transplant failure are immunologic rejection and infection. Immunodeficiency depends on the amount of immunosuppression the patient receives to prevent rejection. Immunosuppressive agents leave the patient prone to opportunistic infection.[1] Reverse protective isolation may be advisable if the patient has development of leukopenia, a decrease in white blood cells. In other aspects of care, transplant recipients are similar to other critical surgical patients with severe chronic illnesses who need measures that minimize the risk for infection.

The American Society of Transplant Surgeons (www.asts.org) and the International Society of Transplantation meet regularly to exchange ideas and information among people of different scientific backgrounds. The aim is to achieve the best possible patient survival rather than merely transplant survival.

The Organ Transplant Registry of the American College of Surgeons, in conjunction with the National Institutes of Health, collect data on transplantation procedures and approve and fund various registries. The Federal Organ Transplantation and Procurement Act of 1983 provided financial grants for the initial development of regional organ procurement centers and a transplant registry.

A national task force has been established to analyze medical, legal, ethical, economic, and social issues of concern in organ procurement and transplantation.

Organ procurement organizations (OPOs) collect organs and tissues from donors, exchange organs geographically, and register patients in need of a transplant. The registry includes information about the patient's blood group and tissue typing. Computer lists of patients waiting for donor organs are maintained by the United Network for Organ Sharing (UNOS) and the North American Transplant Coordinator Organization 24-Hour Alert. Regional organ procurement organizations coordinate with these registries to match donated organs with compatible recipients nationwide. The position of the recipient on the waiting list is determined by the severity of the illness. Pediatric patients are given additional consideration.

Other countries have similar mechanisms. For example, the United Kingdom Transplant Register has membership in the Euro Transplant Register. Organs procured within the United Kingdom can be transported by air to another country in Europe, and vice versa, for a histocompatible recipient. The number of patients awaiting transplants exceeds the supply of available donor organs. As a result, many patients die while waiting for a suitable organ to become available.

Many people carry a signed Uniform Donor Card or other identification (e.g., the reverse side of a driver's license) that states that certain or all organs and tissues may be removed for transplantation in the event of death. Such cards, or a living will, constitute legal written consent under the Uniform Anatomical Gift Act enacted by all 50 states. Written or telephone consent is still obtained from the family of a potential donor before procurement may commence.

Time is paramount when critical organs are involved because their value depends on preservation of maximum functional viability. The time factor is less urgent with less critical tissue. When a potential donor has been identified, a transplantation coordinator contacts the regional registry and procurement team.

Organ Procurement

Immunologic rejection and the shortage of donor organs remain the principal deterrents to transplantation. The goal is selection of a donor-recipient match with adequate histocompatibility to permit an organ to function without complications. Organs and tissues come from two primary sources: cadaver (heartbeating and nonheartbeating) and living related donors (Table 45.3).

Tissue donors are between newborn and 80 years of age. All donors of vital organs must be free of sepsis or malignant processes, between newborn age and 65 years of age, and with good function of the donor organ. Technical aspects of the procurement procedure must ensure the viability of organs throughout the entire period between procurement and transplantation.

Cadaver Donor

Death is confirmed with irreversible cessation of all functions of the brain and brainstem. The criteria for **brain death** are listed in Table 45.4. For suitability for organ or tissue donation after death, cadaver donors are classified as either heartbeating or nonheartbeating.

Heartbeating donors are those with confirmed brain death in whom the vital organs can be preserved in vivo.[2,3] In these donors, brain death usually has resulted from severe neurologic trauma, such as head or spinal cord injury, hemorrhage, or anoxia. Death must occur in a location in which a cardiopulmonary support system is immediately available (i.e., in the emergency department, operating room [OR], or other critical care unit).[2,3]

TABLE 45.2 Organ Donation and Transplantation Beliefs According to Religious or Cultural Groups

Religious or Cultural Group	Donate Organs	Accept Transplant	Notes
African Methodist Episcopal Zion (AME)	Yes, encouraged	Yes	See donation as a way of helping others.
Amish	Yes, if assured of successful procedure for recipient	Yes	Use modern medical services.
Anglican	Yes	Yes	Church of England stated that donation was a Christian duty.
Assembly of God	Individual choice	Individual choice	No official policy.
Baha'i	Yes	Yes	Very supportive.
Baptist	Individual choice	Individual choice	Process must offer improvement and extension of life.
Brethren	Yes	Yes	See donation as a way of helping others.
Buddhism	Yes, donors are honored Individual choice	Yes	See donation as an act of compassion.
Catholicism	Yes, encouraged as an act of charity and love	Yes	Pope Benedict XVI was an organ donor when serving as Cardinal.
			Not permitted as Pope.
Christian Church (Disciples of Christ)	Yes, encouraged to share God's love	Individual choice	Humans were created for the glory of God.
Christian Science	Individual choice	Individual choice	Prefer to use spiritual means of healing over medical.
Church of the Nazarene	Individual choice	Individual choice	No official policy.
Confucianism	Traditional: No Modern: Individual choice	Individual choice	The body was a gift from parents and must not be violated.
Episcopal	Yes, encouraged	Yes	Donation part of self-sacrifice for others.
Evangelical	Individual choice	Individual choice	No official policy.
Greek Orthodox	Yes	Yes	Donation is used to better human life.
Gypsy (Romany)	No	Individual choice	Body should be intact at burial for the afterlife.
Hinduism	Individual choice	Individual choice	No prohibitions.
	One of the gods, Ganesha, was a young male with an elephant head transplant		Belief in reincarnation is not hindered by donation.
Islam	Individual choice	Individual choice	Priority to save human life is supported by Shariah law.
Jehovah's Witnesses	Individual choice	Individual choice	Will accept an organ that has been drained of blood.
Jesus Christians	Yes, encouraged	Yes	Very small sect; strongly encourage both living and after death donation.
Judaism	Yes, encouraged to save a life	Yes	*Pikuach Nefesh* is a Halakhic legal concept that permits organ donation to save a life.
Lutheran	Yes	Yes	An expression of sacrificial love.
Mennonite	Individual choice	Individual choice	No official policy.
Moravian	Individual choice	Individual choice	No official policy.
Mormon (Church of Jesus Christ of Latter Day Saints)	Individual choice	Individual choice	Encouraged to view the pros and cons before making decision.
Pentecostal	Individual choice	Individual choice	No official policy.
Presbyterian	Individual choice	Individual choice	No official policy

TABLE 45.2 Organ Donation and Transplantation Beliefs According to Religious or Cultural Groups—cont'd

Religious or Cultural Group	Donate Organs	Accept Transplant	Notes
Protestantism	Yes, encouraged	Yes	Encouraged to donate.
Quakers (Society of Friends)	Individual choice	Individual choice	No official policy.
Rastafarianism	Not prohibited, but extremely rare	Not accepted because of fear of contamination of the body	Prefer all natural ways of life. The body is only a shell for the spirit.
Seventh-Day Adventist	Yes, encouraged	Yes	Sect operates several specialized transplant hospitals.
Shinto	No donation from dead bodies	Individual choice, but prefer living donor	The dead body is considered impure and must not be interfered with.
	Permit living donation		
Sikhism	Individual choice	Individual choice	The body is of no use when dead.
			The spirit is reborn into a new body at death.
			No prohibitions.
Taoism	Traditionalist: No donation	Individual choice	Emphasis on natural ways.
	Modernist: Individual choice; the body is only a shelter for the spirit		Spirit is unchanged by changes in the body.
United Church of Christ	Yes, encouraged	Yes	Very supportive.
Unitarian Universalist	Yes, encouraged	Yes	Seen as an act of love.
United Methodist	Yes, encouraged	Yes	Suggest all members carry donor cards.
Wesleyan Church	Yes, encouraged	Yes	Seen as a Christian act of love.

TABLE 45.3 Organ Procurement Parameters *NOTE: Organs are evaluated by condition. Age is not a barrier. For additional information see www.organdonor.gov*

Donor Organ	Physiologic Status of Donor	Time Between Procurement and Transplantation	Other Considerations
Heart			
	Heartbeating cadaver donor	3-6 hours, fresh tissue.	Heartbeating cadaver donor: total heart and segments of great vessels.
	Nonheartbeating cadaver donor	Cryopreserved valves can be used within 1-2 years.	Nonheartbeating cadaver donor: heart valves only. Size match is important.
			Donor criteria include no cardiac disease and normal cardiac enzymes.
Lung			
	Heartbeating cadaver donor	1-4 hours.	Heartbeating cadaver donor lung may be given en bloc to one recipient. The lungs may be separated or divided into segments (lobes) for several recipients.
	Living related donor		One lobe from living related donor is transplanted into recipient.
			Size match is important.
			Donor criteria include no evidence of trauma, negative sputum culture, normal chest x-ray.

Continued

TABLE 45.3 Organ Procurement Parameters *NOTE: Organs are evaluated by condition. Age is not a barrier. For additional information see www.organdonor.gov*—**cont'd**

Donor Organ	Physiologic Status of Donor	Time Between Procurement and Transplantation	Other Considerations
Heart-Lung En Bloc			
	Heartbeating cadaver donor	1-4 hours.	Heartbeating cadaver donor heart and lungs are transplanted en bloc into recipient.
			Size match is important. Donor criteria same as for individual heart or lung donation.
Liver			
	Heartbeating cadaver donor	8-24 hours.	Heartbeating cadaver donor liver may be divided into two segments for two separate recipient patients.
	Living related donor		Small segment of living related donor's liver is transplanted into recipient.
			Size match is important.
			Donor criteria include normal liver function, normal liver enzymes and bilirubin, no evidence of trauma.
Kidney			
	Heartbeating cadaver donor	48-72 hours, Ideally, should be transplanted within 12 hours.	Heartbeating and nonheartbeating cadaver donor kidneys are given to two separate recipients.
	Nonheartbeating cadaver donor in highly selected circumstances	Procured within 45 minutes of cardiac arrest, with immediate in situ cooling.	
	Living related donor		One kidney from living related donor is transplanted into recipient.
			Donor criteria include normal renal function, normal serum creatinine, no evidence of trauma.
Pancreas			
	Heartbeating cadaver donor	12-24 hours.	Heartbeating cadaver donor pancreas is transplanted as a whole or partial organ for one recipient.
	Living related donor		Tail segment of pancreas from living related donor may be transplanted into recipient.
			Donor criteria include normal pancreatic function, normal blood glucose regulation, normal serum amylase, no evidence of diabetes mellitus, no evidence of trauma.
Kidney-Pancreas			
	Heartbeating cadaver donor	12-24 hours.	Heartbeating cadaver donor kidneys and pancreas are simultaneously transplanted into recipient. Usually performed for diabetic nephropathy. Donor criteria are the same as for individual kidney or pancreas donation.

For organ donation, an individual who is brain dead is maintained on mechanical ventilation or cardiopulmonary bypass to prevent ischemic damage to the vital organs. Maintenance of a heartbeating donor before and during organ procurement includes the following:

- Systolic blood pressure above 90 mm Hg
- Central venous pressure of 5 to 10 mm Hg
- Hydration with crystalloids and colloids
- Urine output minimum of 100 mL/hr (ideally, 200 to 300 mL/hr)
- Ventilation with 100% oxygen
- Core body temperature of 98.6° F (37° C)

Nonheartbeating donors are not suitable for the procurement of parenchymal organs. With nonheartbeating donors, cardiopulmonary or ventilatory support was not provided after brain death. As a result, the major organs have suffered thrombosed vascular structures and ischemia. Skin, bone, heart valves, blood vessels, and corneas may be acceptable for procurement from select nonheartbeating donors (see Table 45.1).

TABLE 45.4 Brain Death Criteria

Criteria	Clinical Assessment
Irreversible coma not caused by pharmacologic agent, hypothermia, or unknown cause.	No response to external stimuli. No cerebral brain activity on EEG over a period of 10 minutes. EEG activity has no prognostic value for estimation of cerebellar and brainstem activity.
Absence of spontaneous movement, decerebrate posturing, and decorticate posturing **Apnea** with no spontaneous respiration not influenced by hypothermia or pharmacologic agent.	Spinal nerve reflexes may be unaffected because these reflexes do not require cortical (brain) activity. Elevated carbon dioxide in the blood is not a stimulus for breathing. No spontaneous respiratory effort for 3 minutes when removed from ventilatory assist device. $Paco_2$ >55 mm Hg.
No cranial nerve reflexes.	Fixed and dilated pupils. Pupils are unreactive to light. No corneal reflex (no blinking when cornea is touched). No oculocephalic reflex (doll's eyes). No oculovestibular reflex (no response to ice water instilled in ear). No response to pain on face and head (pin prick, supraorbital pressure). No response to upper or lower airway stimulation (no gag or cough reflex when suctioned or stimulated by endotracheal tube).

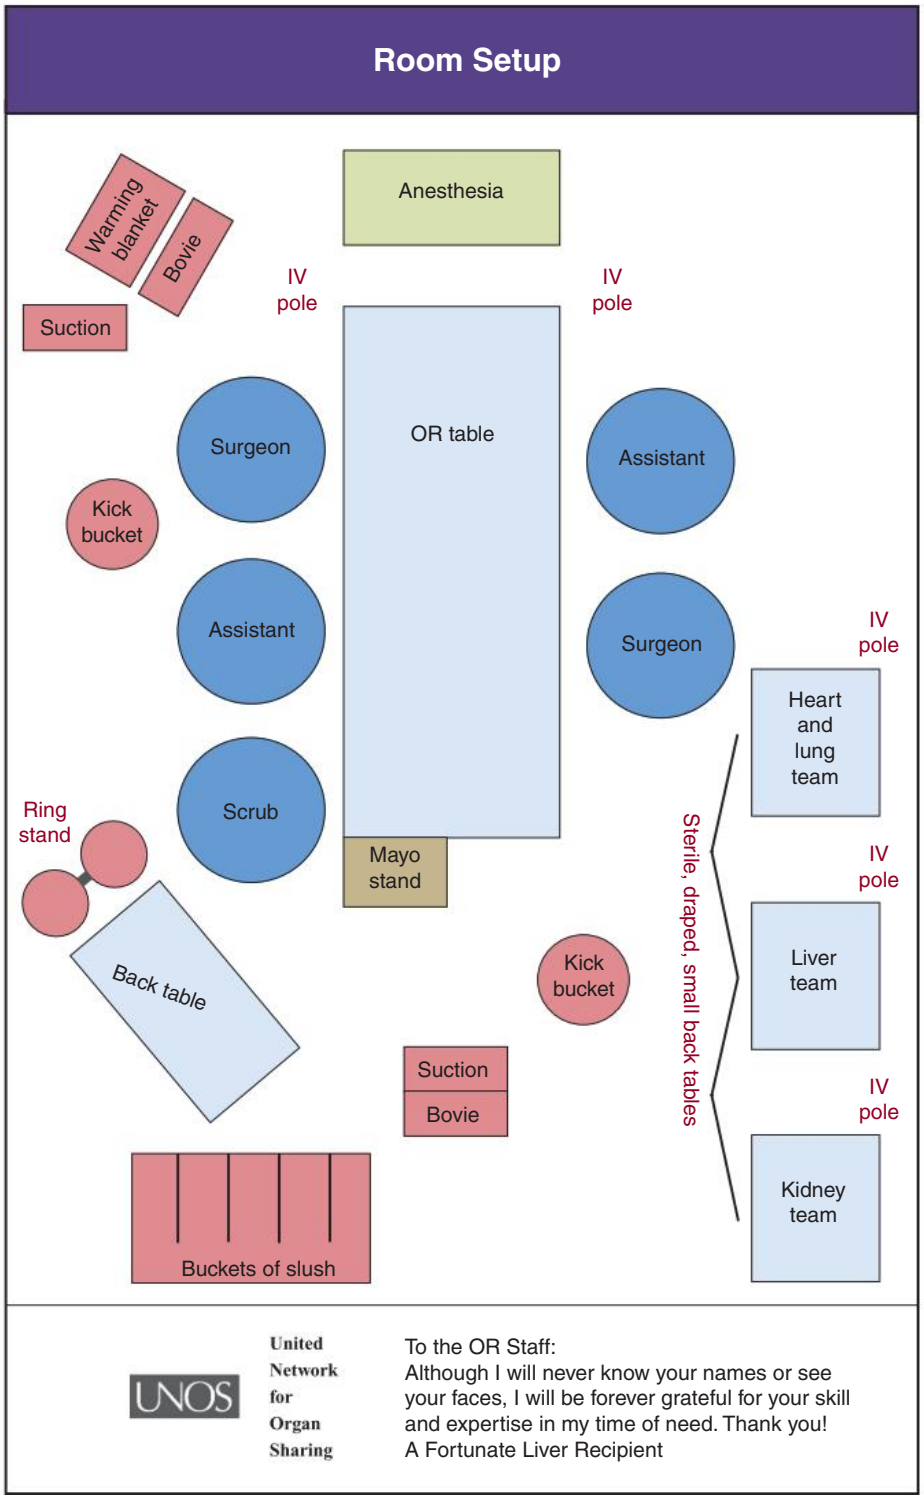
EEG, Electroencephalogram.

Multiple Organ Procurement

The heartbeating donor is brought to the OR and treated with the same respect and care given to any other patient. A sample multiple organ procurement room setup is depicted in Fig. 45.1. Organs and tissues are removed under sterile conditions by a procurement team and preserved and transported to the recipient. The procurement team includes two surgeons, two assistants, and a scrub person. A circulating nurse and a scrub person from the host facility assist with the procedure. An anesthesia provider also is necessary to maintain vital functions until the aorta is cross-clamped and cardiopulmonary support is no longer needed. A procurement coordinator from an affiliated organ procurement agency or organ bank usually accompanies the team and assists wherever needed throughout the procurement process. The procurement team brings the necessary supplies for packaging the organ and tissue for transport.

The procurement process includes the following functions:

1. The procurement coordinator facilitates the procurement process by:
   a. Obtaining blood samples and arranging tissue typing to assist the organ bank with the potential placement of procured organs.
   b. Documenting necessary information, making any needed phone calls, and coordinating the host facility personnel with the procurement team.
   c. Assisting the physician with communications with the donor family.
   d. Calling the procurement team.
   e. Assisting the circulating nurse and scrub person with the setup of the procurement room.
   f. Bringing the necessary cannulas for organ preservation.
2. The circulating nurse and scrub person assist in the procurement process by:
   a. Gathering sterile supplies, including:
      (1) Laparotomy drape pack and 10 extra medium drapes. Ten or more sets of gowns and gloves are needed.
      (2) Nonabsorbable sutures for ligating ties (usually 0, 2-0, 3-0, 4-0 silk) and for closure (usually a size 2 monofilament suture on a large cutting needle) as requested by the surgeon.
      (3) Ten umbilical tapes at least 30 inches long.
      (4) Four suction canisters and suction tubing with tips.
      (5) Two electrosurgical units, two dispersive electrodes, and handpieces with long and short blades.
      (6) Twelve scalpel blades, No. 10 and No. 15.
      (7) Two packs of bone wax.
      (8) Four asepto syringes.
      (9) Twenty packs of laparotomy sponges.
      (10) Cold sterile normal saline solution, 6 L, for irrigation.
      (11) Autosuture cart (GIA and TA) for bowel or pancreas donors.
   b. Setting up sterile instrumentation, including:
      (1) Chest tray with sternal saw and self-retaining chest retractor.
      (2) Major abdominal laparotomy tray and large self-retaining abdominal retractor; some teams bring their own sterile instrument trays.
      (3) Vascular tray.
      (4) Minor tray for organ preparation table (**benching table**).
      (5) Basin set for main table and each benching table.
   c. Providing nonsterile equipment, including:
      (1) Two electrosurgical units and dispersive electrodes.
      (2) Suction containers to accommodate at least 24 L of fluid.
      (3) Power source for sternal saw.
      (4) One IV pole for each benching table.
      (5) Warming blanket under the patient.
      (6) Defibrillator.
      (7) Skin preparation solution.
      (8) Isopropyl alcohol (70%) to make slush, or slush machine if available.
      (9) Crushed ice; dry ice is not used for organ preservation.
      (10) Head lights for primary surgeons.
   d. Medications and blood to have available:
      (1) Heparin: 60,000 units.
      (2) Furosemide (Lasix): 20 to 100 mg.
      (3) Two units of packed red blood cells (typed and cross-matched).
3. The anesthesia provider assists in the procurement process by:
   a. Ventilating the donor with 100% oxygen.
   b. Monitoring electrocardiogram (ECG), blood pressure, urinary output, and fluid and electrolyte balance.
   c. Administering drugs as necessary (e.g., dopamine or dobutamine for vasomotor regulation, muscle relaxants to neutralize spinal reflexes and relax the abdomen, osmotic diuretics for renal function, and heparin for anticoagulation).
   d. Monitoring and replacing blood as appropriate.



• **Fig. 45.1** Room setup for multiple organ procurement. (From Seifert PC: *Cardiac surgery: perioperative patient care,* St. Louis, 2002, Mosby. Courtesy UNOS, United Network for Organ Sharing.)

Procedure: Organ Recovery—Single or Multi-Organ

Skin Prep:	Solution varies according to surgeon preference. Prep from clavicle to mid-thigh.	Position of Patient:	Supine with arms out or tucked, depending on organs to be recovered and surgeon preference. Place warming blanket under patient or use a lower-body Bear Hugger.
Drapes:	Laparotomy drapes are acceptable with a wider area of exposure. Free draping is also acceptable and may be preferred.		

Return electrode, ECG electrodes, and other devices should be placed on the posterior side of the body away from the sterile field.

Sutures and Needles
Depends upon surgeon preference—examples

Ties:	0, 2-0, 3-0, and 4-0 silk ties* #1 and #4 silk ties*
Suture:	2-0 silk on cutting or taper needle* 4-0 & 5-0 prolene on taper needle* 1 or 2 nylon on cutting needle for closure*
Other:	Ligaloops/endoloops, umbilical tapes* Vessel paws, bone wax*
Hold:	Large and small hemaclips Skin stapler with rotating head
Dressing:	Sterile 4x4s* Shroud kit*

* *Some organ recovery agencies' customized packs will contain these items. Check with your recovery agency to prevent duplication.*
** *If no slush machine, contact your recovery agency for the formula for making slush. This procedure needs to be initiated at least one hour prior to the recovery case.*

Instruments and Equipment
Specific tray names will vary according to institution

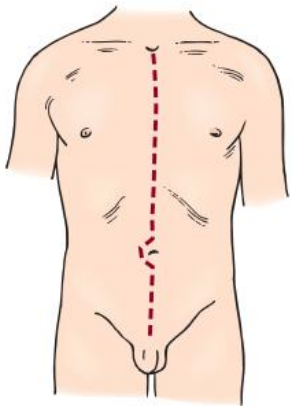
Basic:	Skin prep tray*	Razors
	Gowns × 5-10*	Towels × 5
	Electrocautery units × 2	Grounding pad × 2*
	Lap tapes*	Raytec sponges
	Blades - #10 × 3, #15 × 2, #11 × 2*	
	Suction sets × 2-3 (for large fluid volumes)	
	Suction tips × 2 ea. Yankaur, Poole, or octopus	
	Major laparotomy tray	
Special:	Vascular tray	Assorted vascular clamps
	Sternal saw	Sternal retractor
	Extra long balfour	Mallet
	Vascular stapler (hold)	GIA, LDS (hold)
	Gallbladder dilators (hold)	Large basins × 2-3 (hold)
Extras:	Sterile ice	Slush (or capabilities)**
	Defibrillator with sterile internal paddles available	
	Headlight available	
	Ice machine available or several bags of unsterile ice	
	IV poles (one for each organ to be recovered)	

Visiting recovery teams may bring additional items, which you may need to autoclave.

• **Fig. 45.1, cont'd**

e. Monitoring and maintaining core body temperature and initiating cooling: cold fluids (usually lactated Ringer's solution or Collins' solution with 30,000 units of heparin) are infused intravascularly 10 minutes before the aorta and vena cava are cross-clamped for heart removal. After the heart removal begins, the anesthesia provider turns off the anesthesia machine and leaves the room.

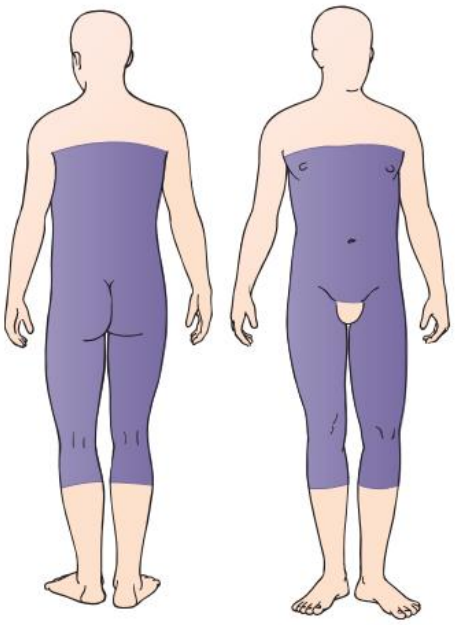
4. Incisions are made by the procurement surgeon to provide maximum access to organs and tissues:
   a. A midline sternal-splitting incision is made from the suprasternal notch to the pubis to remove vital thoracic and abdominal organs (Fig. 45.2). It takes 2 to 3 hours to procure parenchymal (perfused) organs. Additional incisions are made as necessary.
   b. Eyes are enucleated by an eye procurement specialist to preserve the corneas. Glass or plastic globes may be put in the sockets to maintain the shape. An ice pack is placed over the eyelids after procurement of the eyes, and the head is slightly elevated to minimize fluid accumulation. The patient is no longer on the ventilator, so the anesthesia provider is no longer at the head of the table.
   c. Skin is taken with a dermatome from flat body surfaces, excluding the upper chest, neck, face, arms, lower legs, and feet (Fig. 45.3). Skin procurement may take 1 to 1½ hours. Extra absorbent padding is advised because interstitial fluids seep from the tissues.
   d. Skin is excised, and the muscles are separated. Long bones and iliac crests are removed in toto (Fig. 45.4) and are replaced with wooden, fiberglass, or metal dowels to maintain structural integrity. Bone procurement may take 5 to 6 hours to complete.



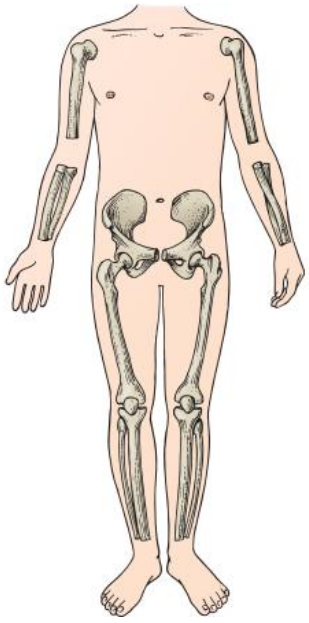
• **Fig. 45.2** Midline sternal-splitting incision from suprasternal notch to pubis is made for procurement of thoracic and abdominal organs from heartbeating cadaver donor.

   e. Multiple incisional closures may take 1 to 1½ hours. Care is taken to close the incisions with regard to physical appearance. The family may want open viewing at a funeral home.

5. The sequence of organ removal is coordinated to maintain the viability of the organs. Several small sterile tables should be set up so organ and tissue packaging for transport can be completed away from the main sterile field. Minor dissection instrumentation may be needed for organ **benching**.
   a. Perfused tissues are taken first.
      (1) The kidneys and liver are mobilized and cannulated for in situ cooling.



• **Fig. 45.3** For cadaveric allografts, skin is removed with dermatome from anterior and posterior flat surfaces between midchest and knees.



• **Fig. 45.4** Long bones and iliac crests are procured for bone allografts. Humerus, tibia, and fibula are cut distally. Radius, ulna, and femur are disarticulated at both ends. Pelvis is cut at pubic and sacroiliac joints.

(2) The aorta is cross-clamped, and the heart is removed first, followed by the liver and then the kidneys, pancreas, and intestines. Mesenteric nodes and the spleen are sampled for tissue typing.
(3) A combined heart-lung procurement (en bloc) may be performed after the other organs have been removed. The organs are removed with their vascular and structural attachments intact. A bronchoscopy may be necessary for assessment of the lungs. The lungs are ventilated during the procurement process, and a prostaglandin drip is infused.

b. Nonperfused tissues are taken last.
(1) Enucleation of the eyes for corneal procurement usually follows retrieval of the parenchymal organs.
(2) Skin is taken, followed by vessels and bone.

6. Closure should be as esthetic as possible for later viewing at funeral services. Most closures are done as single-layer closures. Prosthetic bone space-holders brought by the procurement team are placed. Ice packs are placed over eye sockets, and the head of the bed is elevated to minimize fluid accumulation around the eye sockets.
7. The procurement coordinator provides the necessary paperwork for the surgeons and team to use for documentation.

Additional Considerations in Cadaver Organ Procurement

The procurement coordinator remains at the host facility after the procurement team has departed. The coordinator's role extends into the aftercare given to the donor's body and the psychologic support and debriefing of the OR team. After the closure and dressing of all incisional wounds, the donor's body should be bathed and all drainage tubes and IV access lines removed. The patient's body should be treated respectfully at all times.

The body should be labeled with identification tags and placed on a clean transport cart. The head of the stretcher should be elevated 20 to 30 degrees. Ice packs should remain over the eye sockets to decrease serous pooling, for the benefit of the mortician who prepares the body for viewing. The donor's body is prepared as esthetically as possible for the benefit of the family and loved ones.

Psychologic Support of the OR Team. The OR team may experience a sense of sadness and loss. These feelings are normal and to be expected. Death is not a common event in the OR. Although patients are technically brain dead before arrival in the OR, they give the outward appearance of being sustained on life support as in general anesthesia. After the aorta and vena cava are cross-clamped, ventilatory support is no longer needed and the anesthesia provider turns off the ventilator. The sudden silence can feel overwhelming.

The OR team may need the added support given by the procurement coordinator, who has experienced the same feelings and understands the psychologic impact of each stage of the procurement process. Personnel who specialize in procurement state that they feel the same sense of loss despite years of experience and exposure. An understanding of the outcome is important in the grieving process. Participation in the aftercare of the body helps provide the OR team with a sense of closure and completion of patient care.

Some of the same sadness may be shared by the critical care nursing staff members who helped monitor and maintain the donor's vital signs before transfer to the OR. Although the urge to be emotionally strong may exist, the shedding of tears of sorrow is therapeutic.

Psychologic Support for the Family of the Donor. The donor's family needs support and communication from the procurement coordinator. The coordinator becomes known to the family and maintains communication with them for several months or longer as needed; the coordinator also provides referrals for follow-up counseling if the need arises. The coordinator informs the family of the progress of the recipients. In select situations, donor and recipient families may be brought together and may form lasting friendships.

The financial aspects of donor maintenance and subsequent organ procurement are paid by the procurement agency and are not the responsibility of the donor's family. Medical bills accumulated

before the patient was identified as a potential donor are paid by the donor's family.

Living Related Donor

There are distinct advantages to procurement of a kidney, lobe of the liver or lung, tail segment of the pancreas, or marrow from a living related donor. The results are better than those with non-biologically related cadaver organs because donor-recipient matches are usually good (identical twin sources are ideal for compatibility). Waiting time is also reduced, and the procedure is planned and performed in controlled circumstances. The ethical concerns include the generalized risk of surgery to the donor.

The use of living donors involves the following special protocol:

1. Adult donors, who are preferred over adolescents or children, must be able to give informed consent voluntarily and without coercion. Children are used as donors only for a twin or for a patient with predictable results, which is sometimes the case between siblings for bone marrow donation. If the donor is a minor, court (legal) and parental or guardian consents are required to avoid bias. The donor must fully comprehend the sacrifice; if the physician deems it advisable, a psychiatric examination is included along with intelligence testing.
2. The donor must be in excellent health. The donor's physician confers with him or her and performs the preoperative physical examination to facilitate informed consent. Before a nephrectomy, renal arteriograms are performed to confirm the presence of bilateral kidneys and to identify the renal vasculature.[4]
3. The donor should have no psychiatric complications. Donor reactive depression may follow organ removal if adequate gratitude is not shown by all concerned.

Preservation of Organ Allografts

The successful use of donor tissue depends on rapid organ resection and cooling because the period of ischemia must be kept to a minimum. Long-term preservation of tissue remains a problem; current techniques use a variety of cryoprotective agents. Uncontrolled freezing may produce lethal cell injury; therefore this technique is used for skin, bone, semen, and blood suspensions but not for whole organs. Hypothermia above freezing at 39.2° F (4° C), with or without the perfusion with cold solutions, reduces general metabolic demands and thereby provides a safety margin. Methods of hypothermia include the following:

- Simple flush techniques with cold electrolyte solutions and storage via immersion in an electrolyte or flush-out solution in a plastic container that is kept at a hypothermic temperature.
- Hypothermic continuous pulsatile perfusion with an oxygenated electrolyte solution.

In 1987, potassium-based organ-preservation solutions were developed at the University of Wisconsin by Dr. Folkert Belzer (1930–1995). These solutions are known as UW (ViaSpan) and Belzer MPS solutions, and they extend the preservation time of the liver to 24 hours and of the kidney and pancreas to 72 hours. A total organ perfusion system (TOPS) consists of a machine that pumps an artificial blood substitute through the donor organ during transport. Minicomputers and microsensors regulate pH levels, blood pressure, and nutrient levels. The potential for altering the immunogenicity of an organ and improving its regenerative processes is the focus of research in perfusion techniques.

The organ is placed in a sterile container filled with perfusate. This container is placed in sterile double-plastic bags and packed in ice. Dry ice is not used. If the organ will be transported to another facility, a Styrofoam ice cooler generally is used as the outer container.

Immunologic Rejection

The body possesses an innate tendency to reject and destroy any foreign material except tissue from an identical twin; therefore transplanted cells from donors even slightly dissimilar to the recipient may be rejected.

Organ rejection involves the patient's immunologic system. Both the cellular and the humoral immune systems seem to be involved in the responses to transplanted cells. Activation of the immune system is a response to antigens introduced by the donor graft. An immunologic reaction usually is accompanied by a febrile systemic reaction, local inflammation, and deteriorating function of the graft.

A knowledge of antigens, individual-specific and species-specific, and their genetic transmission is important for the avoidance of violent reactions. Many factors influence the strength and rate of a rejection reaction: acquired immunologic tolerance, lymphatic depression, or previous sensitization by blood transfusions, pregnancies, or transplants. Rejection may be reversible with intensive therapy, or it may be progressive and lead to the cessation of transplant function.

Combating Rejection

Attempts must be made to find compatible donors and to minimize rejection. T cells can be spun from donor vertebral marrow and transfused into the recipient to prevent or minimize rejection. This action primes the recipient's system for organ acceptance. The recipient's body can then recognize the transplanted organ as being familiar, which thus minimizes or prevents rejection.

Preoperative Matching of the Donor to the Recipient

Tissue typing and matching are used to determine the genetic disparity between the donor and the recipient. Histocompatibility implies acceptability by one individual of tissue from another. Histocompatibility tests, although not infallible, assist in donor-recipient selection and result in improved organ survival from both living and cadaver sources. The better the histocompatibility match and degree of genetic similarity between the donor and the recipient, the less serious the rejection.

Histocompatibility testing, or tissue typing, is based on the detection of cell-surface antigens known to affect rejection. Favorable results are expected when few histocompatibility antigens are detected. Preformed antibodies appear to have a harmful effect on graft survival. Histocompatibility testing uses serologic methods that include cell culture techniques and in vitro analysis for the study of cell-to-cell interaction and identification of the mediator of the interaction. Complex assay techniques measure the effects of antibodies and lymphocytes against donor tissue in a culture setup. Crossmatching between the recipient's serum and the donor's peripheral blood target cells is accomplished with multiple serologic reagents or flow cytometry with fluorescent-labeled monoclonal antibodies.

Immunosuppressive Therapy in the Recipient

Specific alterations in immune responses are produced by inactivating or destroying lymphoid cells that are capable of responding to the antigens. The goal is to selectively suppress antigenic reactions to the transplant without impairing the body's defense

against pathogenic organisms. To allow the transplant to remain and function, an attempt is made to neutralize or modify the body's protective antigenic mechanisms through the use of various immunosuppressive agents. This barrier can be pierced at least temporarily by creating an increase in transplant tolerance or by paralyzing the recipient's immunologic system.

Because the lymphocytes and globulins seem to be mainly responsible for rejection, an attempt is made to vary their synthesis. Antibody formation and immune reaction can be suppressed by certain factors; the protocol for these methods is fairly standard in all transplantation centers.

1. Cyclosporin (Sandimmune), a soil fungus derivative, is a potent immunosuppressant that acts mainly on thymus-derived lymphocytes (T cells), the cells primarily responsible for rejection. This drug reduces rejection, especially in the early or inductive phase, without suppressing the entire immune system. It may be given orally or IV. It is always used with low doses of adrenal corticosteroids but usually not with other immunosuppressive agents. Its absorption rate is variable. The toxic effects on the kidneys must be monitored. Verapamil, a calcium channel blocker, may be given to reduce renal toxicity.[4]
2. Immunosuppressive agents, such as FK-506 or 5R-506, may be preferred to cyclosporine to prevent rejection.
3. Monoclonal antilymphocyte globulin, muromonab-CD3 (Orthoclone OKT3), is derived from mouse antibodies and is used for the successful treatment of established allograft rejection without affecting the entire immune system. Monoclonal antibodies have the ability to reverse the initial episode of rejection by binding to specific targeted surface antigens on mature T cells. They suppress only the activity of T cells that cause acute rejection.
4. Polyclonal antilymphocyte globulin, antibodies derived from horse serum, may be used for the induction of immunosuppression or for the reversal of rejection. It usually is given with other immunosuppressive agents.
5. Corticosteroids, such as prednisone, have an antiinflammatory effect that is useful in reversing early rejection reactions. There is an inverse relationship between steroids and lymphocytes. T cells migrate from the circulation to lymphoid tissue.
6. Agents cytostatic or cytotoxic to lymphatic tissue, such as azathioprine (Imuran), suppress the entire immune system and have serious side effects on other systems. They also interfere with DNA synthesis. Extracorporeal perfusion with these drugs and localized radiation to the transplant may be used either separately or concurrently.
7. Heterologous horse or rabbit antithymocyte globulin or antilymphocytic globulin or serum acts against circulating T cells and induces suppressor cells.

The use of immunosuppressive measures is not without complications. Leukopenia and susceptibility to infection are common sequelae. Therapy may not totally abolish rejection by the host but may delay the onset and decrease the incidence of rejection episodes during the crucial first month or two after transplantation.

Pretransplantation Transfusions

Blood transfusions from a living related donor expose the recipient to a limited number of leukocyte antigens and seem to reduce the risk for sensitization to the prospective donor transplant and thereby increase graft survival. Different blood products, including platelets, and pharmacologic conditioning may be part of a pretransplantation transfusion protocol to induce specific immune modification in the recipient. Random preoperative blood transfusions before cadaver organ transplantation may increase the risk for sensitization but may improve allograft survival.

Kidney Transplantation

Kidney transplantation has significantly improved the quality of life for many patients with chronic renal disease. Patients may choose to accept transplantation rather than remain on hemodialysis for the rest of their lives. Indication for transplantation is end-stage renal disease, most often glomerulonephritis, pyelonephritis, polycystic disease, or nephrosclerosis.[4]

Recipients may be infants (at least 8 to 12 months with a body weight of 6 to 8 kg) to adults 70 years of age without severe extrarenal disease, malignant disease, or active sepsis. Nephrectomy is not performed before transplantation unless the patient has uncontrollable hypertension. Patients with detected presensitization states may need to wait longer for a suitably matched cadaver donor; statistically these patients have a lower 1-year graft survival rate than do unsensitized patients.

Recipients are carefully prepared preoperatively with kidney dialysis, regulation of fluid and electrolyte intake, pretransplantation blood transfusions, and control of hypertension. Proper donor-recipient matching is performed.

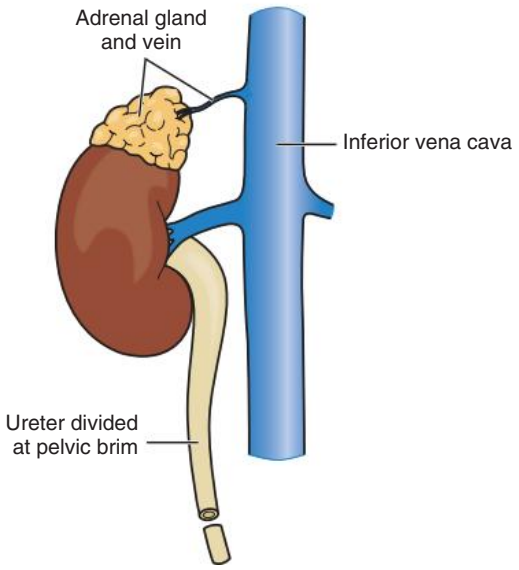
Donor preparation is equally important. The removal of a kidney is associated with low morbidity, but living related donors must guard against injuring the remaining kidney for the rest of their life. Donors are therefore advised to avoid body-contact sports.

Transplantation Procedure

Unless a cadaver donor organ is used, two adjoining ORs and teams are used for the transplantation procedure. One team procures and preserves the donor kidney, and the other team prepares the recipient site and transplants the kidney. The kidney is transplanted immediately after it is procured.

Donor Nephrectomy

In a living related donor, the kidney is removed through a flank incision (Fig. 45.5). Adequate renal perfusion and urinary output,



• **Fig. 45.5** Resection of right donor kidney.

maintenance of adequate blood pressure and ureteral blood supply, and gentleness in manipulation are extremely important intraoperatively. As soon as the kidney with its vascular attachments and ureter is excised, it is flushed with cold heparinized solution to remove red blood cells. Total ischemia time is usually less than 1 hour. The donor's incision is closed per routine technique.

Recipient Procedure

The iliac fossa is the standard site for transplantation in an adult patient (Fig. 45.6). The hypogastric artery is anastomosed to the renal artery, and the common iliac vein is anastomosed to the renal vein (Fig. 45.7). Reconstruction of the urinary tract is the main technical problem. Ureteroneocystostomy, the implantation of a donor ureter into the bladder, is the preferred technique for urinary drainage. Alternative methods include ureteroureterostomy and ureteropyelostomy.

Complications of Renal Transplantation

The complications of renal transplantation may be renal-related or extrarenal. The most common renal-related complications include rejection (the dominant cause of graft failure), recurrent nephritis, acute tubular necrosis, and technical failure from genitourinary or vascular problems. Postoperative management is similar to that for other surgical patients, with emphasis on the initial adequacy of renal function, prevention of the hazardous effects of immunosuppressive therapy, and observation for allograft rejection.[5] The following are the possible types of rejection:

- *Hyperacute, caused by presensitization:* Hyperacute rejection is an immediate acute rejection that occurs right after the anastomosis of blood vessels or within 24 hours. It includes thrombosis and extensive destruction of allograft vasculature.
- *Accelerated, caused by presensitization:* With accelerated rejection, the graft may function for up to 5 days, after which there is a rapid loss of renal function. Treatment for both hyperacute and accelerated rejection is immediate removal of the transplant.
- *Acute:* Acute rejection usually occurs 1 week to 4 months after transplantation and is often reversible unless the immune response is severe. Systemic and local symptoms, and reduced urinary output and abnormal laboratory findings, are present.
- *Chronic:* Antibodies that develop long after transplantation produce an insidious onset with mild hypertension and diminishing renal function. This type of rejection is not reversible. Acute and chronic rejection may be diagnosed by renal biopsy.

Extrarenal complications are usually caused by immunosuppressive or corticosteroid therapy and include infection (the leading cause of death on a long-term basis), pneumonitis, hepatitis, gastrointestinal bleeding, and psychologic problems from a perpetual fear of rejection. Immunosuppressive therapy must be used with caution.

The results of kidney transplantation are gratifying; life can be significantly prolonged. Causes for concern are chronic liver failure and vascular disease (which is a major cause of death in patients on dialysis and may occur in a long-term transplant recipient). The incidence of malignant neoplasm in patients surviving renal transplantation more than 1 year exceeds that expected in the general population. More information about kidney procurement and transplantation is available from the National Kidney Foundation at www.kidney.org.

Heart Transplantation

Heart transplantation may be performed in select patients with end-stage cardiac disease such as irreversible extensive myocardial failure, widespread atherosclerotic deterioration, and ischemic disease with symptoms at rest. Transplant recipients usually are younger than 55 years and have a life expectancy of less than 1 year. Patients may be following a regimen of dopamine infusion or supported by ventricular assist devices while waiting for a suitable donor.

A suitable heartbeating cadaver donor must have a blood type compatible with the recipient, be approximately the same weight and size as the recipient, and have no evidence of cardiac disease. Donors are usually younger than 40 years, but exceptions may be made.

Optimal preservation of the donor heart is crucial so it can resume full activity after transplantation.[6] Ischemia time must be less than 6 hours. After removal, the donor heart is rapidly cooled to 39.2° F (4° C) and is transported to the recipient.[6]

The transplantation team prepares the recipient while the donor heart is being procured in another OR or is being transported from another hospital.[6] The recipient is brought to the OR. When the procurement team has inspected the donor heart and deemed it suitable, the transplantation team is notified by the procurement coordinator. After the induction of anesthesia, a pulmonary

artery catheter and transesophageal echocardiography (TEE) probe are placed. A median sternotomy is performed.

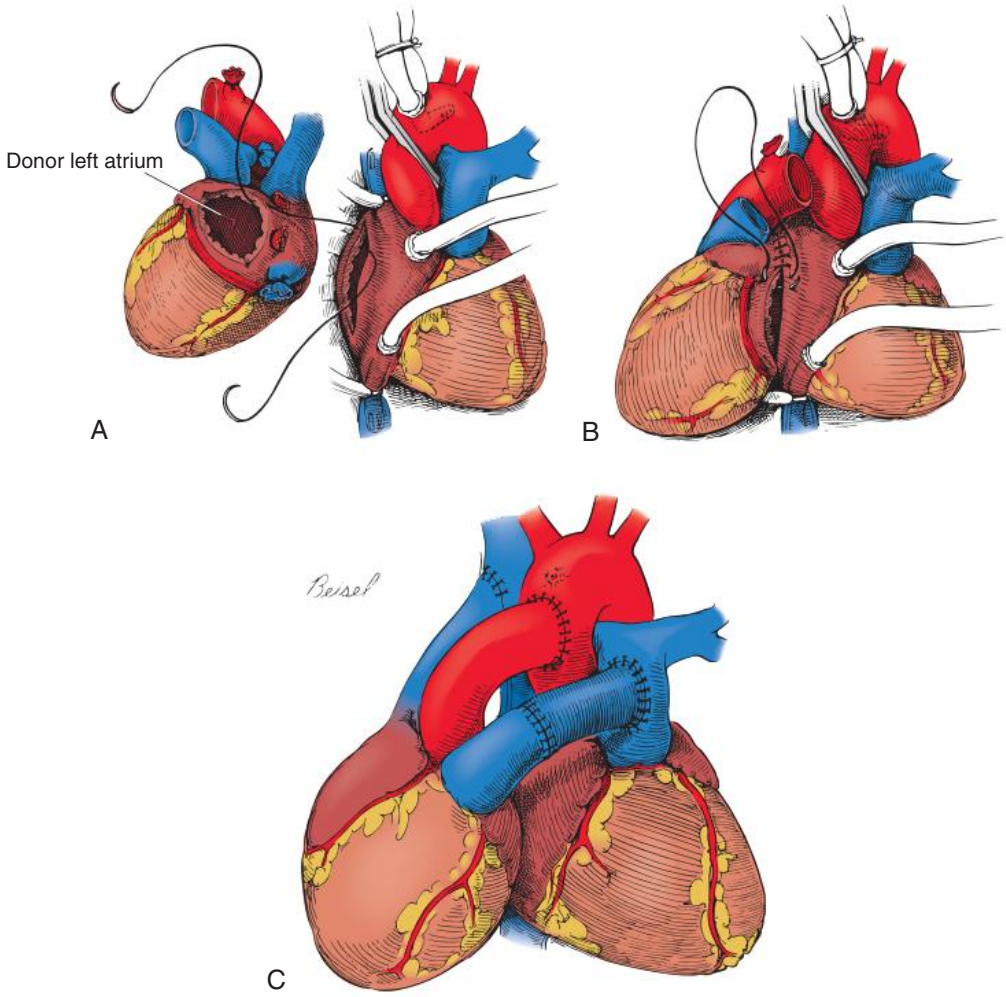
Most recipients with long-standing cardiac disease have had previous sternotomies, and adhesions may be present. Careful dissection is necessary to avoid potential embolization from a dilated left ventricle.[6] The myocardium is not manipulated until the aorta is cross-clamped, and the recipient's heart is not mobilized until the donor heart is ready for transplantation. The surgical procedure is similar to routine open heart procedures that use cardiopulmonary bypass. The following two surgical modalities are used for cardiac transplantation:

1. *Orthotopic heart transplantation:* The ventricles, atrial appendages, and most of the coronary sinus are excised from the donor heart. The opened atria, aorta, and pulmonary artery of the recipient heart are anastomosed to the donor heart. The sinoatrial nodes of both the donor and the recipient are left intact (Fig. 45.8). Spontaneous nerve regeneration is more likely to occur in younger patients who receive a younger donor organ. Studies have shown that 21% of heart recipients have some sympathetic nerve generation at the ventricular level. The amount of nerve regeneration improves exercise tolerance in the patient.
2. *Heterotopic transplantation:* The donor heart is inserted in an abnormal position in the right side of the chest as an assist device to enhance cardiac function. The recipient's heart is not removed. This less desirable alternative procedure may be indicated when increased pulmonary vascular resistance is a result of left ventricular failure in the recipient's heart. The donor's right atrium is anastomosed to the recipient's right atrium. Anastomoses are completed between the aorta and pulmonary veins of the donor to the left atrium of the recipient (Fig. 45.9).

Most deaths occur in the first 2 postoperative months—the crucial period of immunologic rejection. Electrocardiographic changes, such as a drop in voltage, reduced cardiac output, arteritis, myocardial ischemia, and myocardial necrosis, occur during rejection. The diagnosis and monitoring of acute rejection may be facilitated with serial transvenous endomyocardial biopsies, which also may confirm the effectiveness of therapy. Using fluoroscopy, a forceps is passed through a catheter into the apex of the right ventricle via the right internal jugular vein and a small sample of myocardium is removed for histologic study.

A major obstacle to long-term survival is the development of obliterative coronary artery disease in the transplanted heart. The rejection process accelerates atherosclerosis. Improvement in survival rates is attributed to early and more accurate diagnosis of rejection and vigorous measures to prevent the atherosclerosis, which is thought to result from immunologic injury to the intima of the coronary vessels.

An increase in malignant neoplasms in heart transplant patients has been observed and attributed to immunosuppressive drugs.[7] Patients who have undergone a heart transplant need personalized support to maintain a will to live and to adjust to psychologic problems that may arise at any time.

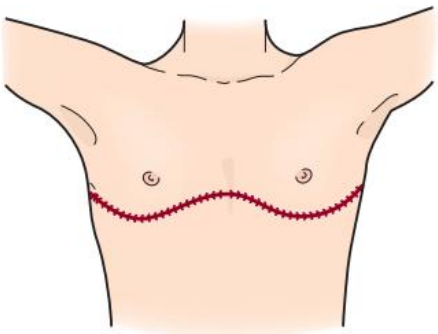


• **Fig. 45.9** Heterotopic cardiac transplantation. **A** and **B,** Left atrial anastomosis. **C,** A remnant of the donor superior vena cava (SVC) is anastomosed to the side of the recipient SVC. The donor ascending aorta and pulmonary artery are anastomosed end-to-side to their respective counterparts. A graft may be interposed between donor and recipient pulmonary arteries to provide additional length.

Combined Heart-Lung Transplantation

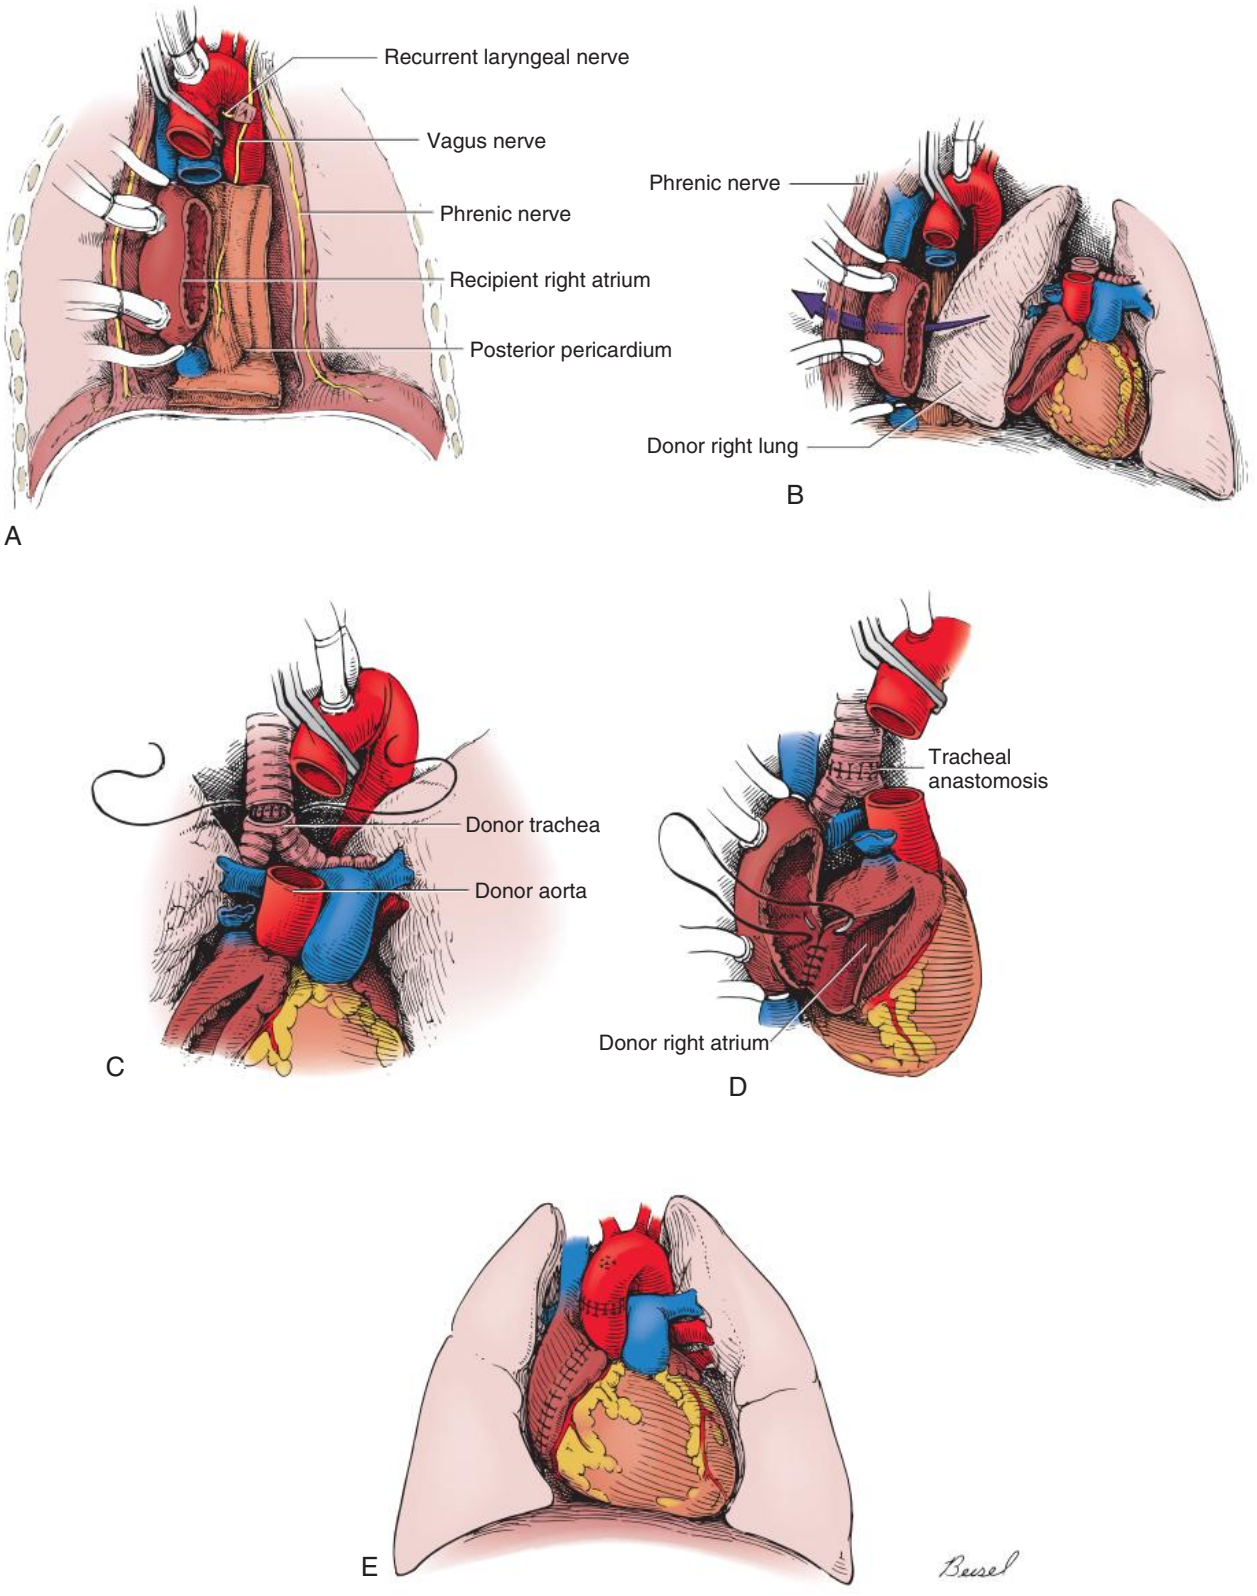
The organs of the cardiopulmonary system can be transplanted as an **en bloc** unit. Patients with primary pulmonary hypertension or pulmonary vascular disease secondary to congenital heart disease may be candidates for heart-lung transplantation. Patients with cystic or pulmonary fibrosis and chronic end-stage pulmonary disease also may receive combined transplants.[8] If cardiac function in these patients has not been affected by the disease, their hearts may be used as heartbeating donor cardiac transplants for another patient.[6,8]

In both the donor and the recipient, the trachea is transected above the carina and the heart and lungs are removed en bloc.[8] This surgical technique preserves the recipient's phrenic, vagus, and recurrent laryngeal nerves on pedicles, a portion of the right atrium and vena cava, and the aortic arch. A clamshell incision is the approach of choice (Fig. 45.10). The donor heart and lungs must fit without compression within the recipient's thoracic cavity. Size match is critical for the success of the procedure.[8] The donor trachea, right atrium, and aorta are anastomosed to corresponding structures in the recipient (Fig. 45.11).



• **Fig. 45.10** Clamshell incision for double-lung transplant.

Cyclosporine given both preoperatively and postoperatively enhances healing of the tracheal anastomosis and combats cellular-mediated rejection. Bacterial pneumonia from subclinical bacterial contamination in the donor tracheobronchial tree is the most common cause of morbidity and mortality after heart-lung transplantation.



• **Fig. 45.11** Heart-lung transplantation. **A,** The recipient heart and lungs have been excised, exposing the posterior pericardium. Note the location of the phrenic, vagus, and recurrent laryngeal nerves and the right and left phrenic nerve pedicles. **B,** The recipient heart and lungs are brought onto the field; the right lung is passed beneath the recipient atriocaval remnant and right phrenic nerve to lie in the right pleura; the left lung will be placed beneath the left phrenic nerve and positioned in the left pleural space. **C,** The tracheal anastomosis is performed, followed by the right atrial anastomosis **(D)** and, finally, the aortic anastomosis **(E)**.

Lung Transplantation

Transplantation of a single lung, usually the left one, may be performed in a patient with end-stage pulmonary fibrosis who depends on oxygen therapy. Both lungs may be replaced sequentially as two single-lung transplants rather than as an en bloc combined heart-lung transplant. Children with bronchopulmonary dysplasia, primary pulmonary hypertension, or congenital hiatal (diaphragmatic) hernia may benefit from a partial lung transplant.[8] A lobe from a living relative may be transplanted instead of a whole lung from a cadaver source.[8]

Optimal preservation of the donor organ is vitally important, and timing is critical. Ischemic time must be less than 4 hours; results improve as ischemic time decreases. Recipient preparation usually occurs simultaneously with donor procurement.

Single-lung transplantation involves bronchus-to-bronchus, pulmonary artery–to–pulmonary artery, and recipient pulmonary veins–to–donor atrial cuff anastomoses. The omentum is wrapped around the bronchus to provide additional blood supply and support the anastomosis.

Many special problems affect the success of clinical lung transplantation, as follows:

- Recipients usually have some degree of pulmonary infection at the time of the surgical procedure. The recipient's remaining lung, if diseased, may be a source of infection.
- Ventilation-perfusion imbalance between the transplanted lung and the remaining lung may result in reduced function of the transplant.
- Imminent rejection is not easily recognized.
- Vascular and fibrotic changes produced by rejection create ischemia and anoxia.
- Healing at the site of bronchial anastomosis is a problem, but less so with cyclosporin and an omental wrap.
- The procedure is technically difficult. The size of the donor lung, hilar structures, and bronchus must approximate those of the recipient.

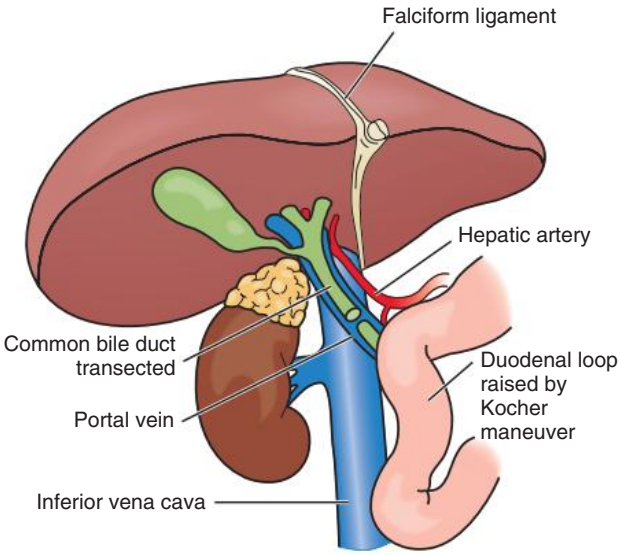
Liver Transplantation

Hepatic transplantation may be performed in select patients with nonmalignant end-stage liver disease. The ideal recipients are patients with primary liver disease. Successful liver transplantation is performed on infants and children with biliary atresia who have development of chronic liver failure or on those with other liver or biliary problems.[5] A preexisting infection in any part of the body is a distinct contraindication because the patient's preoperative status is poor and the patient lacks the protective proteins normally produced by the liver. Postoperative infection is always a marked danger.

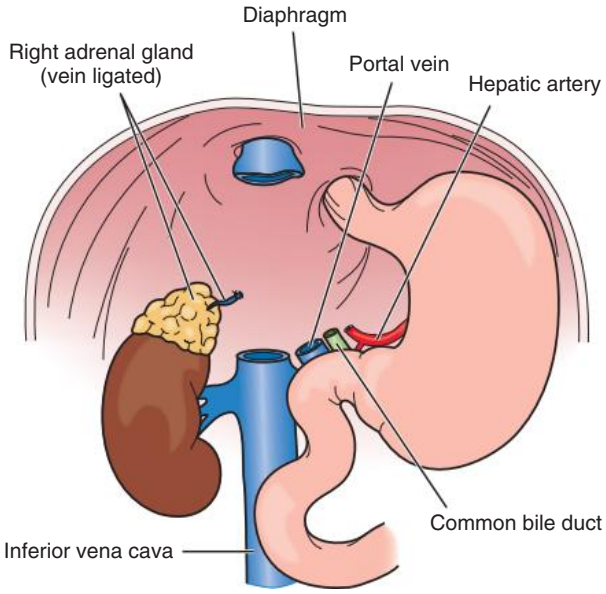
The liver is susceptible to damage from ischemia. However, a donor liver can be preserved for up to 24 hours with the infusion of cold Belzer-MPS solution.

The liver may be separated into two sections and used for two recipients. The left lobe or a left lateral segmental graft may be transplanted into an infant or child; the right side, which is larger, can be transplanted into an adult.[8] For this reduced-size liver transplantation (RSLT) procedure, one team divides the donor organ while another team performs a hepatectomy on the recipient.

Successful living related liver transplantation is performed on infants and children with biliary atresia with development of chronic liver failure or on those with other liver or biliary problems. The adult donor gives the left lobe (the smaller lobe) if the recipient is an infant or a child. The liver grows as the child grows over time.



• **Fig. 45.12** Procurement of donor liver.

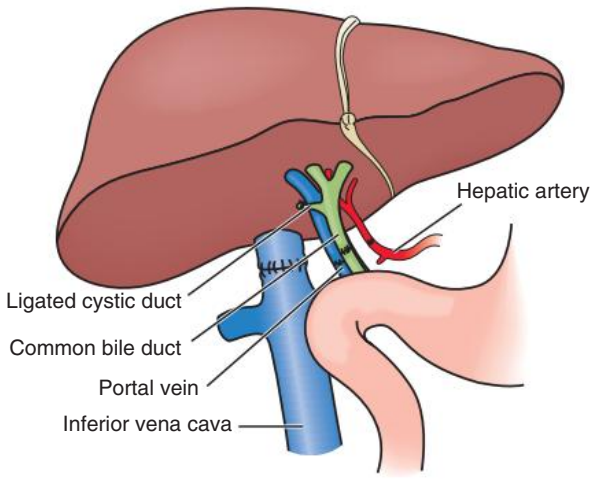


• **Fig. 45.13** Recipient liver resection.

Anatomic complexity, friability of tissue, and vascularity of the liver contribute to the technical hazards of liver transplantation (Fig. 45.12). The surgical procedure may take more than 6 hours to complete and requires both extensive dissection and ligation of vessels to avoid postoperative hemorrhage. The vena cava must be mobilized. After it is divided, the diseased liver is removed and the donor organ anastomosed to the upper and then the lower vena cava as quickly as possible (Fig. 45.13).

During this critical period, venous return from the lower half of the body must be decompressed via a venovenous extracorporeal membrane oxygenation (ECMO) pump from the iliac to the axillary arteries. After anastomoses of the portal vein and hepatic artery, any bleeding must be controlled before reconstruction of the bile duct (Fig. 45.14).

Rejection may be noted by changes in laboratory findings, such as alterations in serum enzyme levels and elevated serum bilirubin values. Cellular infiltration of the graft causes impairment of clotting factors, liver cell necrosis, and impaired function.



• **Fig. 45.14** Donor liver in situ after completion of anastomosis.

Complications from reconstruction of the biliary tract may lead to graft failure.

Pancreas Transplantation

Various techniques have been used in clinical pancreatic transplantation in the treatment of patients with severe diabetes and associated systemic complications. The goal is to provide physiologic islet function to achieve more satisfactory carbohydrate metabolism, to restore normal glucose homeostasis, and to prevent or halt secondary complications associated with diabetes mellitus. The whole pancreas, the distal segment, or isolated islets may be transplanted. The whole organ is obtained from a cadaver source. A kidney may be transplanted along with the pancreas en bloc with the associated segment of aorta and other structures.

A composite splanchnic organ graft may be obtained; this type of graft includes the entire pancreas, the spleen, and a segment of the duodenum. A segment of pancreas, usually the tail and body, can be obtained from a living related donor and placed into the extraperitoneal space in the iliac fossa. The splenic artery and vein of the donor segment are anastomosed to the external iliac artery and vein of the recipient. Islet cells or beta cells may be isolated for transplantation; beta cells are injected into the liver.

The transplantation procedure must allow exocrine secretions to drain from the pancreatic ducts. This is accomplished most commonly with pancreaticocystostomy for urinary drainage or pancreaticojejunostomy for enteric drainage. Insulin is secreted into the systemic circulation via arterial anastomoses between the donor organ and the recipient vessels.

Small Intestine Transplantation

The small bowel can be procured from a living related donor or cadaver donor. From a living related donor, a minimal segment of 39 to 59 inches (100 to 150 cm) of small intestine with a branch of the superior mesenteric artery and vein may be transplanted to correct short-bowel syndrome, genetic enzyme deficiencies, or malabsorption disorders in children. The whole small bowel alone or in combination with the liver and other digestive structures can be used from a cadaver donor. Because the body reacts to the lymphoid tissue transplanted with the intestine, the donor transplant organ may be irradiated to kill the lymph cells but not the mucosal cells.

Survival rates for intestinal transplant are around 50%. Most complications are related to reactions in the lymph tissue, heavy bacterial load of the gut, and technical graft failure.

Pediatric indications for intestinal transplant include the following:

- Volvulus
- Gastroschisis
- Necrotizing enterocolitis
- Intestinal atresia
- Trauma
- Hirschsprung's disease
- Obstruction

Adult indications for intestinal transplant include the following:

- Crohn's disease
- Trauma
- Ischemia caused by thrombosis
- Familial polyposis
- Gardner's syndrome
- Desmoid tumor
- Radiation enteritis
- Budd-Chiari syndrome
